The US FDA has approved two combination treatments using GnRH antagonists for the management of heavy menstrual bleeding associated with uterine fibroids in premenopausal women with a treatment duration of up to 24 months: (1) relugolix 40 mg, estradiol 1 mg, and norethindrone acetate 0.5 mg once daily and (2) elagolix 300 mg twice daily in combination with estradiol 1 mg and norethindrone acetate 0.5 mg once daily. Linzagolix, an oral GnRH antagonist (dispensed as a 100-mg or 200-mg once-daily tablet), is available in Europe for the treatment of moderate to severe fibroid symptoms.

B. Surgical Measures

Surgical intervention is based on the patient's symptoms, desire for future fertility or uterine preservation, and long-term treatment goals. A variety of surgical measures are available for the treatment of myomas: myomectomy (hysteroscopic, laparoscopic, abdominal, or robotic) and hysterectomy (vaginal, laparoscopic-assisted vaginal, laparoscopic, abdominal, or robotic). Submucous myomas may be amenable to hysteroscopic resection. *Myomectomy is the surgical treatment of choice for women who wish to preserve fertility.*

Because the risk of surgical complications increases with the increasing size of the myoma, preoperative reduction of myoma size is sometimes desirable before hysterectomy. GnRH analogs, such as depot leuprolide, available in 1- and 3-month intramuscular formulations, can be used preoperatively for 3- to 4-month periods to temporarily reduce the size of myomas and surrounding vascularity. GnRH analogs can also serve as a bridge to surgery in patients who are anemic. By stopping menses, patients may increase their hemoglobin level, potentially decreasing their need for blood transfusion perioperatively.

Uterine artery embolization is a minimally invasive treatment for uterine fibroids in which embolic materials are injected into the uterine artery via femoral artery catheterization to occlude fibroid blood supply, causing them to shrink. Uterine artery embolization is *not* intended for women who desire future childbearing. Magnetic resonance–guided high-intensity focused ultrasound (MRgFUS), laparoscopic myolysis/radiofrequency ablation (RFA), and laparoscopic uterine vessel occlusion are other interventions used to treat fibroids with outcomes not shown to be superior to UAE.

Prognosis

In patients desiring future fertility, myomectomy may be offered. Patients should be counseled that approximately 12% of patients undergo repeat surgery within 8 years. Additionally, postoperative pelvic adhesions may impact fertility, and cesarean delivery may be necessary for future pregnancy secondary to disruption of the myometrium. Approximately 80% of women have long-term improvement in symptoms following uterine artery embolization. However, direct comparison of patients undergoing myomectomy or uterine artery embolization has shown that fibroid-related quality of life at 2 years post-procedure is higher among women undergoing myomectomy. Definitive surgical therapy (ie, hysterectomy) is curative.

When to Refer

Refer to a gynecologist for treatment of symptomatic leiomyomata.

When to Admit

For acute abdomen associated with an infarcted leiomyoma or for hemorrhage not controlled by outpatient measures.

CERVICAL POLYPS

ESSENTIALS OF DIAGNOSIS

- Irregular or postcoital bleeding.
- Polyps visible in the cervical os on speculum examination.

Clinical Findings

Cervical polyps commonly occur during the reproductive years, particularly after age 40, and are occasionally noted in postmenopausal patients. Cervical polyps are visible in the cervical os on speculum examination. The cause is not known, but inflammation may play an etiologic role. The principal symptoms are discharge and abnormal vaginal bleeding. However, abnormal bleeding should not be ascribed to a cervical polyp without evaluating the patient for AUB as indicated.

Cervical polyps should be differentiated from polypoid neoplastic disease of the endometrium, small submucous pedunculated myomas, large nabothian cysts, and endometrial polyps. Cervical polyps rarely contain foci of dysplasia (0.5%) or of malignancy (0.5%). Small, asymptomatic polyps in women < age 45 may be left untreated.

Treatment

Small cervical polyps can generally be removed in the office by avulsion with uterine packing forceps or ring forceps.

When to Refer

- Polyp with a wide base.
- Inability to differentiate endocervical from endometrial polyp.

PELVIC PAIN

ESSENTIALS OF DIAGNOSIS

- Determine if pain is acute or chronic.
- Categorize if pain is cyclic or continuous.
- Consider nongynecologic causes.

1. Primary Dysmenorrhea

Primary dysmenorrhea is pain associated with menstrual cycles in the absence of pathologic findings. Primary dysmenorrhea usually begins within 1–2 years after menarche and may become progressively more severe. Prevalence increases up to age 20 and then decreases with both increasing age and parity. Half to three-quarters of menstruating people are affected by dysmenorrhea at some time, and 5–6% have incapacitating pain.

Clinical Findings

Primary dysmenorrhea is low, midline, wave-like, cramping pelvic pain often radiating to the back or inner thighs. Cramps may last for ≥ 1 days and may be associated with nausea, diarrhea, headache, and flushing. The pain is produced by uterine vasoconstriction, anoxia, and sustained contractions mediated by prostaglandins. The pelvic examination is normal between menses; examination during menses may produce discomfort, but there are no pathologic findings.

Treatment

NSAIDs (ibuprofen, ketoprofen, mefenamic acid, naproxen) are generally helpful. The medication should be started 1–2 days before expected menses. Symptoms can be suppressed with use of combined hormonal contraceptives, depo-medroxyprogesterone acetate (DMPA), etonogestrel subdermal implant (Nexplanon), or the hormonal IUD. Other therapies that have shown some benefit include local heat, exercise, and high-frequency transcutaneous electrical nerve stimulation around the time of menses. These options may be offered to patients who desire nonhormonal therapy, although they have less supporting evidence.

2. Endometriosis

General Considerations

Endometriosis is an aberrant growth of endometrium outside of the uterus, particularly in the dependent parts of the pelvis and in the ovaries. Its principal manifestations are chronic pain and infertility. While **retrograde menstruation** is the most widely accepted cause, its pathogenesis and natural course are not fully understood. The overall prevalence in the United States is 6–10%.

Clinical Findings

The clinical manifestations of endometriosis are variable and unpredictable in both presentation and course. Dysmenorrhea, chronic pelvic pain, and dyspareunia are among the well-recognized symptoms. Many patients with endometriosis, however, remain asymptomatic, and most patients with endometriosis have a normal pelvic examination. However, in some, pelvic examination can reveal tender nodules in the cul-de-sac or rectovaginal septum, uterine retroversion with decreased uterine mobility, uterine tenderness, or adnexal mass or tenderness.

Endometriosis should be distinguished from pelvic inflammatory disease, ovarian neoplasms, and uterine myomas. Bowel invasion by endometrial tissue may produce blood in the stool that must be distinguished from that produced by bowel neoplasm.

Imaging is useful mainly in the presence of a pelvic or adnexal mass. Transvaginal ultrasonography is the imaging modality of choice to detect the presence of deeply penetrating endometriosis of the rectum or rectovaginal septum; MRI should be reserved for equivocal cases of rectovaginal or bladder endometriosis. A presumptive clinical diagnosis may be made based on the combination of symptoms, physical examination, and imaging findings. However, a definitive diagnosis of endometriosis is made only by histology of lesions removed at surgery.

Treatment

A. Medical Treatment

Medical treatment, including use of NSAIDs or a variety of hormonal therapies, is effective in the amelioration of pain associated with endometriosis. *Hormonal regimens are designed to inhibit ovulation and to lower hormone levels*, thus preventing cyclic stimulation of endometriotic implants and inducing atrophy. The American Society of Reproductive Medicine views endometriosis as a chronic disease for which medical management should be prioritized and surgical intervention limited. Commonly used hormonal regimens include the following:

1. *Combined hormonal (estrogen-progestin) contraceptives are first-line treatment because they have a favorable side effect profile and provide relief for many patients.* Continuous use of any of the combination oral contraceptives, the contraceptive patch, or the vaginal ring is the preferred for treatment of endometriosis.
2. Progestins, specifically oral norethindrone acetate and subcutaneous DMPA, have been approved by the US FDA for treatment of endometriosis-associated pain. The etonogestrel implant has also been shown to decrease endometriosis-related pain.
3. The hormonal IUD has been shown to be effective in reducing endometriosis-associated pelvic pain and may be considered before surgery.
4. GnRH agonists (such as leuprolide acetate, 3.75 mg intramuscular injection monthly or 11.25 mg intramuscular injection every 3 months) are highly effective in reducing pain associated with endometriosis; however, they are not superior to other methods such as combined hormonal contraceptives. Side effects of vasomotor symptoms and bone demineralization may be relieved by "add-back" therapy, such as conjugated equine estrogen, 0.625 mg orally daily, or norethindrone acetate, 5 mg orally daily.
5. GnRH antagonists, like GnRH agonists, suppress pituitary gonadotropin production and create a hypoestrogenic state; however, they are effective immediately rather than requiring 7–14 days for GnRH suppression. Injectable and oral forms (eg, cetrorelix and elagolix, respectively) are available.
6. Danazol is an androgenic medication used to treat endometriosis-associated pain but is not commonly used due to androgenic side effects. It may be used for 4–6 months and is typically prescribed orally in divided doses from 400 mg daily to 800 mg daily.
7. Aromatase inhibitors (such as anastrozole or letrozole) in combination with conventional therapy (eg, progestin, combined hormonal contraceptive, or GnRH analog) have been evaluated with positive results in premenopausal patients with endometriosis-associated pain and pain recurrence.

B. Surgical Measures

Surgical treatment of endometriosis—particularly extensive disease—is effective both in reducing pain and in promoting fertility. Laparoscopic ablation of endometrial implants significantly reduces pain. Ablation of implants and, if necessary, removal of ovarian endometriomas enhance fertility, although subsequent pregnancy rates are inversely related to the severity of disease. Patients with disabling pain for whom childbearing is not a consideration can be treated definitively with hysterectomy plus bilateral salpingo-oophorectomy. Hormone therapy should be considered to relieve menopausal symptoms and to reduce bone loss after oophorectomy.

Prognosis

There is little systematic research regarding either the progression of the disease or the prediction of clinical outcomes. The prognosis for reproductive function in early or moderately advanced endometriosis appears to be good with conservative therapy. Hysterectomy, with bilateral salpingo-oophorectomy, often is regarded as "definitive" treatment of endometriosis in patients with intractable pelvic pain, adnexal masses, or multiple previous ineffective conservative surgical procedures. However, *symptoms may recur even after hysterectomy and oophorectomy.*

When to Refer

Refer to a gynecologist for laparoscopic diagnosis or surgical treatment.

When to Admit

Rarely necessary except for acute abdomen associated with ruptured or bleeding endometrioma.

3. Other Etiologies of Pelvic Pain

Additional causes of pelvic pain may include **adenomyosis, fibroids, pelvic inflammatory disease (PID), malpositioned IUD,** or **other abnormalities of the pelvic organs, including the bowel or bladder.**

Clinical Findings

The history may be suggestive of the causes mentioned above. Physical examination may be useful to narrow the differential diagnosis.

Diagnosis

Targeted physical examination may help identify the anatomic source of pelvic pain. Treatment for PID is advised for sexually active patients with pelvic pain and examination findings of cervical motion tenderness, uterine tenderness, or adnexal tenderness without another explanation for the pain. Pelvic imaging is useful for diagnosing uterine fibroids or other anomalies. **Adenomyosis** (the presence of endometrial glands and stroma within the myometrium) may be detected with ultrasound or MRI. Laparoscopy may help diagnose endometriosis or other pelvic abnormalities not visualized by imaging.

Treatment

Treatment should be directed at the underlying cause. For example, PID should be treated with antibiotics as described below. If pain symptoms are marked or prolonged or unresponsive to medical management, diagnostic laparoscopy may be warranted. Definitive surgery depends on the intraoperative findings and the underlying etiology. For example, adenomyosis or endometriosis may respond to hormonal approaches, but if those are unsuccessful, hysterectomy remains the definitive treatment of choice for patients for whom childbearing is not a consideration.

4. Chronic Pelvic Pain

Chronic pelvic pain is generally defined as noncyclic pain in the pelvic area that has persisted for 3 to 6 months or longer and is unrelated to pregnancy. It is a common gynecologic condition accounting for 20% of all gynecologic referrals. There are multiple potential causes and contributing factors. A stepwise approach is needed to identify and treat all possible causes of the pain.

When to Refer

- Standard therapy fails to relieve pain.
- Suspicion of pelvic pathology, such as endometriosis, leiomyomas, adenomyosis, or PID.

PELVIC ORGAN PROLAPSE

General Considerations

Pelvic organ prolapse, including cystocele, rectocele, and enterocele, are vaginal hernias commonly seen in multiparous patients. **Cystocele** is a hernia of the bladder wall into the vagina, causing a soft anterior fullness. Cystocele may be accompanied by **urethrocele**, which is not a hernia but a prolapse of the urethra into the vagina. **Rectocele** is a herniation of the terminal rectum into the posterior vagina, causing a collapsible pouch-like fullness. **Enterocele** is a vaginal vault hernia containing small intestine, usually in the posterior vagina and resulting from a deepening of the rectouterine pouch. Two or all three types of hernia may occur in combination. The cause of pelvic organ prolapse is multifactorial. Risk factors include vaginal birth, genetic predisposition, advancing age, prior pelvic surgery, connective tissue disorders, and increased intra-abdominal pressure associated with obesity or straining associated with chronic constipation or coughing.

Clinical Findings

Symptoms of pelvic organ prolapse may include a sensation of a bulge or protrusion in the vagina, a sense of incomplete bladder or bowel emptying, and dyspareunia.

Treatment

Treatment depends on the extent of prolapse, associated symptoms, impact on the patient's quality of life, the patient's age, and desire to retain the uterus and preserve ability for coitus.

A. General Measures

Supportive measures include a high-fiber diet and laxatives to improve constipation. Weight reduction in patients with obesity and limitation of straining and heavy lifting are helpful. Pelvic muscle training (**Kegel exercises**) is a simple, noninvasive intervention that may improve pelvic function; it has demonstrated clear benefit for patients with urinary or fecal symptoms. **Pessaries** may reduce a cystocele, rectocele, or enterocele and are helpful in patients who do not wish to undergo surgery or who are poor surgical candidates.

B. Surgical Measures

The most common surgical procedure is vaginal or abdominal hysterectomy with additional attention to restoring apical support with a suspension procedure, such as by vaginal uterosacral suspension, sacrospinous fixation, or by abdominal sacral colpopexy. Since stress urinary incontinence and urinary retention may coexist with apical prolapse, patients should be evaluated for these conditions before surgery. *An anti-incontinence procedure may be done in conjunction with prolapse surgery if indicated.* Some procedures incorporate the use of surgical mesh. *Due to the finding of serious associated complications, in April 2019, the US FDA withdrew its approval of surgical mesh for the indication of transvaginal repair of pelvic organ prolapse.* Patients who previously have received transvaginal mesh for the surgical repair of pelvic organ prolapse and have no associated symptoms or complications should continue with their annual checkups and other routine follow-up care. They should let their clinician know that they have a surgical mesh implant, especially if they plan to have another pelvic surgery or related medical procedure. In addition, they should notify their clinician if they develop symptoms such as persistent vaginal bleeding or discharge, pelvic or groin pain, or dyspareunia.

Generally, surgical repair of pelvic organ prolapse is reserved until after completion of childbearing. If a patient with symptomatic prolapse desires pregnancy, the same procedures for vaginal suspension can be performed without hysterectomy, though limited data on pregnancy outcomes or prolapse outcomes are available. For older patients who do not desire coitus, colpocleisis (the partial obliteration of the vagina) is an effective and straightforward procedure. Uterine suspension with sacrospinous cervicocolpopexy may be an effective approach in older patients who wish to avoid hysterectomy but preserve coital function.

When to Refer

- Refer to urogynecologist or gynecologist for incontinence evaluation.
- Refer if nonsurgical therapy is ineffective.
- Refer for removal of mesh if symptoms develop.

Raju R et al. Evaluation and management of pelvic organ prolapse. Mayo Clin Proc. 2021;96:3122. [PMID: 34863399]

PREMENSTRUAL SYNDROME

General Considerations

*The **premenstrual syndrome (PMS)** is a recurrent, variable cluster of troublesome physical and emotional symptoms that develop during the 5 days before the onset of menses and subside within 4 days after menstruation begins.* PMS intermittently affects about 40% of all premenopausal patients, primarily those 25–40 years of age. In about 5–8% of those affected, the syndrome may be severe. Although not every patient experiences all the symptoms or signs at one time, many describe bloating, breast pain, headache, swelling, irritability, aggressiveness, depression, inability to concentrate, libido change, lethargy, and food cravings. When emotional or mood symptoms predominate, along with physical symptoms, and there is a clear functional impairment with work or personal relationships, the term **"premenstrual dysphoric disorder" (PMDD)** may be applied. The pathogenesis of PMS/PMDD is still uncertain, and treatment methods are mainly empiric. The clinician should provide support for both the patient's emotional and physical distress, including the following:

1. Careful evaluation of the patient, with understanding, explanation, and reassurance.
2. Advise to keep a daily diary of all symptoms for 2–3 months, such as the **Daily Record of Severity of Problems**, to evaluate the timing and characteristics of symptoms. If symptoms occur throughout the month rather than in the 2 weeks before menses, the patient may have depression or other mental health diagnosis instead of or in addition to PMS or PMDD.

Treatment

For mild to moderate symptoms, a program of aerobic exercise; reduction of caffeine, salt, and alcohol intake; and use of alternative therapies, such as acupuncture and herbal treatments with *Vitex agnus-castus* (chasteberry) have some data to support their use. However, there are no US FDA-approved herbal treatments for premenstrual symptoms.

Medications that prevent ovulation, such as hormonal contraceptives, may lessen physical symptoms. This includes continuous use of combined hormonal contraceptive (CHC) methods (pill, patch, or vaginal ring). The drospirenone and 20 mcg ethinyl estradiol contraceptive pill (commercial name Yaz) is US FDA-approved for PMDD.

When mood disorders predominate, several SSRIs have been shown to be effective in relieving tension, irritability, and dysphoria with few side effects. First-line medication therapy includes serotonergic antidepressants (citalopram, escitalopram, fluoxetine, sertraline, venlafaxine) either daily or only on symptom days. Fluoxetine and sertraline are US FDA-approved for PMDD.

GnRH agonist with "add-back" therapy (eg, conjugated equine estrogen, 0.625 mg orally daily, with medroxyprogesterone acetate, 2.5–5 mg orally daily) is an alternative second-line option in patients who do not respond to CHCs or SSRIs. Cognitive behavioral therapy may also provide some benefit.

Ciccone N et al. The pharmacotherapeutic management of premenstrual dysphoric disorder. Expert Opin Pharmacother. 2023;24:145. [PMID: 35974667]

MENOPAUSE

See Chapter 20, Women's Health Issues.

POLYCYSTIC OVARY SYNDROME

ESSENTIALS OF DIAGNOSIS

- Clinical or biochemical evidence of hyperandrogenism.
- Oligoovulation or anovulation.
- Polycystic ovaries on ultrasonography.

General Considerations

Polycystic ovary syndrome (PCOS) is a common endocrine disorder of unknown etiology affecting 5–10% of those of reproductive age. The **Rotterdam Criteria**, endorsed by the National Institutes of Health, identifies *hyperandrogenism, ovulatory dysfunction, and polycystic ovaries as the key diagnostic features of the disorder in adult menstruating persons*; at least two of these features must be present for diagnosis.

Clinical Findings

PCOS often presents as a menstrual disorder (ranging from amenorrhea to heavy menstrual bleeding) and infertility. Skin disorders due to peripheral androgen excess, including hirsutism and acne, are common. Patients may also show signs of insulin resistance and hyperinsulinemia, with increased risk for early-onset type 2 diabetes mellitus and metabolic syndrome. *Unrecognized or untreated PCOS is a risk factor for CVD.* In addition, prolonged anovulation increases long-term risk of endometrial cancer secondary to chronic exposure to unopposed estrogen. Patients who do become pregnant are at increased risk for perinatal complications, such as gestational diabetes and preeclampsia.

Differential Diagnosis

Anovulation in the reproductive years may also be due to (1) primary ovarian insufficiency (high FSH, low estradiol); (2) functional hypothalamic amenorrhea, often associated with rapid weight loss or extreme physical exertion (low to normal FSH for age); (3) discontinuation of hormonal contraceptives (return to ovulation typically occurs within 90 days); (4) pituitary adenoma with elevated prolactin (galactorrhea may or may not be present); and (5) hyperthyroidism or hypothyroidism. To rule out other etiologies in patients with suspected PCOS, serum FSH, estradiol, prolactin, and TSH should be evaluated. *Because of the high risk of insulin resistance and dyslipidemia, all patients with confirmed PCOS should have diabetes and lipid screening.* Patients with clinical evidence of androgen excess should have total testosterone and a morning, early follicular phase 17-hydroxyprogesterone measured. Patients with stigmata of Cushing syndrome should have a 24-hour urinary free cortisol or a low-dose dexamethasone suppression test. Congenital adrenal hyperplasia and androgen-secreting adrenal tumors also tend to have high circulating androgen levels and anovulation with polycystic ovaries; these disorders must also be ruled out in patients with presumed PCOS and high serum androgens.

Treatment

In patients with PCOS and obesity, weight reduction and exercise are often effective in reversing the metabolic effects and inducing ovulation. For patients who do not respond to weight loss and exercise and do not desire pregnancy, combined hormonal contraceptives are first-line treatment to manage hyperandrogenism and menstrual irregularities. Intermittent or continuous progestin therapy or a hormonal IUD may be used for endometrial protection in patients who cannot or choose not to use combined hormonal contraceptives. Metformin therapy may be used as a second-line therapy to improve menstrual function. Metformin has little or no benefit in the treatment of hirsutism, acne, or infertility. Contraceptive counseling should be offered to prevent unplanned pregnancy in case of a return of ovulatory cycles. For patients who are seeking pregnancy and remain anovulatory, letrozole (first line), clomiphene, or other medications can be used for ovarian stimulation (see section on Infertility below). Patients with PCOS have increased risk for multiple gestation with ovarian stimulation.

If hirsutism does not improve after 6 months of treatment with combined hormonal contraceptives, an antiandrogen, such as spironolactone, may be added. Topical eflornithine cream applied to affected facial areas twice daily for 6 months may be helpful in most women. Hirsutism may also be managed with depilatory creams, electrolysis, and laser therapy. The combination of laser therapy and topical eflornithine may be particularly effective.

Weight loss, exercise, and treatment of unresolved metabolic derangements are important in preventing CVD. Patients with PCOS should be managed aggressively and should have regular monitoring of lipid profiles and glucose. Patients who are unable to reduce body weight with lifestyle modifications may benefit from use of GLP-1 receptor agonists to lower body weight, improve metabolic parameters, and normalize menstrual cycles.

When to Refer

- If expertise in diagnosis is needed.
- If patient is infertile.

Bader S et al. A systematic review of GLP-1 on anthropometrics, metabolic and endocrine parameters in patients with PCOS. Womens Health (Lond). 2024;20:17455057241234530. [PMID: 38444070]

Huddleston HG et al. Diagnosis and treatment of polycystic ovary syndrome. JAMA. 2022;327:274. [PMID: 35040896]

INFERTILITY

A couple is said to be infertile if pregnancy does not result after 1 year of penile-vaginal intercourse without contraception. Up to 20% of couples experience infertility in their reproductive lives; the incidence of infertility increases with age, with a decline in fertility beginning in the early 30s and accelerating in the late 30s. Couples in which the woman is younger than 35 years who do not achieve pregnancy within 1 year of trying may be candidates for infertility treatment, and within 6 months for women aged 35 years and older. *The male partner contributes to about 40% of cases of infertility*, and a combination of factors is common.

A. Initial Testing

During the initial interview, the clinician can present an overview of infertility and discuss an evaluation and management plan (including information about adoption, when appropriate). Private consultations with each partner separately are then conducted. Pertinent details (eg, sexually transmitted infection history or prior pregnancies) should be obtained. The ill effects of cigarettes, alcohol, and other illicit or non-prescribed drugs (eg, anabolic steroids and opiates) on fertility should be discussed. Prescription medications that impair male potency and factors that may lead to scrotal hyperthermia, such as tight underwear or frequent use of saunas or hot tubs, should be discussed. The gynecologic history should include the menstrual pattern, the use and types of contraceptives, frequency and success of coitus, and correlation of intercourse with time of ovulation.

General physical and genital examinations are performed on the pregnancy capable partner. Basic laboratory studies include assessment of **ovarian reserve** (eg, antimüllerian hormone, day 3 FSH and estradiol) and thyroid function tests. If the patient has regular menses with moliminal (late luteal phase) symptoms, the likelihood of ovulatory cycles is very high. *A luteal phase serum* *progesterone above 3 ng/mL establishes ovulation.* Couples should be advised that coitus resulting in conception occurs during the 6-day window before the day of ovulation. Ovulation predictor kits have largely replaced basal body temperatures for predicting ovulation, but temperature charting may be used to identify most fertile days. Basal body temperature charts cannot predict ovulation; they can only retrospectively confirm that ovulation occurred.

A semen analysis should be completed to rule out male factor infertility (see Chapter 26).

B. Further Testing

1. Gross deficiencies of sperm (number, motility, or appearance) require a repeat confirmatory analysis.
2. A screening pelvic ultrasound and hysterosalpingography to identify uterine cavity or tubal anomalies should be performed. Hysterosalpingography is performed within 3 days following the menstrual period. This radiographic study will demonstrate uterine abnormalities (septa, polyps, submucous myomas) and tubal obstruction. Patients who have had prior PID or abnormal tubes seen on hysterosalpingography or laparoscopy should receive antibiotic prophylaxis with doxycycline, 100 mg orally twice daily for 5 days.
3. Absent or infrequent ovulation requires additional laboratory evaluation. Elevated FSH and low estradiol and antimüllerian hormone levels indicate ovarian insufficiency. Patients with elevated prolactin levels should be evaluated for pituitary adenoma. Patients over age 35 may require further assessment of ovarian reserve. *A markedly elevated FSH (> 15–20 IU/L) on day 3 of the menstrual cycle suggests inadequate ovarian reserve.* Although less widely performed, a **clomiphene citrate challenge test**, with measurement of FSH on day 10 after administration of clomiphene from days 5–9, can help confirm a diagnosis of diminished ovarian reserve. The number of antral follicles during the early follicular phase of the cycle can provide useful information about ovarian reserve and can confirm serum testing. An antimüllerian hormone level can be measured at any time during the menstrual cycle.
4. If all the above testing is normal, **unexplained infertility** is diagnosed.

Treatment

A. Medical Measures

Fertility may be restored by treatment of endocrine abnormalities, particularly hypothyroidism or hyperthyroidism. Patients who are anovulatory because of low body weight or exercise may become ovulatory when they gain weight or decrease their exercise levels; conversely, patients with obesity who are anovulatory may become ovulatory with loss of even 5–10% of body weight.

B. Surgical Measures

Excision of ovarian tumors or ovarian foci of endometriosis can improve fertility. Microsurgical relief of tubal obstruction due to salpingitis or tubal ligation will reestablish fertility in many cases, although with severe disease or proximal obstruction, **in vitro fertilization (IVF)** is preferable. Peritubal adhesions or endometriotic implants often can be treated via laparoscopy.

In a male with a varicocele, sperm characteristics may be improved following surgical treatment. For men who have sperm production but obstructive azoospermia, trans-epidermal sperm aspiration or microsurgical epidermal sperm aspiration has been successful.

C. Induction of Ovulation

Induction of ovulation may be performed in combination with **intrauterine insemination**, in which washed ejaculated sperm are injected directly into the upper uterine cavity using a small catheter threaded through the cervix, for patients with oligoovulation/anovulation or unexplained infertility.

1. Clomiphene citrate—Clomiphene citrate stimulates gonadotropin release, especially FSH. It acts as a selective estrogen receptor modulator, similar to tamoxifen and raloxifene, and binds to the estrogen receptor. A low level of estrogen decreases the negative feedback on the hypothalamus, thereby stimulating GnRH, and increasing the release of FSH and LH from the anterior pituitary. When FSH and LH are present in the appropriate amounts and timing, ovulation occurs.

After a normal menstrual period or induction of withdrawal bleeding with progestin, clomiphene 50 mg orally should be given daily for 5 days, typically on days 3–7 of the cycle. If ovulation does not occur, the clomiphene dosage is increased to 100 mg orally daily for 5 days. While doses of 150 mg may be used, doses > 100 mg do not appear to improve clinical pregnancy rates. The rate of ovulation following clomiphene treatment is approximately 80% in the absence of other infertility factors. The pregnancy rate is 30–40%, and twinning occurs in about 7% of these pregnancies. Three or more fetuses are rare (< 0.5% of cases). Pregnancy is most likely to occur within the first three ovulatory cycles and unlikely to occur after cycle 6. In addition, several studies have suggested a twofold to threefold increased *risk of ovarian cancer* with the use of clomiphene for more than 1 year, so treatment with clomiphene is usually limited to a maximum of six cycles.

2. Letrozole—Available data suggest that the *aromatase inhibitor letrozole is more effective than clomiphene for induction of ovulation in women with PCOS.* There is a reduced risk of multiple pregnancy, a lack of antiestrogenic effects, and a reduced need for ultrasound monitoring. The dose of letrozole is 2.5–7.5 mg daily, starting on day 3 of the menstrual cycle. In patients who have a history of estrogen-dependent tumors, such as breast cancer, letrozole is preferred over other agents because the estrogen levels with this medication are much lower.

3. Human menopausal gonadotropins (hMG) or recombinant FSH—hMG or recombinant FSH is indicated in cases of hypogonadotropism and most other types of anovulation resistant to clomiphene treatment. Because of the complexities, laboratory tests, and expense associated with this treatment, these patients should be referred to an infertility specialist.

D. Artificial Insemination in Azoospermia

If azoospermia is present, artificial insemination by a donor usually results in pregnancy, assuming female function is normal. *Using frozen sperm provides the opportunity for screening for sexually transmitted infections, including HIV infection.*

E. Assisted Reproductive Technology (ART)

Couples who have not responded to traditional infertility treatments and those with occlusive tubal disease, severe endometriosis, oligospermia, and immunologic or unexplained infertility, may benefit from ART. All ART procedures involve ovarian stimulation to produce multiple oocytes, oocyte retrieval by transvaginal sonography–guided needle aspiration, and handling of the oocytes outside the body. With **IVF**, the eggs are fertilized in vitro and the embryos transferred to the uterus. **Intracytoplasmic sperm injection** allows fertilization with a single sperm. While originally intended for couples with male factor infertility, it is now used in two-thirds of all IVF procedures in the United States.

The chance of a multiple gestation pregnancy (ie, twins, triplets) is increased in all assisted reproductive procedures, increasing the risk of preterm delivery and other pregnancy complications. However, the increasing use of single embryo transfer has resulted in far fewer multiple births from ART.

Prognosis

The prognosis for conception and normal pregnancy depends on the underlying cause. In the absence of identifiable causes of infertility, 60% of couples will achieve a spontaneous pregnancy within 3 years.

When to Refer

Refer to a reproductive endocrinologist if ART is indicated or surgery is required.

Waanbah BD et al. Letrozole as first-line drug for ovulation induction in treatment-naïve infertile polycystic ovarian syndrome women. J Obstet Gynaecol Res. 2021;47:3583. [PMID: 34355476]

CONTRACEPTION & FAMILY PLANNING

Unintended pregnancies are a worldwide problem but disproportionately impact developing countries. There were 121 million unintended pregnancies annually from 2015 to 2019, corresponding to a global rate of 64 per 1000 women aged 15–49; 61% of these cases resulted in an abortion. In middle- and high-income countries, the unintended pregnancy rate fell by 21% from 1990–1994 to 2015–2019, whereas it fell by 18% in low-income countries over this time frame. Annual average unintended pregnancy rates in the United States were estimated at 35 per 1000 during 2015–2019. It is important for clinicians to educate their patients about the benefits of contraception and to provide options that are appropriate and desirable for the patient. The WHO and the CDC provide medical eligibility criteria based on a patient's medical condition. Additionally, patients who are not in mutually monogamous relationships should use condoms for protection from STIs.

1. Oral Contraceptives

A. Combined Oral Contraceptives

1. Efficacy and methods of use—Combined (estrogen and progestin) oral contraceptives have a perfect use failure rate of 0.3% and a typical use failure rate of 8%. *Their primary mode of action is suppression of ovulation.* The pills can be started on the first day of the menstrual cycle, the first Sunday after the onset of the cycle, or on any day of the cycle. If started more than 5 days after the first day of the cycle, a backup method should be used for the first 7 days. If an active pill is missed at any time, and no intercourse occurred in the past 5 days, two pills should be taken immediately, and a backup method should be used for 7 days. If intercourse occurred in the previous 5 days, emergency contraception should be offered. A backup method should be used for 7 days.

2. Benefits of oral contraceptives—Noncontraceptive benefits of oral contraceptives include lighter menses and improvement of dysmenorrhea, decreased risk of ovarian and endometrial cancer, and improvement in acne. Functional ovarian cysts are less likely with oral contraceptive use. There is also a beneficial effect on bone mass.

3. Selection of an oral contraceptive—*Any of the combination oral contraceptives containing 35 mcg or less of ethinyl estradiol, 3 mg of estradiol valerate, or 14.2mg of estetrol are suitable for most women.* There is some variation in potency of the various progestins in the pills, but there are essentially no clinically significant differences for most patients among the progestins in the low-dose pills. There is insufficient evidence that triphasic oral contraceptives provide any benefit compared to monophasic oral contraceptives in terms of effectiveness, bleeding patterns, or discontinuation rates. Therefore, *monophasic pills are recommended as a first choice for patients starting oral contraceptive use*. Patients with acne or hirsutism may benefit from treatment with desogestrel, drospirenone, or norgestimate since they are the least androgenic progestins. Pills are typically packaged in 21- or 28-day cyclic regimens but may be taken continuously to allow the user to decide if and when to have a withdrawal bleed. *Studies have shown no significant risk from long-term amenorrhea in patients taking continuous oral contraceptives.* The low-dose oral contraceptives commonly used in the United States are listed in Table 21–2.

4. Drug interactions—Several medications interact with oral contraceptives potentially decreasing their efficacy, typically by inducing microsomal enzymes in the liver. Some commonly prescribed medications in this category are phenytoin, phenobarbital (and other barbiturates), primidone, topiramate, carbamazepine, rifampin, and St.

Table 21–2. Commonly used low-dose oral contraceptives (listed within each category in order of increasing estrogen dose, except for Nextellis and the Progestin-Only Pill category, which is in alphabetical order).

Name	Progestin	Estrogen (Ethinyl Estradiol, except as noted)
Combination		
Alesse[1,2]	0.1 mg levonorgestrel	20 mcg
Loestrin 1/20[1]	1 mg norethindrone acetate	20 mcg
Multiple brands with this combination available[1,2]	0.15 mg desogestrel	20 mcg
Yaz[1]	3 mg drospirenone	20 mcg
Loestrin 21 1.5/30[1]	1.5 mg norethindrone acetate	30 mcg
Low Ogestrel[1,2]	0.3 mg norgestrel	30 mcg
Levora[1,2]	0.15 mg levonorgestrel	30 mcg
Desogen[1,2]	0.15 mg desogestrel	30 mcg
Yasmin[1,2]	3 mg drospirenone	30 mcg
Brevicon[1,2]	0.5 mg norethindrone	35 mcg
Zovia 1/35[1,2]	1 mg ethynodiol diacetate	35 mcg
Multiple brands with this combination available[1,2]	1 mg norethindrone	35 mcg
Springtec[1,2]	0.25 mg norgestimate	35 mcg
Gildagia[1] (not available in US)	0.4 mg norethindrone	35 mcg
Nextellis	3 mg drosperinone	14.2 mg estetrol
Combination: Extended-Cycle		
LoSeasonique (91-day cycle)[1]	0.10 mg levonorgestrel (days 1–84)/0 mg levonorgestrel (days 85–91)	20 mcg (84 days)/10 mcg (7 days)
Amethyst (28-day pack)	90 mcg levonorgestrel	20 mcg
Seasonique (91-day cycle)[1]	0.15 mg levonorgestrel (days 1–84)/0 mg levonorgestrel (days 85–91)	30 mcg (84 days)/10 mcg (7 days)
Triphasic		
Estrostep[1]	1 mg norethindrone acetate (days 1–5) 1 mg norethindrone acetate (days 6–12) 1 mg norethindrone acetate (days 13–21)	20 mcg 30 mcg 35 mcg
Cyclessa[1]	0.1 mg desogestrel (days 1–7) 0.125 mg desogestrel (days 8–14) 0.15 mg desogestrel (days 15–21)	25 mcg
Tri-Lo-Estarylla[1,2]	0.18 mg norgestimate (days 1–7) 0.215 mg norgestimate (days 8–14) 0.25 mg norgestimate (days 15–21)	25 mcg
Trivora[1,2]	0.05 mg levonorgestrel (days 1–6) 0.075 mg levonorgestrel (days 7–11) 0.125 mg levonorgestrel (days 12–21)	30 mcg 40 mcg 30 mcg
Ortho-Novum 7/7/7[1,2]	0.5 mg norethindrone (days 1–7) 0.75 mg norethindrone (days 8–14) 1 mg norethindrone (days 15–21)	35 mcg
Tri Estarylla[1,2]	0.18 mg norgestimate (days 1–7) 0.215 mg norgestimate (days 8–14) 0.25 mg norgestimate (days 15–21)	35 mcg
Multiple brands with this combination available[1,2]	0.5 mg norethindrone (days 1–7) 1 mg norethindrone (days 8–16) 0.5 mg norethindrone (days 17–21)	35 mcg
Quadriphasic		
Natazia	2 mg dienogest (days 3–8) 3 mg dienogest (days 9–26)	Estradiol valerate 3/2/2/1 mg

(*continued*)

Table 21–2. Commonly used low-dose oral contraceptives (listed within each category in order of increasing estrogen dose, except for Nextellis and the Progestin-Only Pill category, which is in alphabetical order). (continued)

Name	Progestin	Estrogen (Ethinyl Estradiol, except as noted)
Progestin-Only Pill		
Camila[1,2]	0.35 mg norethindrone to be taken continuously	None
Opill[3]	0.075 mg norgestrel to be taken continuously	None
Slynd	4 mg drospirenone (days 1–24)	None
Zelleta[2]	0.075 mg desogestrel to be taken continuously (not available in United States or Canada)	None

[1] Generic equivalent available.
[2] Multiple other brands available.
[3] Non-prescription oral contraceptive (US only).

John's wort. Patients taking these medications should use another means of contraception for maximum safety.

Antiretroviral medications, specifically ritonavir-boosted protease inhibitors, may significantly decrease the efficacy of combined oral contraceptives. Other antiretrovirals, such as nonnucleoside reverse transcriptase inhibitors, have smaller effects on oral contraceptive efficacy.

5. Contraindications and adverse effects—Oral contraceptives have been associated with several adverse effects; they are contraindicated with some conditions and should be used with caution in others (Table 21–3).

A. Myocardial infarction—The risk of MI is higher with use of oral contraceptives in certain populations, but the risk attributable to oral contraceptives is low in reproductive age women. Cigarette smoking, obesity, hypertension, diabetes mellitus, and hypercholesterolemia increase this risk. *People older than 35 who smoke cigarettes and patients with other cardiovascular risk factors should use other non-estrogen–containing methods of birth control.*

Table 21–3. Contraindications to use of combined hormonal contraceptives.

Absolute contraindications
- Pregnancy or < 21 days postpartum
- Thrombophlebitis or thromboembolic disorders (past or present)
- Stroke or CAD (past or present)
- Cancer of the breast (known or suspected)
- Undiagnosed abnormal vaginal bleeding
- Estrogen-dependent cancer (known or suspected)
- Hepatocellular adenoma (past or present)
- Uncontrolled hypertension
- Age ≥ 35 and smoking ≥ 15 cigarettes daily
- Known thrombophilia
- Migraine with aura
- Active hepatitis
- Surgery or orthopedic injury requiring prolonged immobilization

Relative contraindications
- Migraine without aura
- Hypertension
- Heart or kidney disease
- Diabetes mellitus (with nephropathy/retinopathy, vascular disease, or > 20 years duration)
- Symptomatic gallbladder disease
- 21 to < 30 days postpartum
- 30 to 42 days postpartum with risk factors for VTE

B. Thromboembolic disease—A three- to fivefold increased rate of VTE is found in oral contraceptive users, but the absolute risk is low (5–6 per 100,000 woman-years compared to a rate of 50–300 per 100,000 pregnancies). Several studies have reported a twofold increased risk in users of oral contraceptives containing the progestins gestodene (not available in the United States), drospirenone, or desogestrel, compared with women using oral contraceptives with levonorgestrel and norethindrone. Users in whom thromboembolism develops should stop using oral contraceptives, as should those at increased risk for thromboembolism associated with surgery, fracture, serious injury, hypercoagulable condition, or immobilization. Those with a known thrombophilia should not use estrogen-containing contraceptives.

C. Cerebrovascular disease—Overall, a small increased risk of hemorrhagic stroke and subarachnoid hemorrhage and a somewhat greater increased risk of thrombotic stroke have been found; smoking, hypertension, and age over 35 years are associated with increased risk. Users should stop using estrogen-containing contraceptives if such warning symptoms as severe headache, blurred or lost vision, or other transient neurologic disorders develop.

D. Carcinoma—*Oral contraceptives appear to be associated with minimal to no increased risk of breast cancer.* Patients with a family history of breast cancer or those who started oral contraceptive use at a young age are not at increased risk. Combination oral contraceptives reduce the risk of endometrial carcinoma by 40% after 2 years of use and 60% after 4 or more years of use. The risk of ovarian cancer is reduced by 30% with pill use for < 4 years, by 60% with pill use for 5–11 years, and by 80% with use for 12 or more years. Oral contraceptives have been associated with developing benign hepatocellular adenomas and peliosis hepatis (blood-filled cavities) (but not focal nodular hyperplasia or HCC); hepatocellular adenomas may rarely cause rupture of the liver, hemorrhage, and death. The risk of hepatocellular adenoma increases with higher dosage, longer duration of use, and older age.

E. Hypertension—Oral contraceptives may cause hypertension in some users; the risk is increased with longer duration of use and older age. Users in whom hypertension develops while using oral contraceptives should use other non-estrogen–containing contraceptive methods. However, *with regular blood pressure monitoring, nonsmokers with well-controlled mild hypertension may use oral contraceptives.*

F. Headache—Migraine or other vascular headaches may occur or worsen with pill use. If severe or frequent headaches develop while using this method, it should be discontinued. *Those with migraine headaches with aura should not use oral contraceptives due to the increased risk of stroke.*

G. Lactation—Combined oral contraceptives may impair the quantity of breast milk. Any effects on milk supply are small and are not associated with developmental abnormalities in infants. Combination oral contraceptives should not be started earlier than 4 weeks postpartum to allow for establishment of lactation and to avoid compounding the increased risk of postpartum thromboembolic disease. Progestin-only pills, levonorgestrel implants, and DMPA are alternatives with no adverse effects on milk supply.

H. Obesity—Traditionally, clinical trials evaluating oral contraceptives generally have only included participants of normal weight. Obesity is an independent risk factor for thromboembolic complications. However, *patients with obesity should not be denied effective contraception because of concerns about oral contraceptive complications or efficacy.* Evidence suggests that efficacy for most oral contraceptives is similar for individuals with obesity or overweight compared to individuals of normal weight. The oral contraceptive pill containing estetrol/drospirenone (commercial name Nextstellis) may have slightly decreased efficacy in those with a BMI > 30.

I. Other disorders—Cholestatic jaundice may occur in patients taking birth control pills if they previously experienced it during pregnancy.

6. Minor side effects—Nausea and dizziness may occur in the first few months of pill use. Unscheduled spotting or breakthrough bleeding may occur; this may be helped by switching to a pill of slightly higher estrogen dosage. Missed menstrual periods may occur, especially with low-dose pills. A pregnancy test should be performed if pills have been skipped or an expected menstrual period is missed. Fluid retention may occur. Chloasma may occur, as in pregnancy, and is increased by exposure to sunlight.

B. Progestin-Only Pills

1. Efficacy and methods of use—A formulation containing 0.35 mg of norethindrone alone (minipill) is available in the United States. The efficacy is similar to that of combined oral contraceptives but *depends highly on consistent use* (eg, taking the pill within the same 3-hour window every day). The minipill is believed to prevent conception by causing thickening of the cervical mucus (making it hostile to sperm), by altering ovum transport (which may account for the slightly higher rate of ectopic pregnancy with these pills), and by inhibiting implantation. Ovulation is inhibited inconsistently with this method. The minipill is begun on the first day of a menstrual cycle and then taken continuously for as long as contraception is desired; there is no "placebo week." A progestin-only pill containing drospirenone was approved by the US FDA in 2019, and a desogestrel-only pill is available in several countries outside the United States. A norgestrel-only pill was approved for over-the-counter use by the US FDA in 2023. Drospirenone, desogestrel, and norgestrel have longer half-lives than norethindrone, which allows for more forgiveness with the timing of administration. Their main mechanism of action is ovulation suppression.

2. Advantages—*The low dose of progestin and absence of estrogen make progestin-only pills safe for women with contraindications to estrogen therapy*. Because estrogen may decrease initial milk production during lactation, progestin-only pills are *an ideal choice for breastfeeding women*. They may be preferred by patients who want minimal doses of hormones and by patients who are over age 35. Progestin-only pills lack the cardiovascular side effects of combination pills.

3. Complications and contraindications—There are few contraindications to the progestin-only pill (ie, current breast cancer). Progestin-only pills typically should be avoided in patients with malabsorptive disease, current or past ischemic heart disease, and history of stroke. Progestin-only pill users often have bleeding irregularities (eg, prolonged flow, spotting, amenorrhea); such patients may need regular pregnancy tests if there is a concern about contraceptive effectiveness. Many of the absolute contraindications and relative contraindications listed in Table 21–3 apply to the progestin-only pills; however, the contraceptive benefit of progestin-only pills may outweigh the risks for patients who smoke, who are over age 35, or who have conditions such as DVT or superficial venous thrombosis or known thromboembolic disorders or diabetes mellitus with vascular disease. Minor side effects of combination oral contraceptives such as mild headache also may occur with progestin-only pills.

Bearak JM et al. Country-specific estimates of unintended pregnancy and abortion incidence: a global comparative analysis of levels in 2015-2019. BMJ Glob Health. 2022;7:e007151. [PMID: 35332057]

Teal S et al. Contraception selection, effectiveness, and adverse effects: a review. JAMA. 2021;326:2507. [PMID: 34962522]

2. Contraceptive Injections & Implants (Long-Acting Progestins)

The **injectable progestin depot medroxyprogesterone acetate (DMPA)** is approved for contraceptive use in the United States. There has been extensive worldwide experience with this method over the past three decades. The medication is given as a deep intramuscular injection of 150 mg every 3 months and has a typical use failure rate of 4%. A subcutaneous preparation, containing 104 mg of DMPA is also available in the United States. Common side effects include irregular bleeding, amenorrhea, weight gain, and headache. It is associated with bone mineral loss that is reversible after discontinuation of the method. Users commonly have irregular bleeding initially and subsequently develop amenorrhea. Return to ovulation may be delayed after its discontinuation. Contraindications are similar to those for progestin-only pills.

A **single-rod, subdermal progestin implant, etonogestrel (Nexplanon)**, is approved for use in the United States. Nexplanon is a 40-mm by 2-mm rod containing 68 mg of the progestin etonogestrel that is inserted in the inner aspect of the nondominant arm. It is approved for use for 3 years, but data suggest it maintains effectiveness through 5 years. Hormone levels drop rapidly after removal, and there is no delay in the return of fertility. In clinical trials, there were no pregnancies reported through 3 years of use. Typical use failure is 0.1%. The side-effect profile is similar to that of progestin-only pills and DMPA. Irregular bleeding has been the most common reason for discontinuation.

Teal S et al. Contraception selection, effectiveness, and adverse effects: a review. JAMA. 2021;326:2507. [PMID: 34962522]

3. Other Combined Hormonal Contraceptives

A **transdermal contraceptive patch** is available in two formulations. One delivers a daily dose of norelgestromin (150 mcg) and ethinyl estradiol (35 mcg) and measures 14 cm^2. The second delivers 120 mcg levonorgestrel and 30 mcg ethinyl estradiol daily and measures 20 cm^2. The patch is applied to the lower abdomen, upper torso, or buttock once a week for 3 consecutive weeks, followed by 1 week without the patch. It appears that the average steady-state concentration of ethinyl estradiol with the patch is approximately 60% higher than with a 35-mcg pill. However, there is no evidence for an increased incidence of estrogen-related side effects. The mechanism of action, side effects, and efficacy are similar to those associated with oral contraceptives, although compliance may be better. However, discontinuation due to side effects is more frequent. Neither patch is approved for individuals with BMI ≥ 30. The ethinyl estradiol/norelgestromin patch is contraindicated because of increased risk of VTE while the ethinyl estradiol/levonorgestrel patch is contraindicated due to lower efficacy for these users.

A **contraceptive vaginal ring** that releases 120 mcg of etonogestrel and 15 mcg of ethinyl estradiol daily (**NuvaRing**) is available. The ring is soft and flexible and is placed in the upper vagina for 3 weeks, removed, and replaced 1 week later, or can be removed and immediately replaced after 3 weeks for continuous use, similar to oral contraceptives. The **1-year reusable segesterone acetate/ethinyl estradiol vaginal ring (Annovera)** is worn for 3 weeks and removed for 1 week, and that pattern is repeated for a total of 13 cycles. The efficacy, mechanism of action, and systemic side effects of combined hormonal vaginal rings are similar to those associated with oral contraceptives. Ring users may experience increased vaginal discharge.

4. Intrauterine Devices

In the United States, the following IUDs are available: the **hormone (levonorgestrel)-releasing Mirena, Liletta, Kyleena**, and **Skyla** IUDs and the **copper-bearing TCu380A (Paragard)** and **Miurella.** The **Miurella** IUD was approved by the FDA in early 2025 and contains 175 mm^2 of copper compared to 380 mm^2 in the Paragard IUD. The mechanism of action of the copper IUD is thought to involve either spermicidal or inhibitory effects on sperm capacitation and transport. The hormonal IUDs' contraceptive effect is through thickening of cervical mucus and suppression of the endometrial lining. They may inhibit ovulation, but not reliably.

Skyla is US FDA-approved for use for 3 years, Kyleena for 5 years, Liletta and Mirena for 8 years, and the TCu380A for 10 years. The hormonal IUDs have the advantage of reducing cramping and menstrual flow. The levonorgestrel 52-mg IUD is also US FDA-approved for the treatment (for up to 5 years) of heavy menstrual bleeding.

IUDs are highly effective, with failure rates similar to those achieved with permanent contraception. IUDs may be used in nulliparous women and adolescents. Hormonal IUDs may have a protective effect against upper tract infection similar to that of oral contraceptives.

A. Placement

IUD placement can be performed at any time during the menstrual cycle if pregnancy can be reasonably excluded. At the time of placement, screening for gonorrhea and chlamydia can be performed, but placement should not be delayed for results. All patients should be counseled regarding potential pain during placement and the risks, benefits, and alternatives of different options for pain management. Lidocaine (as paracervical block or topical) may help reduce pain during placement. IUDs can be safely placed in the immediate (within 10 minutes) postpartum and postabortal periods. Both types of IUDs (hormonal and copper-bearing) may be placed after vaginal delivery or prior to closure of the uterus at the time of cesarean delivery. Delayed postpartum placement is also acceptable. Placement immediately following abortion is acceptable if there is no sepsis.

B. Contraindications and Complications

Contraindications to use of IUDs are outlined in Table 21–4.

Table 21–4. Contraindications to IUD use.

Absolute contraindications
Pregnancy
Acute or subacute pelvic inflammatory disease or purulent cervicitis
Significant anatomic abnormality of uterus
Unexplained uterine bleeding
Wilson disease or copper allergy (copper IUD)
Breast cancer (hormonal IUD)
Cervical, endometrial, or gestational trophoblastic neoplasia
Relative contraindications
Active liver disease (hormonal IUD)
Menorrhagia or severe dysmenorrhea (copper IUD)

1. Pregnancy—An IUD should not be placed in a pregnant uterus. If pregnancy occurs due to IUD failure, there is a greater chance of spontaneous pregnancy loss (spontaneous abortion/miscarriage) if the IUD is left in situ (50%) than if it is removed (25%). *People using an IUD who become pregnant should have the IUD removed if the string is visible.* It can be removed at the time of abortion if that is desired. If the string is not visible and the patient wants to continue the pregnancy, the patient should be informed of the increased risk of pregnancy loss, infection, preterm birth, and abruption. They should be informed that any flu-like symptoms such as fever, myalgia, headache, or nausea warrant immediate medical attention for possible septic abortion. Since the risk of ectopic pregnancy is increased in patients who become pregnant with an IUD in situ, clinicians should search for adnexal masses in the setting of early pregnancy with an IUD in place and should always evaluate for adequate products of conception following abortion.

2. Pelvic infection—The risk of pelvic infection attributable to IUD placement is rare. The subsequent risk of pelvic infection appears to be primarily related to the risk of acquiring STIs.

3. Heavy menstrual bleeding or severe dysmenorrhea—The copper IUD can cause heavier menstrual periods, bleeding between periods, and more cramping, so it is generally not suitable for patients who already suffer from these problems. Alternatively, the levonorgestrel 52-mg IUD is approved by the US FDA to treat heavy menstrual bleeding. NSAIDs are also helpful in decreasing bleeding and pain in IUD users.

4. Complete or partial expulsion—Spontaneous expulsion of the IUD occurs in up to 10% of women during the first year of use. Any IUD should be removed if the body of the device can be seen or felt in the cervical os.

5. Missing IUD strings—If the transcervical string cannot be seen, this may signify unnoticed expulsion, perforation of the uterus with abdominal migration of the IUD, or simply retraction of the string into the cervical canal or uterus. Once pregnancy is ruled out, the clinician may probe for the IUD with sterile sound or forceps designed for IUD removal. If the IUD cannot be detected, pelvic ultrasound will demonstrate if the IUD is intrauterine. Alternatively, anteroposterior and lateral radiographs of the pelvis can evaluate for an extrauterine IUD. If the IUD is in the abdominal cavity, it should generally be removed by laparoscopy or laparotomy.

Teal S et al. Contraception selection, effectiveness, and adverse effects: a review. JAMA. 2021;326:2507. [PMID: 34962522]
Turok DK et al. Levonorgestrel vs. copper intrauterine devices for emergency contraception. N Engl J Med. 2021;384:335. [PMID: 33503342]

5. Diaphragm & Cervical Cap

The **diaphragm (with a spermicidal gel)** is a safe and effective contraceptive method with features that make it acceptable to some users and not others. When positioned properly, it rests in the vagina behind the pubic bone anteriorly and in the posterior fornix posteriorly. Typical use failure is 17%. The advantages of this method are that it has no systemic side effects and gives significant protection against pelvic infection and cervical dysplasia as well as pregnancy. The disadvantages are that it must be inserted near the time of coitus and that pressure from the rim predisposes some users to cystitis after intercourse.

The **cervical cap (with a spermicidal gel)** is similar to the diaphragm but fits snugly over the cervix only. The cervical cap is more difficult to insert and remove than the diaphragm. The main advantages are that it can be used by patients who cannot be fitted for a diaphragm because of a relaxed anterior vaginal wall or because of repeated bladder infections stemming from diaphragm use. However, reported typical use failure rates are 14% in nulliparous women and 29% in parous women.

Because of the small risk of toxic shock syndrome, a cervical cap or diaphragm should not be left in the vagina for over 24 hours. The cervical cap should not be used during menses.

6. Contraceptive Foam, Cream, Film, Sponge, Jelly, & Suppository

These products are available without prescription, are easy to use, and have typical failure rates of 10–22%. All contain the spermicide **nonoxynol-9**, which also has some viricidal and bactericidal activity. The US FDA requires products containing nonoxynol-9 to include a warning that *the products do not protect against HIV or other STIs;* use of these products can irritate the vagina and rectum and may *increase* the risk of HIV acquisition from an infected partner. A different on-demand vaginal contraceptive, a vaginal pH regulator gel containing lactic acid–citric acid–potassium bitartrate (commercial name **Phexxi**), was US FDA-approved for use in the US in 2020; it requires a prescription. The supporting clinical trial estimated 27.5 pregnancies per 100 woman-years.

Phexxi—a nonhormonal contraceptive gel. Med Lett Drugs Ther. 2020;62:129. [PMID: 32970042]

7. Condoms

The **male condom** of latex, polyurethane or animal membrane affords protection against pregnancy—equivalent to that of a diaphragm and spermicidal jelly; latex and polyurethane (but not animal membrane) condoms also offer protection against many STIs, including HIV. When a spermicide, such as vaginal foam, is used with the condom, perfect use failure rate is approximately 2% and typical use, 13%. The disadvantages of condoms are dulling of sensation and potential spillage of semen due to condom tearing or slipping, or leakage with detumescence of the penis. Latex condoms should not be used with oil-based lubricants since these can degrade the condom and make it less effective.

Two **female condoms**, one made of polyurethane and the other of synthetic nitrile, are available in the United States. The reported failure rates range from 5% to 21%;

the efficacy is comparable to that of the diaphragm. *These are the only female-controlled method that offers significant protection against both pregnancy and STIs.*

8. Contraception Based on Awareness of Fertile Periods

These methods are most effective when the couple restricts intercourse to the post-ovulatory phase of the cycle or uses a barrier method at other times. Well-instructed, motivated couples may achieve low pregnancy rates with fertility awareness methods. Examples of some of these include monitoring cervical mucus changes, basal body temperature fluctuations, and menstrual cycle calculations to avoid having intercourse on fertile days. However, comparative efficacy trials of these methods against other contraceptive methods have not been performed.

9. Emergency Contraception

Emergency contraception can decrease the risk of pregnancy after intercourse but before the establishment of pregnancy. These methods should be started as soon as possible and within 120 hours after unprotected coitus: (1) Levonorgestrel, 1.5 mg orally as a single dose (available in the United States prepackaged as **Plan B** and available over the counter for persons ages 17 years and older), has a 1–3% failure rate when taken within 72 hours. It remains efficacious up to 120 hours after intercourse, though less so compared with earlier use, and is indicated for use within 72 hours. (2) If the levonorgestrel regimen is not available, a combination oral contraceptive containing ethinyl estradiol and levonorgestrel 1.5 mg given twice in 12 hours may be used. Used within 72 hours, the failure rate of these regimens is approximately 3%, but antinausea medication is often necessary. (3) Ulipristal acetate, a selective progesterone receptor modulator, taken orally as a single 30 mg dose, has been shown to be more effective than levonorgestrel, especially when used between 72 and 120 hours, particularly among patients with overweight and obesity. Patients should wait 5 days after taking ulipristal to start or restart a hormonal contraceptive method and use backup contraception for a week or until the next menses. (4) Copper or levonorgestrel 52-mg IUD placement within 5 days after one episode of unprotected midcycle coitus will also prevent pregnancy. Copper IUD use for emergency contraception is the most effective available method, with first cycle pregnancy rates of 0.1%. *All victims of sexual violence should be offered emergency contraception.*

Salcedo J et al. Society of Family Planning Clinical Recommendation: emergency contraception. Contraception. 2023;121:109958. [PMID: 36693445]

Turok DK et al. Levonorgestrel vs. copper intrauterine devices for emergency contraception. N Engl J Med. 2021;384:335. [PMID: 33503342]

10. Permanent Contraception

In the United States, permanent contraception is the most commonly used method of birth control for couples who do not want more children. Although reversible in some instances, reversal surgery for both women and men is costly, complicated, and not always successful. Therefore, *patients should be counseled carefully regarding permanence of the procedure.*

Female permanent contraception procedures include **laparoscopic bipolar electrocoagulation, salpingectomy, plastic ring application on the uterine tubes**, or **minilaparotomy with tubal resection**. Salpingectomy may be preferred for the added benefit of decreasing ovarian cancer risk. The advantages of laparoscopy are minimal postoperative pain, small incisions, and rapid recovery. The advantages of minilaparotomy are that it can be performed with standard surgical instruments under local or general anesthesia. However, there is more postoperative pain and a longer recovery period. The cumulative 10-year failure rate for all methods combined is 1.85%, varying from 0.75% for postpartum partial salpingectomy and laparoscopic unipolar coagulation to 3.65% for spring clips; this fact should be discussed with patients preoperatively. Some studies have found an increased risk of menstrual irregularities as a long-term complication of tubal ligation, but findings in different studies have been inconsistent.

Male permanent contraception by vasectomy is a safe, simple procedure in which the vas deferens is severed and sealed through a scrotal incision under local anesthesia. Failure rate is reported at 1 in 2000. See also Chapter 26.

When to Refer

Refer to experienced clinicians for etonogestrel subdermal (Nexplanon) placement, IUD placement, tubal occlusion or ligation, or vasectomy.

Fang NZ et al. Female permanent contraception trends and updates. Am J Obstet Gynecol. 2022;226:773. [PMID: 34973178]

Velez D et al. Vasectomy: a guidelines-based approach to male surgical contraception. Fertil Steril. 2021;115:1365. [PMID: 33879342]

11. Abortion

When abortion was legalized in the United States in 1973 under the *Roe v. Wade* US Supreme Court decision, the related maternal mortality rate fell markedly because illegal and self-induced abortions were replaced by safer procedures. Abortions in the first trimester of pregnancy are performed by vacuum aspiration under local anesthesia or with medical regimens. Dilation and evacuation, a variation of vacuum aspiration, is generally used in the second trimester. Techniques utilizing intra-amniotic instillation of hypertonic saline solution or various prostaglandin regimens, along with medical or osmotic dilators, are occasionally used after 18 weeks. Several medical abortion regimens using mifepristone and multiple doses of misoprostol have been reported as being effective in the second trimester. Overall, legal abortion in the United States has a mortality rate of < 1:100,000. In 2022, the *Dobbs v. Jackson Women's Health Organization* decision overturned the 1973 US Supreme Court decision and held that the Constitution does not confer a right to abortion. This has left the legality of abortion at the state level and has resulted in various states enacting abortion bans and others blocking such bans. Since the *Dobbs* decision, although abortion has been restricted or banned in many states, a small but consistent *increase* in the national monthly number of abortions has been seen, thought to be driven at least in part by the availability of telehealth abortion. Yet, an analysis of mortality rates by state abortion restriction level following *Dobbs* found that an increasing number of restrictive abortion laws was associated with increasing maternal and infant mortality, and the presence of a trigger law banning abortion after *Dobbs* was significantly associated with increased all-cause mortality in reproductive-aged females, maternal mortality, and infant mortality. *Clinicians need to be aware of laws regarding availability of abortion in the jurisdiction of their practice.*

Complications resulting from abortion may include retained products of conception (often associated with infection and heavy bleeding), uterine perforation, and unrecognized ectopic pregnancy. Immediate analysis of the removed tissue for products of conception can exclude or corroborate the diagnosis of ectopic pregnancy. Women who have fever, bleeding, or abdominal pain after abortion should be examined; use of broad-spectrum antibiotics and reaspiration of the uterus are frequently necessary. Hospitalization is advisable if postabortal endometritis requires administration of intravenous antibiotics. Patients undergoing self-managed abortion may need emergency care for hemorrhage, septic shock, or uterine perforation.

Prophylactic antibiotics are recommended before surgical abortion; for example, a single dose of doxycycline 200 mg orally can be given 1 hour before the procedure. Rh immune globulin should be given to Rh-negative women following abortion at or beyond 12 weeks' gestation. Contraception should be thoroughly discussed and provided at the time of abortion, including the option of immediate postabortal IUD placement.

Mifepristone (RU 486) is approved by the US FDA as an oral abortifacient at a dose of 200 mg orally on day 1, followed by misoprostol 800 mcg buccally 24–48 hours later. The WHO recommended regimen includes mifepristone orally followed by misoprostol vaginally, sublingually, or buccally. These combinations are 93% successful in terminating pregnancies of up to 70 days' gestation with few complications. There is a 5–10% risk of incomplete abortion requiring curettage and approximately 1% risk of requiring intervention for excessive bleeding. Overall, the risk of uterine infection is lower with medical than with surgical abortion.

FEMALE SEXUAL DYSFUNCTION

General Considerations

Female sexual dysfunction is a common problem and is defined as causing *personal distress in one or more of the following domains: desire, arousal, orgasm, or pain*. Depending on the questions asked, surveys have shown that from 35% to 98% of women report sexual concerns. Questions related to sexual functioning should be asked as part of the routine medical history. Three helpful questions to broach the topic are "*Are you currently involved in a sexual relationship?*," "*With men, women, or both?*," and "*Do you have any sexual concerns or any pain with sex?*" If not involved in a sexual relationship, the patient should be asked if there are any concerns that are contributing to a lack of sexual behavior. If a history of sexual dysfunction is elicited, a complete history of factors that may affect sexual function should be taken. These factors include reproductive history (including pregnancies and mode of delivery) as well as history of infertility, STI, rape or sexual violence, gynecologic or urologic disorders, endocrine abnormalities (such as diabetes mellitus or thyroid disease), neurologic problems, CVD, psychiatric disease and pharmacologic treatment, as well as over-the-counter, illicit, and non-prescribed drug use. A detailed history of the specific sexual dysfunction should be elicited, and a gynecologic examination should focus on findings that may contribute to sexual complaints.

Etiology

A. Disorders of Sexual Desire

Sexual desire in women is a complex and poorly understood phenomenon. Relationship conflict, fear or anxiety related to previous sexual encounters, or history of sexual abuse or violence may contribute to a lack of desire. Physical factors such as chronic illness, fatigue, depression, and specific medical disorders (such as diabetes mellitus, thyroid disease, or adrenal insufficiency) may also contribute. Menopause and attitudes toward aging may play a role. In addition, sexual desire may be influenced by other sexual dysfunction, such as arousal disorders, dyspareunia, or anorgasmia.

B. Sexual Arousal Disorders

Sexual arousal disorders may be both subjective and objective. Sexual stimulation normally leads to genital vasocongestion and lubrication. Some patients may have a physiologic response to sexual stimuli but may not subjectively feel aroused because of factors such as distractions, negative expectations, anxiety, fatigue, depression, or medications, such as SSRIs or oral contraceptives. Others with vaginal atrophy may lack both a subjective and physiologic response to sexual stimuli.

C. Orgasmic Disorders

Despite subjective and physiologic arousal, patients may experience a marked delay in orgasm, diminished sensation of an orgasm, or anorgasmia. The etiology of orgasmic disorders is complex and typically multifactorial, but the cause of a particular patient's orgasmic disorder is usually amenable to treatment.

D. Sexual Pain Disorder

Female sexual dysfunction can include persistent or recurrent challenges with pain, including (1) pain with vaginal penetration, (2) vulvovaginal or pelvic pain during genital contact, (3) marked fear or anxiety about vulvovaginal or pelvic pain in anticipation of, during, or as a result of genital contact, or (4) marked hypertonicity or overactivity of pelvic floor muscles with or without genital contact (ie, vaginismus). Other medical causes of sexual pain may include vulvovaginitis; vulvar disease, including lichen planus, lichen sclerosus, and lichen simplex chronicus; pelvic disease, such as endometriosis or chronic PID; or vulvovaginal atrophy (associated with genitourinary syndrome of menopause or lactation).

Female Sexual Dysfunction: ACOG Practice Bulletin Summary, NUMBER 213. Obstet Gynecol. 2019;134:203. [PMID: 31241595]

Treatment

A. Disorders of Sexual Interest/Arousal

Low libido is the most common sexual problem for females. *In the absence of specific medical disorders, the focus of therapy is psychological.* Cognitive behavioral therapy, sexual therapy, and couples therapy may all play a role. Two pharmacologic treatments, bremelanotide and flibanserin, have been approved by the US FDA for treatment of **hypoactive sexual desire** in premenopausal women. Bremelanotide (Vyleesi), a melanocortin receptor agonist, is given as 1.75 mg subcutaneously at least 45 minutes before sexual activity. Flibanserin (Addyi), a centrally acting serotonin receptor agonist/antagonist, is a pill used daily; however, to be effective, it must be used long term and cannot be taken within 2 hours of alcohol consumption or in combination with CYP3A4 inhibitors. While not US FDA-approved, the use of bupropion and testosterone, with or without estrogen, also has shown success. There are no available testosterone preparations for females; typical prescribing approach includes use of topical testosterone cream or gel applied in approximately one-tenth of the male prescribed dose. The phosphodiesterase inhibitors used in men do *not* appear to benefit most women with sexual arousal disorders. However, there is evidence to suggest a role for sildenafil in women with sexual dysfunction due to multiple sclerosis, type 1 diabetes mellitus, and spinal cord injury.

B. Orgasmic Disorders

For many women, counseling or sex therapy may be adequate treatment. Vibrators and an US FDA-cleared vacuum device (Eros therapy system) increase clitoral blood flow and may improve the likelihood of orgasm.

C. Sexual Pain Disorders

Specific disorders contributing to sexual pain, such as endometriosis, vulvovaginitis, vulvar dermatoses, or vulvovaginal atrophy, should be treated as outlined in other sections of this chapter. Female sexual pain may be treated initially with sexual counseling, education about anatomy and sexual function, and pelvic floor physical therapy by a specialized provider.

Since the cause of **vulvodynia** (defined as persistent vulvar pain for > 3 months without clear etiology) is unknown, management is difficult. Few treatment approaches have been subjected to methodologically rigorous trials. A variety of topical agents have been tried, although only a few have been useful in improving vulvodynia. Topical estradiol 0.01% cream or compounded estradiol with testosterone 0.05% to 0.1% cream applied at bedtime to the vulvar vestibule benefits some patients, especially those with symptoms beginning after starting hormonal contraceptives. Topical lidocaine may be helpful prior to bothersome sexual activity. Useful oral medications include amitriptyline in gradually increasing doses from 10 mg/day to 50–75 mg/day or gabapentin, starting at 100 mg at bedtime, and increasing to 100 mg three times per day after 3–4 days. Patients who tolerate daytime dosing can be increased to three divided doses of 300 mg or more per dose (maximum 1200 mg three times per day). Various SSRIs have also been used. Biofeedback and physical therapy, with a therapist experienced with the treatment of vulvar pain, have been shown to be helpful. Surgery—usually consisting of vestibulectomy—has been useful for women with introital dyspareunia.

When to Refer

- When symptoms or concerns persist despite first-line therapy.
- For expertise in surgical procedures.

SEXUAL VIOLENCE

ESSENTIALS OF DIAGNOSIS

- The legal definition of rape varies by state and geographic location. The term **"sexual violence"** is used by the CDC and will be used in this discussion. It can be committed by a stranger, but more commonly the assailant is known to the victim, including a current or former partner or spouse (a form of **intimate partner violence [IPV]).**
- All victims of sexual violence should be offered emergency contraception.
- The many individuals affected, the enormous health care costs, and the need for a multidisciplinary approach make sexual violence and IPV important health care issues.

- Knowledge of state laws and collection of evidence requirements are essential for clinicians evaluating possible victims of sexual violence, including IPV.

General Considerations

Types of sexual violence, including rape and sexual assault, are legally defined in different ways in various jurisdictions. Clinicians and emergency department personnel who deal with victims of sexual violence should be familiar with the local laws pertaining to sexual assault. From a medical and psychological viewpoint, it is essential that persons treating victims of sexual violence *recognize the nonconsensual and violent nature of the crime.* About 95% of people who report sexual violence are women. Each year in the United States, > 433,000 cases of sexual assault or rape are reported. Penetration may be vaginal, anal, or oral and may be by the penis, hand, or a foreign object. The assailant may be unknown to the victim or, more frequently, may be an acquaintance or even the spouse.

Health care providers can have a significant impact in increasing the reporting of sexual violence and in identifying resources for the victims. The International Rescue Committee has developed a **multimedia training tool** to encourage competent, compassionate, and confidential clinical care for sexual violence survivors in low-resource settings. This training encourages providers to offer care in the areas of pregnancy and STI prevention as well as assistance for psychological trauma.

Because sexual violence is a personal crisis, each patient will react differently, but anxiety disorders and PTSD are common sequelae. The **rape trauma syndrome** comprises two principal phases: (1) Immediate or acute: shaking, sobbing, and restless activity may last from a few days to a few weeks. The patient may experience anger, guilt, or shame or may repress these emotions. Reactions vary depending on the victim's personality and the circumstances of the attack. (2) Late or chronic: problems related to the attack may develop weeks or months later. Sexual violence survivors are at increased risk for developing several psychological and behavioral adverse effects, including PTSD, sleep disturbances, anxiety, depression, suicide attempts, and medication misuse.

Clinicians and emergency department personnel who deal with victims of sexual violence should work with community rape crisis centers or other sources of ongoing psychological support and counseling.

Examination

The clinician who first sees the alleged victim of sexual violence should be empathetic and prepared with appropriate evidence collection and treatment materials. Standardized information and training, such as the program created by the International Rescue Committee, can be a helpful resource to the providers caring for these patients. Many emergency departments have a protocol for sexual violence victims and personnel who are trained in interviewing and examining victims of sexual violence.

Treatment

1. Give analgesics or sedatives if indicated. Administer tetanus toxoid if deep lacerations contain soil or dirt particles.
2. Give ceftriaxone, 500 mg intramuscularly, plus doxycycline 100 mg twice daily for 7 days orally, to prevent gonorrhea and chlamydia. In addition, give metronidazole 500 mg twice daily for 7 days to treat trichomoniasis. Incubating syphilis will probably be prevented by these medications, but the syphilis testing should be repeated 6 weeks after the assault.
3. Prevent pregnancy by using one of the methods discussed under Emergency Contraception.
4. Vaccinate against hepatitis B.
5. Vaccinate against HPV for survivors aged 9–26 years who have not been vaccinated or are incompletely vaccinated. Follow-up doses should be administered at 1–2 months and 6 months if age > 15 years and only at 6-12 months if < 15 years.
6. Offer HIV prophylaxis (see Chapter 36).
7. Because women who are sexually assaulted are at increased risk for long-term psychological sequelae, such as PTSD and anxiety disorders, it is critical that the patient and her family and friends have a source of *ongoing counseling and psychological support.*

When to Refer

All women who seek care for sexual assault should be referred to a facility that has expertise in the management of victims of sexual violence and is qualified to perform expert forensic examination, if requested.

BARTHOLIN DUCT CYSTS & ABSCESSES

The Bartholin glands (greater vestibular glands) are located bilaterally at 4 and 8 o'clock in the vulvar vestibule. They provide lubrication to the vagina through a duct 2.5 cm long. Obstruction of the Bartholin duct can lead to pain, swelling, and cyst and abscess formation (Figure 21–1).

Purulent drainage or secretions from the gland should be tested for *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and other pathogens, and treated accordingly (see Chapter 38); frequent warm sitz baths may be helpful. Abscesses or cysts that are symptomatic should undergo incision and drainage with additional efforts to keep the drainage tract open (eg, Word catheter or marsupialization). Marsupialization should be considered to prevent recurrences. Antibiotics are unnecessary unless cellulitis is

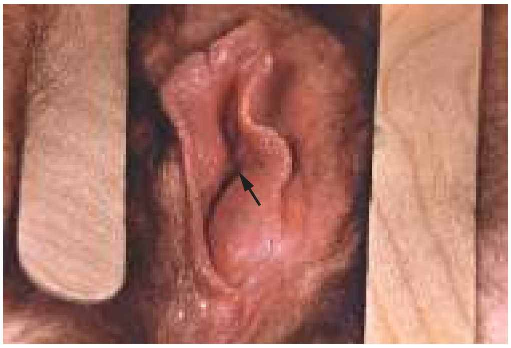

Figure 21–1. Bartholin cyst (abscess). The Bartholin gland is located in the lower two-thirds of the introitus. (From Susan Lindsley, Public Health Image Library, CDC.)

present. In women under 40, asymptomatic cysts do not require therapy; in women over age 40, biopsy or removal should be considered to rule out vulvar carcinoma.

When to Refer

When surgical therapy (marsupialization) is indicated.

Long N et al. Bartholin gland abscess diagnosis and office management. Prim Care. 2021;48:569. [PMID: 34752270]

VAGINITIS

ESSENTIALS OF DIAGNOSIS

- Vaginal irritation.
- Pruritus.
- Abnormal or malodorous discharge.

General Considerations

Inflammation and infection of the vagina are common gynecologic complaints, resulting from a variety of pathogens, allergic reactions to vaginal products, vaginal atrophy, or friction during coitus. The normal vaginal pH is 4.5 or less, and *Lactobacillus* is the predominant organism. Normal secretions during the middle of the cycle, or during pregnancy, can be confused with vaginitis.

Clinical Findings

When the patient reports vaginal irritation, pain, pruritus or unusual or malodorous discharge, a history should be taken, noting the onset, location, duration, and characterization of symptoms including triggers and alleviating factors. Additional history should include the last menstrual period; recent sexual activity; use of contraceptives, tampons, or douches; and recent changes in medications or use of antibiotics. The physical examination should include careful inspection of the vulva and speculum examination of the vagina and cervix. A vaginal, cervical, or urine sample can be obtained for detection of gonococcus and chlamydia, if clinically indicated. Evaluation for yeast, bacterial vaginosis, and *Trichomonas* should be performed. The vaginal pH should be tested; it is frequently > 4.5 in infections due to trichomonads and bacterial vaginosis. A bimanual examination to look for evidence of pelvic infection, namely cervical motion, uterine, or adnexal tenderness, should follow. *Point-of-care testing is available for all three main organisms that cause vaginitis and can be used if microscopy is not available or for confirmatory testing of microscopy.*

A. Vulvovaginal Candidiasis

Pregnancy, diabetes mellitus, and use of broad-spectrum antibiotics or corticosteroids may increase risk of *Candida* infections. Heat, moisture, and occlusive clothing also increase risk. Pruritus, vulvovaginal erythema, and a white curd-like discharge that is not malodorous are often found (Figure 21–2). Microscopic examination with 10% potassium hydroxide reveals hyphae and spores. A swab for cultures or for PCR testing may be performed if *Candida* is suspected but not demonstrated.

B. *Trichomonas vaginalis* Vaginitis

This sexually transmitted protozoal flagellate infects the vagina, Skene ducts, and lower urinary tract in women and the lower genitourinary tract in men. Pruritus and a malodorous frothy, yellow-green discharge occur, along with diffuse vaginal erythema and red macular lesions on the cervix in severe cases ("**strawberry cervix**," Figure 21–3). Motile organisms with flagella seen by microscopic examination of a wet mount with saline solution is confirmatory but such organisms are identified in only 60–70% of cases. Nucleic acid amplification tests are highly sensitive and specific to identify *T vaginalis*. Other rapid diagnostic tests with improved sensitivity compared to wet mount (eg, Affirm VP III and OSOM *Trichomonas* Rapid Test) are commercially available.

C. Bacterial Vaginosis

Bacterial vaginosis is a polymicrobial disease that is not considered a STI, although sexual activity is a risk factor. An overgrowth of *Gardnerella* and other anaerobes is often

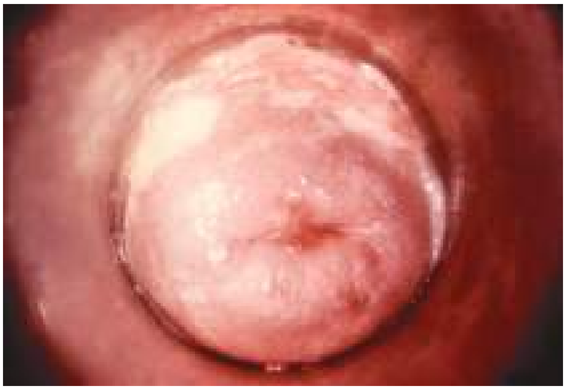

Figure 21–2. Cervical candidiasis. (Public Health Image Library, CDC.)

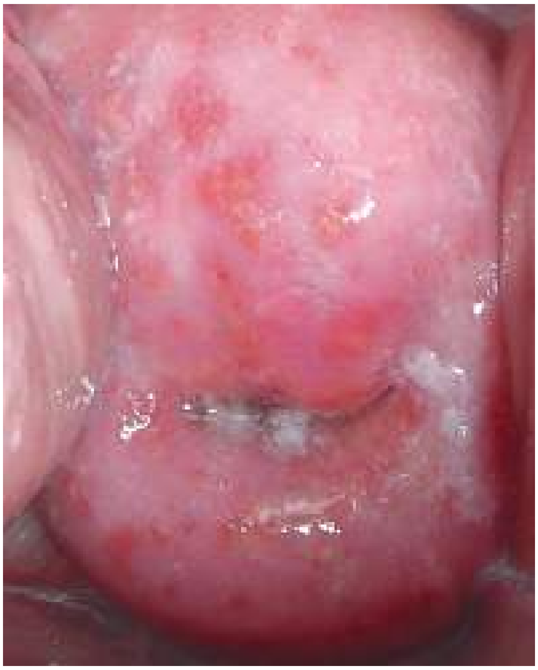


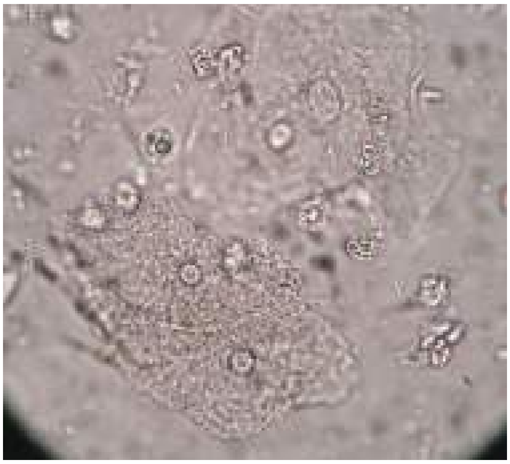
▲ **Figure 21–3.** Strawberry cervix in *Trichomonas vaginalis* infection, with inflammation and punctate hemorrhages. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

associated with increased malodorous discharge without obvious vulvitis or vaginitis. The discharge is grayish and sometimes frothy, with a pH of 5.0–5.5. An amine-like ("fishy") odor is present if a drop of discharge is alkalinized with 10% potassium hydroxide ("**whiff test**"). On wet mount in saline, epithelial cells are covered with bacteria to such an extent that cell borders are obscured (**clue cells**, Figure 21–4). Vaginal cultures are generally not useful in diagnosis; however, molecular testing is available.

▶ Treatment

A. Vulvovaginal Candidiasis

A variety of topical and oral regimens are available to treat vulvovaginal candidiasis. Women with uncomplicated vulvovaginal candidiasis will usually respond to a 1- to 3-day regimen of a topical azole or a one-time dose of oral fluconazole 150 mg. Vulvovaginal candidiasis in pregnancy is typically treated with a topical imidazole vaginally for 7 days. Women with complicated infection (including three or more episodes in 1 year [**recurrent vulvovaginal candidiasis**], severe symptoms and signs, non-albicans species, uncontrolled diabetes mellitus, HIV infection, or corticosteroid treatment) can be treated with three consecutive doses of oral fluconazole, each 3 days apart. In recurrent non-albicans infections, boric acid 600 mg in a gelatin capsule intravaginally once daily for 2–3 weeks is approximately 70% effective. If recurrence occurs, referral to a gynecologist or an infectious disease specialist is indicated.



▲ **Figure 21–4.** Clue cells seen in bacterial vaginosis due to *Gardnerella vaginalis*. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

1. Single-dose regimens—Effective single-dose regimens include topical miconazole (1200-mg vaginal suppository), tioconazole (6.5% cream, 5 g vaginally), or sustained-release butoconazole (2% cream, 5 g vaginally), or oral fluconazole (150-mg tablet).

2. Three-day regimens—Effective 3-day regimens include clotrimazole (2% cream, 5 g vaginally once daily), terconazole (0.8% cream, 5 g, or 80-mg vaginal suppository once daily), or miconazole (4% cream, 5 g, or 200-mg vaginal suppository once daily).

3. Seven-day regimens—The following regimens are effective when given once daily for 7 days: clotrimazole (1% cream), miconazole (2% cream, 5 g, or 100-mg vaginal suppository), or terconazole (0.4% cream, 5 g).

4. Recurrent vulvovaginal candidiasis (maintenance therapy)—After induction treatment with three doses oral fluconazole every 72 hours, fluconazole 150 mg once weekly for 6 months can be used for maintenance therapy.

5. Alternative therapies—Ibrexafungerp (Brexafemme), US FDA-approved in 2021, is indicated for patients who prefer oral therapy but have an intolerance or allergy to fluconazole or a candidal strain resistant to fluconazole. Two 150 mg pills are taken orally twice a day for one day (4 pills total). Otesconazole (Vivjoa), US FDA-approved in 2022, is indicated for recurrent vulvovaginal candidiasis. It has a 12-week dosing regimen with four 150-mg pills taken orally on day 1, three pills taken on day 2, and then one pill taken weekly for 11 weeks starting on day 14. These medications are not approved to be taken during pregnancy.

B. *Trichomonas vaginalis* Vaginitis

Treatment of both partners simultaneously is recommended; metronidazole, 500 mg orally twice a day for 7 days for women, and metronidazole, 2 g orally as a single dose for men.

In the case of treatment failure with metronidazole in the absence of reexposure, the patient should be re-treated with metronidazole, as described above, or tinidazole, 2 g orally once daily for 7 days. If this is not effective in eradicating the organisms, a kit for drug-resistance testing can be requested from the CDC via https://www.cdc.gov/laboratory/specimen-submission/detail.html?CDCTestCode=CDC-10239. Women with *T vaginalis* infection have an increased risk for concurrent infection with other STIs and should be offered comprehensive STI testing.

C. Bacterial Vaginosis

The recommended regimens are metronidazole (500 mg orally, twice daily for 7 days), clindamycin vaginal cream (2%, 5 g, once daily for 7 days), or metronidazole gel (0.75%, 5 g, once daily for 5 days). The National STD Curriculum offers a helpful training module to clinicians to review current recommendations for treatment of vaginitis.

Kissinger PJ et al. Diagnosis and management of *Trichomonas vaginalis*: summary of evidence reviewed for the 2021 Centers for Disease Control and Prevention Sexually Transmitted Infections Treatment Guidelines. Clin Infect Dis. 2022;74(Suppl 2):S152. [PMID: 35416973]

Satora M et al. Treatment of vulvovaginal candidiasis: an overview of guidelines and the latest treatment methods. J Clin Med. 2023;12:5376. [PMID: 37629418]

PELVIC INFLAMMATORY DISEASE
(Salpingitis, Endometritis)

ESSENTIALS OF DIAGNOSIS

- Lower abdominal or pelvic pain.
- Uterine, adnexal, or cervical motion tenderness.
- Absence of a competing diagnosis.

General Considerations

PID is a polymicrobial infection of the upper genital tract associated with the sexually transmitted organisms *N gonorrhoeae* and *C trachomatis* as well as endogenous organisms, including anaerobes, *Haemophilus influenzae*, enteric gram-negative rods, and streptococci. Young age and multiple partners are risk factors for development of PID, a leading cause of infertility and ectopic pregnancy. The use of barrier methods of contraception may provide significant protection.

Clinical Findings

A. Symptoms and Signs

Patients with PID most commonly present with lower abdominal pain. Additional complaints may include AUB and abnormal vaginal discharge. Systemic features such as fever typically indicate more severe disease, including pelvic abscess. Right upper quadrant pain may indicate an associated perihepatitis **(Fitz-Hugh-Curtis syndrome).** Diagnosis of PID is complicated by the fact that patients may have subtle or mild symptoms that are not readily recognized as PID, such as postcoital bleeding, urinary frequency, or low back pain.

B. Minimum Diagnostic Criteria

PID is diagnosed clinically. *Patients with cervical motion, uterine, or adnexal tenderness meet diagnostic criteria for PID and should be treated with antibiotics unless there is a competing diagnosis, such as ectopic pregnancy or appendicitis.*

C. Additional Criteria

No single historical, physical, or laboratory finding is definitive for acute PID. The following criteria may be used to enhance the specificity of the diagnosis: (1) oral temperature higher than 38.3°C, (2) abnormal cervical or vaginal discharge with white cells on saline microscopy (> 1 leukocyte per epithelial cell), (3) elevated ESR, (4) elevated CRP, and (5) laboratory documentation of cervical infection with *N gonorrhoeae* or *C trachomatis*. Testing for gonorrhea and chlamydia should be performed. Treatment should not be delayed while awaiting results.

Differential Diagnosis

Appendicitis, ectopic pregnancy, septic abortion, hemorrhagic or ruptured ovarian cysts or tumors, ovarian torsion, degeneration of a myoma, and acute enteritis should be considered. PID is more likely to occur when there is a prior history of PID, recent sexual contact, recent onset of menses, recent placement of an IUD, or recent intercourse with a partner who has a STI. *Acute PID is highly unlikely when recent (within 60 days) intercourse has not taken place.* A sensitive serum pregnancy test should be obtained to rule out pregnancy. Pelvic ultrasonography is helpful to rule out tubo-ovarian abscess (TOA). Laparoscopy should be considered when imaging is not informative, and the patient has not responded to outpatient treatment for PID or has not improved after 72 hours of inpatient treatment; it should also be considered when an acutely ill patient has a high suspicion of a competing diagnosis requiring surgical intervention (eg, appendicitis). The appendix should be visualized at laparoscopy to rule out appendicitis. Cultures should be obtained at laparoscopy.

Treatment

A. Antibiotics

Early treatment with appropriate antibiotics effective against *N gonorrhoeae*, *C trachomatis*, and the endogenous organisms listed above is essential to prevent long-term sequelae. The sexual partner should be treated appropriately. Most women with mild to moderate disease can be treated successfully as an outpatient. The recommended outpatient regimen is a single dose of ceftriaxone (500 mg intramuscularly; 1 g for persons who weigh ≥ 150 kg) plus doxycycline (100 mg orally twice a day for 14 days) with metronidazole 500 mg orally twice a day **or** a single dose of cefoxitin (2 g intramuscularly) with probenecid (1 g orally) plus doxycycline (100 mg orally twice daily for 14 days) with metronidazole 500 mg orally twice daily for 14 days. For patients with severe disease or those who meet criteria for hospitalization, there are three recommended regimens: cefotetan, 2 g intravenously every 12 hours, or cefoxitin, 2 g intravenously every 6 hours, or ceftriaxone, 1 g intravenously every 24 hours, each given with doxycycline, 100 mg orally or intravenously every 12 hours. If ceftriaxone is used, metronidazole 500 mg orally or intravenously every 12 hours should be added. These regimens should be continued for at least 24 hours after the patient shows significant clinical improvement. Then, an oral regimen should be given for a total course of antibiotics of 14 days with doxycycline, 100 mg orally twice a day and metronidazole, 500 mg orally twice a day.

B. Procedural Interventions

Procedural intervention is reserved for cases of large TOA (> 8 cm), suspected TOA rupture, or cases with a poor response to antibiotics. Interventional radiology drainage may be considered after TOA antibiotic failure or for large TOA. If surgical intervention is pursued, unilateral adnexectomy is acceptable for unilateral abscess. Hysterectomy and bilateral salpingo-oophorectomy may be necessary for overwhelming infection or in cases of chronic disease with intractable pelvic pain.

Prognosis

Despite treatment, long-term sequelae, including repeated episodes of infection, chronic pelvic pain, dyspareunia, ectopic pregnancy, or infertility, develop in one-fourth of women with acute disease. *The risk of infertility increases with repeated episodes of salpingitis*: it is estimated at 10% after the first episode, 25% after a second episode, and 50% after a third episode.

When to Admit

The following patients with acute PID should be admitted for intravenous antibiotic therapy:

- The patient has a TOA (direct inpatient observation for at least 24 hours before switching to outpatient therapy).
- The patient is pregnant.
- The patient cannot follow or tolerate an outpatient regimen.
- The patient has not responded clinically to outpatient therapy within 72 hours.
- The patient has severe illness, nausea and vomiting, or high fever.
- Another surgical emergency, such as appendicitis, cannot be ruled out.

Workowski KA et al. Sexually transmitted infections treatment guidelines, 2021. MMWR Recomm Rep. 2021;70:1. [PMID: 34292926]

CONDYLOMA ACUMINATA

Warty growths on the vulva, perianal area, vaginal walls, or cervix are caused by various types of HPV. Pregnancy and immunosuppression favor growth. Ninety percent of genital warts are caused by HPV 6 and 11. Vulvar lesions may be obviously wart-like or may be diagnosed only after biopsy of suspicious lesions. Vaginal lesions may show diffuse hypertrophy or a cobblestone appearance.

Recommended treatments for vulvar warts include freezing with liquid nitrogen or a cryoprobe, surgical removal, or application of 80–90% trichloroacetic or bichloroacetic acid (with care to avoid the surrounding skin). The pain of bichloroacetic or trichloroacetic acid application can be lessened by a sodium bicarbonate paste applied immediately after treatment. Patient-applied regimens, useful when the entire lesion is accessible to the patient, include imiquimod 5% cream or sinecatechins 15% ointment. Vaginal warts may be treated with cryotherapy with liquid nitrogen or trichloroacetic acid. Extensive warts may require treatment with Co$_2$ laser, electrocautery, or excision under local or general anesthesia.

CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN) (Dysplasia of the Cervix)

ESSENTIALS OF DIAGNOSIS

- The presumptive diagnosis is made by an abnormal Papanicolaou smear.
- Diagnose by colposcopically directed biopsy.

General Considerations

The squamocolumnar junction of the cervix is an area of active squamous cell proliferation. In childhood, this junction is located on the exposed vaginal portion of the cervix. At puberty, because of hormonal influence and possibly because of changes in the vaginal pH, the squamous margin begins to encroach on the single-layered, mucus-secreting epithelium, creating an area of metaplasia (**transformation zone**). Infection with HPV (see Prevention, below) may lead to cellular abnormalities, which over time may develop into squamous cell dysplasia or cancer. There are varying degrees of dysplasia (Table 21–5), defined by the degree of cellular atypia; *all atypia must be observed closely and treatment considered for persistence or progression to high-grade lesions.*

Clinical Findings

There are no specific symptoms or signs of CIN. The presumptive diagnosis is made by cytologic screening of an asymptomatic population with no grossly visible cervical changes. All visible abnormal cervical lesions should be biopsied (Figure 21–5).

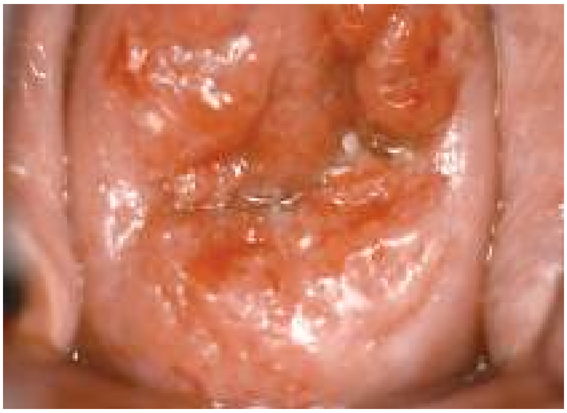

Figure 21–5. Erosion of the cervix due to cervical intraepithelial neoplasia (CIN), a precursor lesion to cervical cancer. (Public Health Image Library, CDC.)

Screening & Diagnosis

A. Cytologic Examination (Papanicolaou Test) and HPV Testing

For immunocompetent patients, the USPSTF recommends cervical cancer screening beginning at age 21, while the American Cancer Society recommends primary HPV testing every 5 years beginning at age 25. The USPSTF recommendation to start screening at age 21 years regardless of the age of onset of sexual intercourse is based on the very low incidence of cancer in younger patients and the potential for adverse effects associated with treatment of young patients with abnormal cytology screening results. In contrast to the high rate of infection with HPV in sexually active adolescents, invasive cervical cancer is very rare in patients younger than age 21 years. The USPSTF 2018 statement recommends screening for cervical cancer in women aged 21–65 years as follows: for women aged 21–29 years, screening with cytology (conventional [Papanicolaou smear] or liquid-based) alone every 3 years; and for women aged 30–65 years, screening with cytology alone every 3 years, with high-risk HPV testing alone every 5 years, or with a combination of cytology and high-risk HPV testing (**co-testing**) every 5 years. These recommendations apply to patients who have a cervix, regardless of their sexual history or HPV vaccination status. They do not apply to patients who have a previous diagnosis of cervical cancer or a high-grade precancerous cervical lesion (ie, CIN grade II or III), patients with immune compromise (eg, living with HIV), or those with in utero exposure to diethylstilbestrol; these patients are classified as high risk and may require more frequent screening.

The USPSTF recommends *against* cervical cancer screening for women younger than age 21 years, for patients older than age 65 years who have had adequate prior screening and are not otherwise at high risk for cervical cancer, and for those who have had a hysterectomy with removal of the cervix and who have no history of cervical cancer or a high-grade precancerous lesion. The goal of screening is to identify high-grade precancerous cervical lesions and prevent their progression to cervical cancer. These high-grade cervical lesions may be treated with excisional and ablative therapies. Screening and management guidelines are continually undergoing evaluation and change frequently. For the most current guidelines, please consult these sources: https://www.uspreventiveservicestaskforce.org/ and https://www.asccp.org/guidelines.

Cytologic reports from the laboratory may describe findings in one of several ways. The **Bethesda System** is a commonly used system that classifies epithelial cell

Table 21–5. Bethesda classification for Papanicolaou tests.

Category	Specifics
Specimen adequacy	Satisfactory for evaluation
	Unsatisfactory for evaluation
General categorization	Negative for intraepithelial lesion or malignancy
	Epithelial cell abnormality
	Other
Epithelial cell abnormalities	
Squamous cell abnormalities	Atypical squamous cells of undetermined significance (ASC-US)
	Atypical squamous cells cannot exclude HSIL (ASC-H)
	Low-grade squamous intraepithelial lesion (LSIL)
	High-grade squamous intraepithelial lesion (HSIL)
	Squamous cell carcinoma
Glandular cell abnormalities	Atypical glandular cells (specify endocervical, endometrial, or not otherwise specified)
	Atypical glandular cells, favor neoplastic
	Endocervical adenocarcinoma in situ
	Adenocarcinoma

abnormalities. The terms to classify squamous cell abnormalities include “atypical squamous cells of unknown significance” (**ASC-US**), “atypical squamous cells cannot exclude high-grade squamous intraepithelial lesion” (**ACS-H**), and “squamous intraepithelial lesions,” including low-grade (**LSIL**) or high-grade (**HSIL**) (see Table 21–5). ***HPV DNA testing*** *can be used adjunctively as a triage test to stratify risk in patients aged 21 years and older with a cytologic diagnosis of ASC-US or LSIL.*

In 2019, the American Society for Colposcopy and Cervical Pathology (ASCCP) published guidelines for surveillance and management of abnormal screening based on a patient’s risk of developing high-grade cervical intraepithelial neoplasia (CIN 3) or higher (adenocarcinoma in situ and cancer). A patient’s “risk estimate” is determined by their current cytology and HPV status as well as past results. Risk estimate tables can be found online at https://www.asccp.org/management-guidelines.

Chor J et al. Cervical cancer screening guideline for individuals at average risk. JAMA. 2021;326:2193. [PMID: 34766970]

B. Colposcopy

Colposcopy is performed by viewing the cervix with 10–20× magnification; this allows for assessment of the size and margins of an abnormal transformation zone and determination of extension into the endocervical canal. The application of 3–5% acetic acid (vinegar) dissolves mucus, and the acid’s desiccating action sharpens the contrast between normal and actively proliferating squamous epithelium. Abnormal changes include white patches and vascular atypia, which indicate areas of greatest cellular activity.

C. Biopsy

Colposcopically directed biopsy and endocervical curettage are office procedures used to identify precancerous and cancerous lesions. Data from both cervical biopsy and endocervical curettage are important in deciding on treatment.

Prevention

Virtually all cervical dysplasias and cancers are associated with HPV infection of the cervix. There are over 100 recognized HPV subtypes. Types 6 and 11 tend to cause genital warts and mild dysplasia and rarely progress to cervical cancer; types 16, 18, 31, and others cause higher-grade dysplasia. The **HPV 9-valent recombinant vaccine (9vHPV)** is indicated for the prevention of cervical, vaginal, and vulvar cancers (in women) and anal cancers (in women and men) caused by HPV types 16, 18, 31, 33, 45, 52, and 58; genital warts (in women and men) caused by HPV types 6 and 11; and precancerous/dysplastic lesions of cervix, vagina, vulva (in women), and anus (in women and men) caused by HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. *The 9vHPV is recommended for vaccination of females and males aged 9–26 and some adults aged 27 to 45 years old based on risk factors.* The older HPV 4-valent vaccine indicated for prevention of diseases related to HPV types 6, 11, 16, and 18 has been discontinued in the United States. The use of HPV vaccination in the United States continues to increase; however, *the HPV vaccination continues to lag far behind other vaccines recommended for adolescents.* In 2022, 58.6% of adolescents were up to date with the HPV vaccine series compared with 48% in 2018.

Because complete coverage of all carcinogenic HPV types is not provided by the 9vHPV vaccine, all women need to have regular cervical cancer screening as outlined above. In addition to vaccination, preventive measures include limiting the number of sexual partners and thus exposure to HPV, correct and consistent condom use, smoking cessation, and avoiding exposure to secondhand smoke.

Treatment

Treatment varies depending on the degree and extent of CIN. Biopsies should precede treatment, except in cases of high-grade cytology and colposcopic impression with concerns for inability to return for follow-up.

A. Ablative Procedures

Ablative procedures using cryosurgery or Co_2 laser may be considered for lesions in which the entire squamocolumnar junction has been visualized on colposcopy (ie, adequate colposcopy) and the entire lesion is visualized.

B. Excisional Procedures

An excisional procedure (ie, LEEP [loop electrosurgical excisional procedure], cold knife cone or laser cone biopsy) is the preferred modality when treatment is planned. Excision includes removal of the entire transformation zone of the cervix.

Follow-Up

Because recurrence is possible—especially in the first 2 years after treatment—and because the false-negative rate of a single cervical cytologic test is approximately 20%, *close follow-up after colposcopy and biopsy is imperative*. Following an excisional or an ablative procedure, HPV-based testing should be performed at 6 months and then annually for 2 years followed by HPV-based testing every 3 years for at least 25 years. Colposcopy and endocervical sampling should be performed for any abnormality.

The ASCCP Guidelines for cervical cancer screening and management of abnormal Papanicolaou smears are available online (https://www.asccp.org/guidelines).

When to Refer

- Patients with CIN II/III should be referred to an experienced colposcopist.
- Patients requiring conization biopsy should be referred to a gynecologist.

Chor J et al. Cervical cancer screening guideline for individuals at average risk. JAMA. 2021;326:2193. [PMID: 34766970]

Draft Research Plan Update for Cervical Cancer Screening. 2021; Oct 28. https://www.uspreventiveservicestaskforce.org/uspstf/document/draft-research-plan/cervical-cancer-screening-adults-adolescents

CARCINOMA OF THE CERVIX

ESSENTIALS OF DIAGNOSIS

- Increased risk in women who smoke and those with HIV or high-risk HPV types.
- Gross lesions should be evaluated by colposcopically directed biopsies and not cytology alone.

General Considerations

Cervical cancer is the fourth most common cancer in women worldwide and the leading cause of gynecologic cancer death among women in developing countries. It is considered an STI as both squamous cell and adenocarcinoma of the cervix are secondary to infection with HPV, primarily types 16 and 18. Patients infected with HIV and with other forms of immunosuppression are at an increased risk for high-risk HPV infection and CIN. *Smoking appears to be a cofactor for squamous cell carcinoma (SCC).* SCC accounts for approximately 75–80% of cervical cancers, while adenocarcinoma accounts for 15%, and adenosquamous carcinoma for 3–5%; neuroendocrine or small cell carcinomas are rare.

SCC appears first in the intraepithelial layers (the preinvasive stage, or carcinoma in situ). Preinvasive cancer (CIN III) is most commonly diagnosed in women 25–35 years of age. Two to 10 years are required for carcinoma to penetrate the basement membrane and become invasive.

Clinical Findings

A. Symptoms and Signs

Early cervical cancer is often asymptomatic. The most common signs are irregular or heavy bleeding and postcoital spotting. Bladder and rectal dysfunction or fistulas and pain are late sequelae.

B. Cervical Biopsy and Endocervical Curettage or Conization

These procedures are necessary steps after a positive Papanicolaou test to determine the extent and depth of invasion of the cancer. Even if the pap test is positive, definitive diagnosis must be established through biopsy before additional treatment is given.

C. “Staging” or Estimate of Gross Spread of Cancer of the Cervix

Staging of invasive cervical cancer is achieved by clinical evaluation, usually conducted under anesthesia. Further examinations, such as ultrasonography, CT, MRI, lymphangiography, laparoscopy, and fine-needle aspiration, are valuable for treatment planning.

Complications

Metastasis to regional lymph nodes occurs with later-stage disease. Paracervical extension can occur in all directions from the cervix. The ureters may become obstructed lateral to the cervix, causing hydroureter and hydronephrosis and consequently impaired kidney function. Almost two-thirds of patients with untreated carcinoma of the cervix die of uremia when ureteral obstruction is bilateral. Pain in the back, in the distribution of the lumbosacral plexus, is often indicative of neurologic involvement. Gross edema of the legs may be indicative of vascular and lymphatic stasis due to tumor. Vaginal fistulas to the rectum and urinary tract are severe late complications. Hemorrhage causes death in 10–20% of patients with extensive invasive carcinoma.

Prevention

Routine cervical cancer screening and vaccination with the recombinant 9-valent HPV vaccine can prevent cervical cancer. The 9-valent HPV vaccine targets the HPV types that pose the greatest risk and protects against low-grade and precancerous lesions caused by other HPV types (see Cervical Intraepithelial Neoplasia).

Treatment

A. Emergency Measures

Vaginal hemorrhage originates from gross ulceration and cavitation in later-stage cervical carcinoma. Ligation and suturing of the cervix are usually not feasible, but emergent vaginal packing, cautery, tranexamic acid, and irradiation are helpful to stop bleeding temporarily. Ligation, resection, or embolization of the uterine or hypogastric arteries may be lifesaving when other measures fail.

B. Specific Measures

Microinvasive carcinoma (**stage IA1**) is treated with conization (if margins are negative on the diagnostic specimen) or simple, extrafascial hysterectomy. **Stages IA2 and IB1** cancers with limited stromal involvement can be treated with simple hysterectomy and pelvic lymphadenectomy. Patients with early-stage disease at low risk for recurrence may be candidates for fertility-sparing surgery. Women with **IB2** cancers typically undergo radical hysterectomy and pelvic lymphadenectomy. Adjuvant chemotherapy or radiation may be used for women with risk factors for recurrence. Women with locally advanced disease (**stage IB3 to IVA**) usually are treated with primary chemoradiation. Metastatic disease (**stage IVB**) typically is treated with chemotherapy.

Prognosis

The overall 5-year relative survival rate for carcinoma of the cervix is 67% in the United States. Survival rates decrease with more advanced disease, with 5-year survival rates for localized, regional, and distant disease reported at 91, 60, and 19%, respectively.

When to Refer

All patients with invasive cervical carcinoma (stage IA or higher) should be referred to a gynecologic oncologist.

American Cancer Society. Survival rates for cervical cancer, by stage. https://www.cancer.org/cancer/cervical-cancer/detection-diagnosis-staging/survival.html. Accessed August 19, 2024.

CARCINOMA OF THE ENDOMETRIUM

ESSENTIALS OF DIAGNOSIS

- AUB is the presenting sign in 90% of cases.
- After a negative pregnancy test, endometrial tissue is required to confirm the diagnosis.

General Considerations

Adenocarcinoma of the endometrium is the most common cancer of the female genital tract in developed countries. It occurs most often in patients 50–70 years of age. Obesity, nulliparity, diabetes mellitus, polycystic ovaries with prolonged anovulation, unopposed estrogen therapy, and the extended use of tamoxifen for the treatment of breast cancer are risk factors. Women with a family history of colon cancer (hereditary nonpolyposis colorectal cancer, Lynch syndrome) are at significantly increased risk, with a lifetime incidence as high as 30%.

Abnormal bleeding is the presenting sign in 90% of cases. Prompt endometrial sampling should be performed for patients with prolonged anovulation, those older than 45 who report abnormal menstrual bleeding, and those with postmenopausal uterine bleeding.

Papanicolaou test of the cervix occasionally shows atypical endometrial cells but is an insensitive diagnostic tool. *Endocervical and endometrial sampling is the only reliable means of diagnosis and is important to differentiate endometrial cancer from hyperplasia, which often can be treated hormonally.* Endometrial biopsy is approximately 90% sensitive for detecting endometrial cancer. Simultaneous hysteroscopy can be valuable in identifying polyps or other lesions within the uterine cavity. Pelvic ultrasonography may be used to evaluate the uterine cavity and the thickness of the endometrial lining. The finding of a thin endometrial lining on ultrasound (4 mm or less) in a postmenopausal patient is clinically reassuring in cases where very little tissue is obtainable through endometrial biopsy. A thickened or irregular endometrial lining should prompt further evaluation for possible hypertrophy, polyps, or neoplasia.

Prevention

Younger patients with chronic anovulation are at risk for endometrial hyperplasia and subsequent endometrial cancer; they can significantly reduce the risk of hyperplasia with the use of oral contraceptives, cyclic progestin therapy, or a hormonal IUD.

Staging

Staging and prognosis are based on surgical and pathologic evaluation only. Examination under anesthesia, endometrial and endocervical sampling, CXR, intravenous urography, cystoscopy, sigmoidoscopy, transvaginal sonography, and MRI will help determine the extent of the disease and its appropriate treatment.

Treatment

Treatment consists of total hysterectomy and bilateral salpingo-oophorectomy. Peritoneal washings for cytologic examination are routinely taken and lymph node sampling may be done. Women with high-risk endometrial cancer (serous adenocarcinoma, clear cell carcinoma, grade 3 deeply invasive endometrioid carcinoma, and stages III/IV disease) are generally treated with surgery followed by chemotherapy, radiation therapy, or both. Molecular subtyping may inform treatment decisions.

Prognosis

With early diagnosis and treatment, the overall 5-year survival for localized disease is approximately 95%. With localized disease, the depth of myometrial invasion is the strongest predictor of survival. Survival rates decrease with increasing stage of disease, with 5-year survival rates reported at 69.8% for regional disease and 18.4% for distant disease.

When to Refer

All patients with endometrial carcinoma should be referred to a gynecologic oncologist.

Crosbie EJ et al. Endometrial cancer. Lancet. 2022;399:1412. [PMID: 35397864]

Karpel HC et al. Treatment options for molecular subtypes of endometrial cancer in 2023. Curr Opin Obstet Gynecol. 2023;35:270. [PMID: 36943683]

CARCINOMA OF THE VULVA

ESSENTIALS OF DIAGNOSIS

- Two independent pathways for development: HPV or chronic inflammation.
- History of prolonged vulvar irritation, with pruritus, local discomfort, or slight bloody discharge.
- Early lesions may suggest or include non-neoplastic epithelial disorders.
- Late lesions appear as a mass, an exophytic growth, or a firm, ulcerated area in the vulva.
- Biopsy is necessary for diagnosis.

General Considerations

Most cancers of the vulva are squamous lesions that classically occur in patients over 50. **Vulvar low-grade squamous intraepithelial lesions (LSIL)** are benign and do not require intervention. **Vulvar HSIL** and **differentiated vulvar intraepithelial neoplasia (dVIN)** are premalignant conditions. Vulvar HSIL (VIN usual type) is associated with HPV, while dVIN is associated with vulvar dermatoses, eg, lichen sclerosus. About 70–90% of premalignant lesions are vulvar HSIL, but HSIL is the precursor for only 20% of vulvar cancers, while dVIN is the precursor for approximately 80% of vulvar cancers. Given that high percentages of HSIL and vulvar cancers are HPV-related, immunization with the HPV vaccine is beneficial to reduce the risk of HPV-related vulvar disease.

Differential Diagnosis

Other vulvar lesions must be considered. VIN may resemble vulvar cancer and must be distinguished by histology. Benign vulvar disorders that should be considered in the diagnosis of carcinoma of the vulva include inflammatory vulvar dermatoses (psoriasis, lichen sclerosus, lichen planus), chronic granulomatous lesions (eg, lymphogranuloma venereum, syphilis), condylomas, epidermal inclusion cysts, hidradenomas, or neurofibromas. Lichen sclerosus and other associated leukoplakic changes in the skin should be biopsied. The likelihood that a superimposed vulvar cancer will develop in a patient with a non-neoplastic epithelial disorder is low (1–5%).

Diagnosis

Biopsy is essential for the diagnosis of VIN and vulvar cancer and should be performed with any localized atypical vulvar lesion, including white patches and hyperpigmented lesions. Multiple skin-punch specimens can be taken in the office under local anesthesia. Colposcopy of vulva, vagina, and cervix can help in identifying areas for biopsy and in planning further treatment.

Staging

Vulvar cancer generally spreads by direct extension into the vagina, urethra, perineum, and anus, with discontinuous spread into the inguinal and femoral lymph nodes. Staging is based on a combined clinical and surgical/pathologic system.

Treatment

Invasive carcinoma confined to the vulva without evidence of spread to adjacent organs or to the regional lymph nodes is treated with radical local excision and inguinal lymphadenectomy or radical local excision alone if invasion is < 1 mm. To avoid the morbidity of inguinal lymphadenectomy, some guidelines recommend sentinel lymph node sampling for women with early-stage vulvar cancer. Patients with more advanced disease may receive preoperative radiation, chemotherapy, or both.

Prognosis

Vulvar SCCs seldom metastasize. With adequate excision, the prognosis is excellent. Patients with invasive vulvar SCC 2 cm in diameter or less, without inguinal lymph node metastases, have an 85–90% 5-year survival rate. If the lesion is larger than 2 cm and lymph node involvement is present, the likelihood of 5-year survival is approximately 40%.

When to Refer

All patients with invasive vulvar carcinoma should be referred to a gynecologic oncologist.

Lukovic J et al. Postoperative management of vulvar cancer. Int J Gynecol Cancer. 2022;32:338. [PMID: 35256421]

OVARIAN TUMORS & OVARIAN CANCER

ESSENTIALS OF DIAGNOSIS

- Symptoms include vague GI discomfort, pelvic pressure, or pain.
- Many cases of early-stage cancer are asymptomatic.
- Pelvic examination and ultrasound are mainstays of diagnosis.

General Considerations

Ovarian tumors are common. Most are benign, but *malignant ovarian tumors are the leading cause of death from gynecologic cancer.* The wide range of types and patterns of ovarian tumors is due to the complexity of ovarian embryology and differences in tissues of origin.

In patients with no family history of ovarian cancer, the lifetime risk in the United States is 1.3%, whereas a woman with one affected first-degree relative has a 5% lifetime risk. Worldwide, the risk of ovarian cancer is 2.7%. Ultrasound or tumor marker screening for patients with one or no affected first-degree relatives has *not* been shown to reduce mortality from ovarian cancer, and the risks associated with prophylactic surgical procedures outweigh the benefits in low-risk women. For patients with two or more affected first-degree relatives, the lifetime risk is 7%. Approximately 3% of women with two or more affected first-degree relatives will have a **hereditary ovarian cancer syndrome** with a lifetime ovarian cancer risk of 40%. Women with a *BRCA1* gene pathogenic variant have a 45% lifetime risk of ovarian cancer and those with a *BRCA2* pathogenic variant, a 20% risk. *Typically, risk-reducing salpingo-oophorectomy is recommended for patients who have completed childbearing and by age 35–40 years for* BRCA1 *carriers, while women with* BRCA2 *may consider delaying until age 40–45 years because of later onset of ovarian cancer.*

Clinical Findings

A. Symptoms and Signs

Most patients with both benign and malignant ovarian neoplasms are either asymptomatic or experience only mild nonspecific GI symptoms or pelvic pressure. Patients with advanced malignant disease may experience abdominal pain and bloating, and a palpable abdominal mass with ascites is often present.

B. Laboratory Findings

Serum CA 125 is elevated in 80% of patients with epithelial ovarian cancer overall but in only 50% with early disease. However, CA 125 may be elevated in premenopausal patients with benign disease (such as endometriosis), minimizing its usefulness in ovarian cancer screening. In premenopausal women with ovarian masses, other tumor markers (such as human chorionic gonadotropin [hCG], LD, or α-fetoprotein) may be indicators of the tumor type.

C. Imaging

Transvaginal sonography is useful for screening high-risk patients but has inadequate sensitivity for screening low-risk patients. Ultrasound is helpful in differentiating ovarian masses that are benign and likely to resolve spontaneously from those with malignant potential. Color Doppler imaging may further enhance the specificity of ultrasound diagnosis.

Differential Diagnosis

Once an ovarian mass has been detected, it must be categorized as functional, benign neoplastic, or potentially malignant. Predictive factors include age, size of the mass, ultrasound features, serum CA 125 level, the presence of symptoms, and whether the mass is unilateral or bilateral. Simple cysts up to 10 cm in diameter are almost universally benign in both premenopausal and postmenopausal patients. Most will resolve spontaneously and may be monitored without intervention. If the mass is larger or unchanged on repeat transvaginal sonography, or if symptomatic, surgical evaluation is warranted.

Treatment

If a malignant ovarian mass is suspected, surgical evaluation should be performed by a gynecologic oncologist. For benign neoplasms, tumor excision or unilateral oophorectomy may be performed if symptomatic. For ovarian cancer in an early stage, the standard therapy is complete surgical staging including hysterectomy and bilateral salpingo-oophorectomy with omentectomy and selective lymphadenectomy. With more advanced disease, aggressive removal of all visible tumor improves survival. Except for patients with low-grade ovarian cancer in an early stage, postoperative chemotherapy is indicated (see Table 44–2). Several chemotherapy regimens are effective in halting progression of disease, such as the combination of cisplatin or carboplatin with paclitaxel; however, overall likelihood of recurrence for all stages of disease is 62% and 80–85% for those with stage III or IV disease.

Prognosis

Regional or distant disease is diagnosed in approximately 75% of women with ovarian cancer. The overall 5-year survival is approximately 31.5% with distant disease, but 72.9% with regional and 92.4% with localized disease.

When to Refer

If a malignant mass is suspected, surgical evaluation should be performed by a gynecologic oncologist.

Centers for Disease Control and Prevention (CDC). Ovarian cancer screening. https://www.cdc.gov/ovarian-cancer/screening/?CDC_AAref_Val=https://www.cdc.gov/cancer/ovarian/basic_info/screening.htm. Accessed August 19, 2024.

Obstetrics & Obstetric Disorders

Vanessa L. Rogers, MD
Scott W. Roberts, MD

DIAGNOSIS OF PREGNANCY

Pregnancy should be diagnosed as promptly as possible. Prenatal care can begin early for a desired pregnancy to eliminate potential risks, such as harmful medications, drug and alcohol use, smoking, and occupational chemical exposure. If an unwanted pregnancy occurs, counseling about options can be provided at an early stage. Clinicians must be aware of laws in their jurisdiction of practice regarding termination.

Pregnancy Tests

All urine or blood pregnancy tests rely on the detection of human chorionic gonadotropin (hCG) produced by the placenta. Levels increase shortly after implantation, approximately double every 48 hours (this rise can range from 30–100% in normal pregnancies), reach a peak at 50–75 days, and fall to lower levels in the second and third trimesters. Pregnancy tests are performed on serum or urine and are accurate at the time of the missed period or shortly after it.

1. In ectopic pregnancies—Compared with intrauterine pregnancies, ectopic pregnancies may show lower levels of hCG that plateau or fall in serial determinations. Quantitative assays of hCG repeated at 48-hour intervals are used in the diagnosis of ectopic pregnancy as well as in cases of molar pregnancy and early pregnancy loss. Comparison of hCG levels between laboratories may be misleading in a given patient because different international standards may produce results that vary by as much as twofold. Consistent follow-up is necessary.

2. In pregnancy of unknown location—Despite a positive pregnancy test, the location and viability of the pregnancy are unknown because it is not seen on transvaginal ultrasound.

Manifestations of Pregnancy

The following symptoms and signs are usually due to pregnancy, but none are diagnostic. A record of the time of coitus or insemination is helpful for diagnosing and dating a pregnancy.

A. Symptoms

Amenorrhea, nausea and vomiting, breast tenderness and tingling, urinary frequency and urgency, "quickening" (perception of first movement noted at about the 18th week), and weight gain are symptoms of pregnancy.

B. Signs (in Weeks From Last Menstrual Period)

Breast changes (enlargement, vascular engorgement, colostrum) begin early in pregnancy and continue until the postpartum period. Cyanosis of the vagina and cervical portio and softening of the cervix occur in about the 7th week. Softening of the cervicouterine junction takes place in the 8th week, and generalized enlargement and diffuse softening of the corpus occurs after the 8th week. The abdomen typically starts to enlarge in the 16th week but depends on body habitus.

The uterine fundus is palpable above the pubic symphysis by 12–15 weeks from the last menstrual period and reaches the umbilicus by 20–22 weeks. Fetal heart tones can be heard by Doppler at 10–12 weeks' gestation.

Differential Diagnosis

The nonpregnant uterus enlarged by myomas can be confused with the gravid uterus, but it is usually firm and irregular. An ovarian tumor may be found midline, displacing the nonpregnant uterus to the side or posteriorly. Ultrasonography and a pregnancy test will provide a diagnosis in these circumstances.

ESSENTIALS OF PRENATAL CARE

Prenatal visits begin as early as possible after the diagnosis of pregnancy. The initial visit should include a history, physical examination, advice to the patient, and appropriate tests and procedures (see *Current Medical Diagnosis & Treatment* on AccessMedicine.com for a discussion of routine prenatal care).

A. Medications

Only medications prescribed or authorized by the obstetric provider should be taken since certain medications are contraindicated during pregnancy (Table 22–1).

Table 22–1. Common drugs that are teratogenic or fetotoxic.[1]

ACE inhibitors
Alcohol
Androgens
Angiotensin-II receptor blockers
Antiepileptics (phenytoin, valproic acid, carbamazepine)
Benzodiazepines
Cyclophosphamide
Diazoxide
Diethylstilbestrol
Disulfiram
Ergotamine
Estrogens
Griseofulvin
Isotretinoin
Lithium
Methotrexate
Misoprostol
NSAIDs (third trimester)
Opioids (prolonged use)
Radioiodine (antithyroid)
Reserpine
Ribavirin
Sulfonamides (second and third trimesters)
Tetracycline (third trimester)
Thalidomide
Tobacco smoking
Warfarin and other coumarin anticoagulants

[1] Many other drugs are also contraindicated during pregnancy. Evaluate any drug for its need versus its potential adverse effects. Further information can be obtained from the manufacturer or from any of several teratogenic registries around the country. Go to https://www.fda.gov/ScienceResearch/SpecialTopics/WomensHealthResearch/ucm134848.htm for more information.

B. Alcohol and Other Drugs

Pregnant persons should be encouraged to abstain from alcohol, tobacco, and all recreational ("street") drugs.

1. Fetal alcohol syndrome—No safe level of alcohol intake has been established for pregnancy. Fetal effects of fetal alcohol syndrome include growth restriction; facial, skeletal, and cardiac abnormalities; and serious CNS dysfunction.

2. Cigarette smoking—There is fetal exposure to carbon monoxide and nicotine from cigarette smoking, which may lead to adverse pregnancy outcomes. An increased risk of placental abruption (abruptio placentae), placenta previa, and premature rupture of the membranes is documented among pregnant persons who smoke. Preterm delivery, low birth weight, and ectopic pregnancy are also more likely among persons who smoke cigarettes. Persons who smoke should quit smoking or at least reduce the number of cigarettes smoked per day to as few as possible. Complete cessation is preferred over reduction with the best outcomes seen in persons who stop smoking prior to 15 weeks' gestation. Clinicians should ask all pregnant persons about their smoking history and offer smoking cessation counseling, since there is more motivation to change at this time. Pregnant persons should also avoid exposure to environmental smoke ("passive smoking"), smokeless tobacco, and e-cigarettes. Pharmacotherapy for smoking cessation has been used with mixed results. Studies of bupropion and nicotine replacement systems are inadequate to properly weigh risks and benefits.

3. Illicit drug use—Cocaine use in pregnancy is associated with an increased risk of premature rupture of membranes, preterm delivery, placental abruption, intrauterine growth restriction, and sudden infant death syndrome. Similar adverse effects on pregnancy are associated with amphetamine use, perhaps reflecting the vasoconstrictive properties of both amphetamines and cocaine. Adverse effects associated with opioid use include intrauterine growth restriction, prematurity, and fetal death. For pregnant persons with opioid use disorder, opioid agonist therapy is the standard of care (see Chapter 48).

C. Radiographs and Noxious Exposures

Radiographs should be avoided unless essential and approved by a clinician. Abdominal shielding should be used whenever possible. The patient should be told to inform her other health care providers that she is pregnant. Chemical or radiation hazards should be avoided as should excessive heat in hot tubs or saunas. Patients should be told to avoid handling cat feces or cat litter and to wear gloves when gardening to avoid infection with toxoplasmosis.

LACTATION

Drugs taken by a nursing mother may accumulate in milk and be transmitted to the infant. LactMed® is an online drug and lactation database for breastfeeding mothers (https://www.ncbi.nlm.nih.gov/books/NBK501922/).

TRAVEL & IMMUNIZATIONS DURING PREGNANCY

During an otherwise normal low-risk pregnancy, travel can be planned most safely up to the 32nd week. Commercial flying in pressurized cabins does not pose a threat to the fetus. An aisle seat will allow frequent walks. Adequate fluids should be taken during the flight. Travel can also increase one's chances of exposure to communicable diseases. Pregnant persons infected with SARS-CoV-2 are at increased risk for preterm birth and for serious illness compared with persons who are not pregnant. Pregnant persons should consider risk reduction strategies as appropriate.

Vaccination against COVID-19 is recommended for persons who are pregnant, trying to get pregnant, or may become pregnant, and who are breastfeeding. The CDC has determined that the benefits of vaccination outweigh any risks. There is no evidence that vaccination causes problems with fertility in men or women. Pregnant persons who have been vaccinated against COVID-19 may receive a dose of the updated vaccine. The CDC also recommends that persons who are 32–36 weeks pregnant during the RSV season receive the RSV vaccine to protect their baby from RSV after birth.

Traveling to endemic areas of yellow fever (Africa or Latin America) or of Zika virus (Latin America) is not advisable; since Zika virus can be sexually transmitted, partner travel should also be discussed (see Chapter 37). Similarly, it is inadvisable to travel to areas of Africa or Asia where chloroquine-resistant falciparum malaria is a hazard since complications of malaria are more common in pregnancy.

Ideally, all immunizations should precede pregnancy. *Live virus products are contraindicated during pregnancy* *(measles, rubella, yellow fever, and smallpox)*. Inactivated polio vaccine should be given subcutaneously instead of the oral live-attenuated vaccine. The varicella vaccine should be given 3 months before becoming pregnant. It is not recommended in pregnancy. Vaccines against pneumococcal pneumonia, meningococcal meningitis, and hepatitis A can be used as indicated. Pregnant persons who have not been previously vaccinated against hepatitis B should be vaccinated during pregnancy. The HPV vaccine is not recommended for pregnant persons. However, adverse outcomes have not been described when used during pregnancy. If a person who has started the vaccine series is pregnant, the remaining doses should be administered after pregnancy.

The CDC lists pregnancy as a high-risk for influenza. Annual influenza vaccination is indicated in all women who are pregnant or will be pregnant during the "flu season." It can be given in the first trimester. The CDC also recommends that every pregnant woman receive a dose of Tdap during each pregnancy irrespective of her prior vaccination history. The optimal timing for such Tdap administration is between 27–36 weeks' gestation, to maximize the antibody response of the pregnant woman against pertussis and the passive antibody transfer to the infant. For any woman who was not previously vaccinated with Tdap and for whom the vaccine was not given during her pregnancy, Tdap should be administered immediately postpartum. Further, any teenagers or adults not previously vaccinated who will have close contact with the infant should also receive it, ideally 2 weeks before exposure to the infant. This vaccination strategy is called "cocooning," and its purpose is to protect the infant aged younger than 12 months who is at particularly high risk for lethal pertussis.

Hepatitis A vaccine contains formalin-inactivated virus and can be given in pregnancy when needed. Pooled immune globulin to prevent hepatitis A is safe and does not carry risk of HIV transmission. Chloroquine and proguanil can be used for malaria prophylaxis in pregnancy.

Water should be purified by boiling when there is potential for microbial contamination, since iodine purification may provide more iodine than is safe during pregnancy.

Prophylactic antibiotics or bismuth subsalicylate should not be used during pregnancy to prevent diarrhea. Oral rehydration and treatment of bacterial diarrhea with erythromycin or ampicillin if necessary are preferred.

MMWR Morb Mortal Wkly Rep. 2023;72:1115. [PMID: 37824423]

OBSTETRIC COMPLICATIONS OF THE FIRST & SECOND TRIMESTERS

VOMITING OF PREGNANCY & HYPEREMESIS GRAVIDARUM

ESSENTIALS OF DIAGNOSIS

- **Vomiting of pregnancy**
  - "Morning sickness" lasts throughout the day.
  - Exerts no adverse effects on the pregnancy and does not presage complications.
- **Hyperemesis gravidarum**
  - Persistent, severe vomiting.
  - Weight loss, dehydration, hypochloremic alkalosis, hypokalemia.
  - May have transient elevation of liver enzymes.
  - Appears related to high or rising serum hCG.
  - Vomiting of pregnancy and hyperemesis gravidarum more common with multifetal pregnancies or hydatidiform mole.

General Considerations

Nausea and vomiting begin soon after the first missed period and cease by the fifth month of gestation. Up to three-fourths of women experience nausea and vomiting during early pregnancy, with the vast majority noting nausea throughout the day.

Persistent, severe vomiting during pregnancy—hyperemesis gravidarum—can be disabling and require hospitalization. Hyperthyroidism can be associated with hyperemesis gravidarum, so it is advisable to determine TSH and free thyroxine (FT_4) values in these patients if they have symptoms of hyperthyroidism.

Treatment

A. Mild Nausea and Vomiting of Pregnancy

In most instances, only reassurance and dietary advice are required. Because of possible teratogenicity, drugs used during the first half of pregnancy should be restricted to those of major importance to life and health. Pyridoxine (vitamin B_6), 50–100 mg/day orally, is nontoxic and may be helpful in some patients. Pyridoxine alone or in combination with doxylamine (10 mg doxylamine succinate and 10 mg pyridoxine hydrochloride, two tablets at bedtime) is first-line pharmacotherapy. Antiemetics, antihistamines, and antispasmodics are generally unnecessary.

B. Hyperemesis Gravidarum

With more severe nausea and vomiting, it may become necessary to hospitalize the patient. In this case, a private room with limited activity is preferred. It is recommended to give nothing by mouth until the patient is improving and maintain hydration and electrolyte balance by giving appropriate parenteral fluids and vitamin supplements as indicated. Antiemetics such as promethazine (12.5–25 mg orally, rectally, or intravenously every 4–6 hours), metoclopramide (5–10 mg orally or intravenously every 6 hours), or ondansetron (4–8 mg orally or intravenously every 8 hours) should be started. Ondansetron has been associated in some studies with congenital anomalies. Data are limited, but the risks and benefits of treatment should be addressed with the patient. If there is an increased risk, it is probably low. Antiemetics will likely need to be given intravenously initially. Rarely, total parenteral nutrition may become necessary but only if enteral feedings cannot be done. As soon as possible, the patient should be placed on a dry diet consisting of six small meals daily. Antiemetics may be continued orally as needed. After inpatient stabilization, the patient can be maintained at home even if she requires intravenous fluids in addition to her oral intake. There are conflicting studies regarding the use of corticosteroids for the control of hyperemesis gravidarum, and it has also been associated with fetal anomalies, specifically oral clefts. The increase in risk is likely small. However, this treatment should be withheld before 10 weeks' gestation and until more accepted treatments have been exhausted.

When to Refer

- Patient does not respond to first-line outpatient management.
- There is concern for other pathology (ie, hydatidiform mole).

When to Admit

- Patient cannot tolerate any food or water.
- Patient cannot ingest necessary medications.
- Weight loss.
- Presence of a hydatidiform mole.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 189: nausea and vomiting of pregnancy. Obstet Gynecol. 2018;131:e15. [Reaffirmed 2024] [PMID: 29266076]

SPONTANEOUS PREGNANCY LOSS

ESSENTIALS OF DIAGNOSIS

- Intrauterine pregnancy < 20 weeks' gestation.
- Low or falling levels of hCG.
- Bleeding, midline cramping pain.
- Open cervical os.
- Complete or partial expulsion of products of conception.

General Considerations

About three-fourths of spontaneous pregnancy losses (spontaneous abortions/miscarriage) occur before the 16th week; of these, three-fourths occur before the 8th week. Almost 20% of all clinically recognized pregnancies result in a spontaneous loss.

More than 60% of spontaneous losses result from chromosomal defects due to maternal or paternal factors; about 15% appear to be associated with maternal trauma, infections, dietary deficiencies, diabetes mellitus, hypothyroidism, antiphospholipid antibody syndrome, or anatomic malformations. There is no reliable evidence that spontaneous pregnancy loss may be induced by psychic stimuli such as severe fright, grief, anger, or anxiety. In about one-fourth of cases, the cause cannot be determined. There is no evidence that video display terminals or associated electromagnetic fields are related to an increased risk of spontaneous pregnancy loss.

It is important to distinguish women with a history of incompetent cervix (a problem during the second trimester) from those with early pregnancy loss in the first trimester. Factors that predispose to incompetent cervix are a history of incompetent cervix with a previous pregnancy, cervical conization or surgery, cervical injury, diethylstilbestrol (DES) exposure, and anatomic abnormalities of the cervix. Before pregnancy or during the first trimester, there are no methods for determining whether the cervix will eventually be incompetent. After 14–16 weeks, ultrasound may be used to evaluate the internal anatomy of the lower uterine segment and cervix for the funneling and shortening abnormalities consistent with cervical incompetence.

Clinical Findings

A. Symptoms and Signs

1. Incompetent cervix—Characteristically, incompetent cervix presents as "silent" cervical dilation (ie, with minimal uterine contractions) in the second trimester. When the cervix reaches 4 cm dilated or more, active uterine contractions or rupture of the membranes may occur secondary to the degree of cervical dilation. This does not change the primary diagnosis.

2. Threatened spontaneous pregnancy loss—Bleeding or cramping occurs, but the pregnancy continues. The cervix is not dilated.

3. Inevitable spontaneous pregnancy loss—The cervix is dilated, and the membranes may be ruptured, but passage of the products of conception has not yet occurred. Bleeding and cramping persist, and passage of the products of conception is considered inevitable.

4. Incomplete pregnancy loss—The cervix is dilated. Some portion of the products of conception remains in the uterus. Only mild cramps are reported, but bleeding is persistent and often excessive.

5. Early pregnancy loss—The pregnancy has ceased to develop, but the conceptus has not been expelled. Symptoms of pregnancy disappear. There may be a brownish vaginal discharge but no active bleeding. Pain does not develop. The cervix is semifirm and slightly patulous; the uterus becomes smaller and irregularly softened; the adnexa are normal.

B. Laboratory Findings

Pregnancy tests show low or falling levels of hCG. A CBC should be obtained if bleeding is heavy. Determine Rh type and give Rh_o(D) immune globulin if Rh-negative. All tissue recovered should be assessed by a pathologist and may be sent for genetic analysis in selected cases.

C. Ultrasonographic Findings

Transvaginal ultrasound can detect the gestational sac 5–6 weeks from the last menstruation, a fetal pole at 6 weeks, and fetal cardiac activity at 6–7 weeks. Serial observations are often required to evaluate changes in size of the embryo. Diagnostic criteria of early pregnancy loss are a crown-rump length of 7 mm or more and no heartbeat or a mean sac diameter of 25 mm or more and no embryo.

Differential Diagnosis

The bleeding that occurs in abortion of a uterine pregnancy must be differentiated from the abnormal bleeding of an ectopic pregnancy and anovulatory bleeding in a nonpregnant person. The passage of hydropic villi in the bloody discharge is diagnostic of hydatidiform mole.

Treatment

A. General Measures

1. Threatened spontaneous pregnancy loss—Studies have failed to demonstrate benefit of bedrest for 1–2 days followed by gradual resumption of usual activities. Abstinence from sexual activity has also been suggested without proven benefit. Data are lacking to support the administration of progestins to all women with a threatened pregnancy loss. If an infection is diagnosed (ie, UTI) during the patient's evaluation, it should be treated.

2. Early pregnancy loss—This calls for counseling regarding the fate of the pregnancy and planning for its elective termination at a time chosen by the patient and clinician. Management can be medical or surgical. Each has risks and benefits. Medically induced first-trimester termination with prostaglandins (ie, misoprostol given vaginally in a dose of 200–800 mcg, followed by one repeat dose if needed 3 hours to 7 days after the first dose) is safe, effective, less invasive, and more private than surgical intervention. If available, a dose of mifepristone, 200 mg orally, should be given 24 hours before administration of misoprostol. If medical management is unsuccessful or if there is excessive bleeding, a surgical procedure (dilation and curettage) may still be needed. Patients must be counseled about the different therapeutic options.

B. Surgical Measures

1. Incomplete pregnancy loss—Prompt removal of any products of conception remaining within the uterus is required to stop bleeding and prevent infection. Analgesia and a paracervical block are useful, followed by uterine exploration with ovum forceps or uterine aspiration. Regional anesthesia may be required.

2. Incompetent cervix—A cerclage is the treatment of choice for incompetent cervix, but a viable intrauterine pregnancy should be confirmed before placement of the cerclage.

Cerclage should be undertaken with caution when there is advanced cervical dilation or when the membranes are prolapsed into the vagina. *Rupture of the membranes and infection are specific contraindications to cerclage.* Testing for *N gonorrhoeae*, *C trachomatis*, and group B streptococci should be obtained before elective placement of a cerclage. *N gonorrhoeae* and *C trachomatis* should be treated before cerclage placement. Testing for group B streptococci is used to guide the need for antibiotics should the patient labor. Patients should consider abstaining from sexual intercourse.

When to Refer

- Patient with history of a second-trimester loss.
- Vaginal bleeding that resembles menstruation in a pregnant patient.
- Patient with an open cervical os.
- No signs of uterine growth in serial examinations of a pregnant patient.
- Leakage of amniotic fluid.

When to Admit

- Open cervical os.
- Heavy vaginal bleeding.
- Leakage of amniotic fluid.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 200: early pregnancy loss. Obstet Gynecol. 2018;132:e197. [Reaffirmed 2021] [PMID: 30157093]

RECURRENT PREGNANCY LOSS

According to the American Society of Reproductive Medicine, recurrent pregnancy loss is defined as the loss of two or more previable (< 24 weeks' gestation or 500 g) pregnancies in succession. Recurrent pregnancy loss affects about 1–5% of pregnancies. Abnormalities related to recurrent pregnancy loss can be identified in approximately 50% of both partners. If a woman has lost three previous pregnancies without identifiable cause, she still has at least a 55% chance of carrying a fetus to viability.

Recurrent pregnancy loss is a clinical rather than pathologic diagnosis. The clinical findings are similar to those observed in other types of pregnancy loss. It is appropriate to begin a medical evaluation in a woman who has had two first-trimester losses.

Treatment

A. Preconception Therapy

Preconception therapy is aimed at detection of maternal or paternal defects that may contribute to pregnancy loss. A thorough history and examination is essential. Maternal testing of a random blood glucose and thyroid function studies (including thyroid antibodies) can be done if the history indicates a possible predisposition to diabetes mellitus or thyroid disease; detection of lupus anticoagulant and other hemostatic abnormalities (proteins S and C and antithrombin deficiency, hyperhomocysteinemia, anticardiolipin antibody, factor V Leiden mutations) and an antinuclear antibody test may be indicated, but in most cases these tests will not be helpful. Hysteroscopy, saline infusion sonogram, or hysterography can be used to exclude submucosal myomas and congenital anomalies of the uterus. In women with recurrent pregnancy losses, resection of a uterine septum, if present, has been recommended. Chromosomal (karyotype) analysis of both partners can be done to rule out balanced translocations (found in 3–4% of infertile partners), but karyotyping is expensive and may not be helpful.

Many therapies have been tried to prevent recurrent loss from immunologic causes. Low-molecular-weight heparin, aspirin, intravenous immunoglobulin, and corticosteroids have been used but the definitive treatment has not been determined (see Antiphospholipid Syndrome, below). Prophylactic low-dose heparin and low-dose aspirin have been recommended for women with antiphospholipid antibodies and recurrent pregnancy loss.

B. Postconception Therapy

The patient should be provided early prenatal care and scheduled frequent office visits. Empiric sex steroid hormone therapy is complicated and should be done by an expert if undertaken.

Prognosis

The prognosis is excellent if the cause of pregnancy losses can be corrected or treated.

Turesheva A et al. Recurrent pregnancy loss etiology, risk factors, diagnosis, and management. Fresh look into a full box. J Clin Med. 2023;12:4074. [PMID: 37373766]

ECTOPIC PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Amenorrhea or irregular bleeding and spotting.
- Pelvic pain, usually adnexal.
- Adnexal mass by clinical examination or ultrasound.
- Failure of serum β-hCG to double every 48 hours.
- No intrauterine pregnancy on transvaginal ultrasound with serum β-hCG > 3500 mIU/mL.

General Considerations

Ectopic implantation occurs in approximately 2% of first trimester pregnancies. About 98% of ectopic pregnancies are tubal. Other sites of ectopic implantation are the peritoneum or abdominal viscera, the ovary, and the cervix. Any condition that prevents or inhibits migration of the fertilized ovum to the uterus can predispose to an ectopic pregnancy, including a history of infertility, pelvic inflammatory disease, ruptured appendix, and prior tubal surgery. Combined intrauterine and extrauterine pregnancy of two embryos (heterotopic) may occur rarely. In the United States, undiagnosed or undetected ectopic pregnancy is one of the most common causes of maternal death during the first trimester.

Clinical Findings

A. Symptoms and Signs

Severe lower quadrant pain occurs in many cases. It is sudden in onset, stabbing, intermittent, and does not radiate. Backache may be present during attacks. Shock occurs in about 10%, often after pelvic examination. At least two-thirds of patients give a history of abnormal menstruation; many have been infertile.

Blood may leak from the tubal ampulla over a period of days, and considerable blood may accumulate in the peritoneum. Slight but persistent vaginal spotting is usually reported, and a pelvic mass may be palpated. Abdominal distention and mild paralytic ileus are often present.

B. Laboratory Findings

The CBC may show anemia and slight leukocytosis. Quantitative serum pregnancy tests will show levels generally lower than expected for normal pregnancies of the same duration. If β-hCG levels are followed over a few days, there may be a slow rise or a plateau rather than the near doubling every 2 days associated with normal early intrauterine pregnancy or the falling levels that occur with spontaneous pregnancy loss.

C. Imaging

Ultrasonography can reliably demonstrate a gestational sac 5–6 weeks from the last menstruation and a fetal pole at 6 weeks if located in the uterus. An empty uterine cavity raises a strong suspicion of extrauterine pregnancy, which can occasionally be revealed by transvaginal ultrasound. A discriminatory zone of serum β-hCG (also known as a threshold level), has been correlated with ultrasound findings of an intrauterine pregnancy; a β-hCG level of 6500 mIU/mL with an empty uterine cavity by transabdominal ultrasound is highly suspicious for an ectopic pregnancy. Similarly, a β-hCG value ≥ 3500 mIU/mL can be indicative of an ectopic pregnancy if no products of conception are detected within the uterine cavity by transvaginal ultrasound. A discriminatory zone, however, should be used with caution and clinical decisions should not be made solely on β-hCG levels; there have been cases where it is not a reliable indicator of intrauterine or ectopic pregnancy.

D. Special Examinations

Laparoscopy is the surgical procedure of choice both to confirm an ectopic pregnancy and in most cases to permit removal of the ectopic pregnancy without the need for exploratory laparotomy.

Ectopic pregnancy should be suspected when postabortal tissue examination fails to reveal chorionic villi. Steps must be taken for immediate diagnosis, including prompt microscopic tissue examination, ultrasonography, and serial β-hCG titers every 48 hours.

Differential Diagnosis

Clinical and laboratory findings suggestive or diagnostic of pregnancy will distinguish ectopic pregnancy from many acute abdominal illnesses such as acute appendicitis, acute pelvic inflammatory disease, ruptured corpus luteum cyst or ovarian follicle, and urinary calculi. Uterine enlargement with clinical findings similar to those found in ectopic pregnancy is also characteristic of an aborting uterine pregnancy or hydatidiform mole.

Treatment

Patients must be warned about the complications of an ectopic pregnancy and monitored closely. In a stable patient with normal liver and kidney function tests, methotrexate (50 mg/m^2) intramuscularly—given as single or multiple doses—is acceptable medical therapy for early ectopic pregnancy. Criteria favoring a therapeutic response to methotrexate are that the pregnancy is < 4 cm in largest dimension and unruptured, with no active bleeding and no fetal heart tones. Several small studies have not found an increased risk of fetal malformations or pregnancy losses in women who conceive within 6 months of methotrexate therapy.

When a patient with an ectopic pregnancy is unstable or when surgical therapy is planned, the patient is hospitalized. Blood is typed and cross-matched. The goal is to diagnose and operate before there is frank rupture of the tube and intra-abdominal hemorrhage. *The use of methotrexate in an unstable patient is absolutely contraindicated.*

Surgical treatment is definitive. In most patients, diagnostic laparoscopy is the initial surgical procedure performed. Depending on the size of the ectopic pregnancy and whether or not it has ruptured, salpingostomy with removal of the ectopic pregnancy or a partial or complete salpingectomy can usually be performed. Clinical conditions permitting, patency of the contralateral tube can be established by injection of indigo carmine into the uterine cavity and flow through the contralateral tube confirmed visually by the surgeon; iron therapy for anemia may be necessary during convalescence. $Rh_o(D)$ immune globulin (300 mcg) should be given to Rh-negative patients.

Prognosis

Repeat tubal pregnancy occurs in about 10% of cases. This should not be regarded as a contraindication to future pregnancy, but the patient requires careful observation and early ultrasound confirmation of an intrauterine pregnancy.

When to Refer

- Severe abdominal pain.
- Palpation of an adnexal mass on pelvic examination.
- Abdominal pain and vaginal bleeding in a pregnant patient.

When to Admit

Presence of symptoms or signs of a ruptured ectopic pregnancy.

Tonick S et al. Ectopic pregnancy. Obstet Gynecol Clin North Am. 2022;49:537. [PMID: 36122984]

GESTATIONAL TROPHOBLASTIC DISEASE (Hydatidiform Mole & Choriocarcinoma)

ESSENTIALS OF DIAGNOSIS

Hydatidiform mole

- Amenorrhea.
- Irregular uterine bleeding.
- Serum β-hCG > 40,000 mIU/mL.
- Passage of grapelike clusters of enlarged edematous villi per vagina.
- Uterine ultrasound shows characteristic heterogeneous echogenic image and no fetus or placenta.
- Cytogenetic composition is 46,XX (85%), of paternal origin.

Choriocarcinoma

- Persistence of detectable β-hCG after mole evacuation.

General Considerations

Gestational trophoblastic disease is a spectrum of disorders that includes hydatidiform mole (partial and complete), invasive mole (local extension into the uterus or vagina), choriocarcinoma (malignancy often complicated by distant metastases), and placental site trophoblastic tumor. Complete moles show no evidence of a fetus on ultrasonography. The majority are 46,XX, with all chromosomes of paternal origin. Partial moles generally show evidence of an embryo or gestational sac; are triploid, slower-growing, and less symptomatic; and often present clinically as spontaneous pregnancy loss. Partial moles tend to follow a benign course, while complete moles have a greater tendency to become choriocarcinoma.

In North America, the frequency of gestational trophoblastic disease is 1:1500 pregnancies. The highest rates occur in Asian patients. Risk factors include prior spontaneous pregnancy loss, a history of mole, and age younger than 21 or older than 35. Approximately 10% of women require further treatment after evacuation of the mole; choriocarcinoma develops in 2–3% of women.

Clinical Findings

A. Symptoms and Signs

1. Hydatidiform mole—Uterine bleeding, beginning at 6–16 weeks, is observed in most instances. In some cases, the uterus is larger than would be expected in a normal pregnancy of the same duration. Excessive nausea and vomiting may occur. Bilaterally enlarged cystic ovaries are sometimes palpable. They result from ovarian hyperstimulation due to excess β-hCG. Preeclampsia-eclampsia may develop during the second trimester of an untreated molar pregnancy, but this is unusual because most are diagnosed early.

2. Choriocarcinoma—Manifestations may be continued or recurrent uterine bleeding after evacuation of a mole or following delivery, spontaneous pregnancy loss, or ectopic pregnancy. An ulcerative vaginal tumor, pelvic mass, or distant metastases may be the presenting manifestation.

B. Laboratory Findings

Hydatidiform moles are generally characterized by high serum β-hCG values, which can range from high normal to the millions. Levels are higher with complete moles than with partial moles. Serum β-hCG values, if extremely high, can assist in making the diagnosis, but they are more helpful in managing response to treatment. Hemoglobin/hematocrit, creatinine, blood type, liver biochemical tests, and thyroid function tests should also be measured. High β-hCG levels can cause the release of thyroid hormone, and rarely, symptoms of hyperthyroidism.

C. Imaging

The preoperative diagnosis of hydatidiform mole is confirmed by ultrasound. Placental vesicles can be easily seen on transvaginal ultrasound. A preoperative CXR is indicated to rule out pulmonary metastases of the trophoblast.

Treatment

Patients with hyperthyroidism may require β-blocker therapy until the mole has been evacuated.

A. Specific (Surgical) Measures

The uterus should be emptied as soon as the diagnosis of hydatidiform mole is established, preferably by suction curettage. The products of conception should be sent to a pathologist for review. Ovarian cysts should not be resected nor ovaries removed; spontaneous regression of theca lutein cysts will occur with elimination of the mole. $Rh_o(D)$ immune globulin should be given if Rh-negative. In patients who have completed their childbearing, hysterectomy is an acceptable alternative. Hysterectomy does not preclude the need for follow-up of β-hCG levels.

B. Follow-Up Measures

Weekly quantitative β-hCG level measurements are initially required. Following successful surgical evacuation, moles show a progressive decline in β-hCG. After a negative weekly test (< 5 mIU/mL) is achieved, the interval may be increased to every 1 month for an additional 6 months. The purpose of this follow-up is to identify persistent nonmetastatic and metastatic disease, including choriocarcinoma, which is more likely to occur if the initial β-hCG is high and the uterus is large. If levels plateau or begin to rise, the patient should be evaluated by repeat laboratory tests, CXR, and dilatation and curettage (D&C) before the initiation of chemotherapy. Effective contraception (preferably birth control pills) should be prescribed to avoid the confusion of elevated β-hCG from a new pregnancy. The β-hCG levels should be negative for 6 months before pregnancy is attempted again. Because the risk of recurrence of a molar pregnancy is 1–2%, an ultrasound should be performed in the first trimester of the pregnancy following a mole to ensure that the pregnancy is normal. In addition, a β-hCG level should then be checked 6 weeks postpartum (after the subsequent normal pregnancy) to ensure there is no persistent trophoblastic tissue, and the placenta should be examined by a pathologist.

C. Antitumor Chemotherapy

If malignant tissue is discovered at surgery or during the follow-up examination, chemotherapy is indicated. For low-risk patients with a good prognosis, methotrexate is considered first-line therapy followed by dactinomycin (see Table 44–3). Patients with high-risk disease should be referred to a cancer center, where multiple-agent chemotherapy probably will be given.

Prognosis

Five-year survival after courses of chemotherapy, even when metastases have been demonstrated, can be expected in at least 85% of cases of choriocarcinoma.

When to Refer

- Uterine size exceeds that anticipated for gestational age.
- Vaginal bleeding similar to menstruation.
- Pregnant patient with a history of a molar pregnancy.

When to Admit

- Confirmed molar pregnancy by ultrasound and laboratory studies.
- Heavy vaginal bleeding in a pregnant patient under evaluation.

OBSTETRICAL COMPLICATIONS OF THE SECOND & THIRD TRIMESTERS

GESTATIONAL HYPERTENSION, PREECLAMPSIA, & ECLAMPSIA

ESSENTIALS OF DIAGNOSIS

Gestational hypertension

- Blood pressure ≥ 140 mm Hg systolic or > 90 mm Hg diastolic after 20 weeks' gestation.
- Blood pressure was normal before pregnancy and returns to normal postpartum.
- Absence of proteinuria.

Preclampsia without severe features

- Blood pressure ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic after 20 weeks' gestation.
- Proteinuria ≥ 0.3 g in 24 hours.

Preeclampsia with severe features

- Blood pressure ≥ 160 mm Hg systolic or ≥ 110 mm Hg diastolic.
- Progressive kidney injury.
- Proteinuria is not always present.
- If proteinuria is absent, diagnosis should still be considered if hypertension is present along with any of the following:
  - Thrombocytopenia.
  - Hemolysis, elevated liver enzymes, low platelets (HELLP).
  - Pulmonary edema.
  - Vision changes or headache.
- When hypertension is present with severe features of preeclampsia, seizure prophylaxis is beneficial.

Eclampsia

- Seizures with findings of preeclampsia.

General Considerations

Chronic hypertension is defined as hypertension that developed before pregnancy or is evident before 20 weeks' gestation. Gestational hypertension is hypertension (in the absence of proteinuria) that develops 20 weeks or later during pregnancy in a previously normotensive patient whose blood pressure returns to normal postpartum. Chronic hypertension is discussed below. Preeclampsia is defined as the presence of newly elevated blood pressure and proteinuria during pregnancy. Eclampsia is diagnosed when seizures develop in a patient with evidence of preeclampsia. Historically, three elements were required for the diagnosis of preeclampsia: hypertension, proteinuria, and edema. Edema was difficult to objectively quantify and is no longer a required element. In addition, proteinuria may not always be present in preeclampsia with severe features.

Preeclampsia-eclampsia most commonly occurs in the third trimester but can occur any time after 20 weeks' gestation and up to 6 weeks postpartum.

Risk factors for early preeclampsia-eclampsia are maternal comorbid conditions, such as hypertension, kidney disease, and SLE.

Preeclampsia-eclampsia is a disease unique to pregnancy, with the only cure being delivery of the fetus and placenta. Preeclampsia develops in approximately 7% of pregnant persons in the United States; of those, eclampsia will develop in 5% (0.04% of pregnant persons). Primiparas are most frequently affected; however, the incidence of preeclampsia-eclampsia is increased with multifetal gestations, preeclampsia in a previous pregnancy, and comorbid diseases such as chronic hypertension, pregestational diabetes, gestational diabetes, thrombophilia, kidney disease, SLE, prepregnancy BMI > 30, antiphospholipid antibody syndrome, maternal age 35 years or older, assisted reproductive technology, and obstructive sleep apnea. Eclampsia is a significant cause of maternal death.

Clinical Findings

The severity of preeclampsia-eclampsia is based on its effect on six major target areas: the CNS, the kidneys, the liver, the hematologic system, the vascular system, and the fetal-placental unit. By evaluating each of these areas for the presence of mild to severe preeclampsia, the degree of involvement can be assessed, and an appropriate management plan can be formulated that balances the severity of disease and gestational age (Table 22–2).

Table 22–2. Indicators of mild and severe preeclampsia-eclampsia and gestational hypertension with severe features.

Site	Indicator	Mild	Severe
CNS	Symptoms and signs	Hyperreflexia	Seizures, blurred vision, scotomas, headache, clonus, irritability
Kidney	Proteinuria Urinary output	> 0.3 g/24 hours[1] > 30 mL/hour	> 0.3 g/24 hours < 30 mL/hour
Liver	AST, ALT, LD	Normal liver enzymes	Elevated liver enzymes, epigastric pain, ruptured liver
Hematologic	Platelets Hemoglobin	Normal Normal	< 100,000/mcL (100 × 10^9/L) Low, normal, or elevated
Vascular	Blood pressure Retina	< 160/110 mm Hg Arteriolar spasm	> 160/110 mm Hg Retinal hemorrhages
Fetal-placental unit	Growth restriction Oligohydramnios Fetal distress	Absent Absent Absent	Present Present Present

[1] Proteinuria may not always be present.

A. Gestational Hypertension

Preeclampsia and gestational hypertension are defined based on similar blood pressure elevations of > 140/90 mm Hg on two occasions at least 4 hours apart but proteinuria is absent with gestational hypertension.

B. Preeclampsia

1. Without severe features—Patients usually have few complaints, and the diastolic blood pressure is < 110 mm Hg. Edema may be present. The platelet count is > 100,000/mcL (100 × 10^9/L), antepartum fetal testing is reassuring, CNS irritability is minimal, epigastric pain is not present, and liver enzymes are not elevated. Proteinuria is present with urine protein ≥ 0.3 g/24 hours or a protein/creatinine ratio of > 0.3.

2. With severe features—Symptoms are more dramatic and persistent. Patients may complain of headache and changes in vision. The blood pressure is often above 160/110 mm Hg. Thrombocytopenia (platelet count < 100,000/mcL [100 × 10^9/L]) may be present and progress to disseminated intravascular coagulation. Proteinuria usually exceeds 0.3 g/24 hours. Severe epigastric pain may be present from hepatic subcapsular hemorrhage with significant stretch or rupture of the liver capsule. HELLP syndrome is an advanced form of severe preeclampsia.

C. Eclampsia

The occurrence of seizures defines eclampsia. It is a manifestation of severe CNS involvement. Other findings of preeclampsia are observed.

Differential Diagnosis

Other diseases that can mimic preeclampsia-eclampsia include chronic hypertension, CKD, primary seizure disorders, gallbladder and pancreatic disease, immune thrombocytopenia, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome.

Treatment

The American College of Obstetricians and Gynecologists (ACOG) supports considering the use of low-dose aspirin (81 mg orally daily) initiated between 12–28 weeks' gestation (optimally before 16 weeks) and continued daily until delivery for women at increased risk for preeclampsia; risk factors include a history of preeclampsia, multifetal gestation, chronic hypertension, diabetes mellitus, kidney disease, or autoimmune diseases (such as SLE or antiphospholipid syndrome). Clinicians may also consider low-dose aspirin (81 mg orally daily) if more than one of the following moderate risk factors are present: nulliparity, obesity, family history of preeclampsia, Black race, age > 35 years, low socioeconomic status, personal history factors (eg, mother having a previous baby with low birth weight), and in vitro fertilization. Diuretics, dietary restriction or enhancement, sodium restriction, and vitamin-mineral supplements (eg, calcium or vitamins C and E) have not been confirmed to be useful. The only cure is delivery of the fetus at a time as favorable as possible for its survival.

A. Gestational Hypertension

The oral agents that are recommended for treatment of hypertension during pregnancy are labetalol (Table 13–10), nifedipine (Table 13–8) and methyldopa (Table 13–12). The goal of treatment for gestational hypertension is a blood pressure of 140/90 mm Hg. *ACE inhibitors, ARBs, and mineralocorticoid receptor antagonists are teratogenic and contraindicated in pregnancy.* Delivery should take place at term in the absence of severe hypertension.

B. Preeclampsia

Early recognition is the key to treatment. This requires careful attention to the details of prenatal care—especially subtle changes in blood pressure and weight. The objectives are to prolong pregnancy, if possible, to allow fetal lung maturity while preventing progression to severe disease and eclampsia. The critical factors are the gestational age of the fetus, fetal pulmonary maturity, and the severity of maternal disease.

1. Preeclampsia-eclampsia without severe features—Home management may be attempted for these patients if they have a stable home situation. Patients must be reliable, have assistance at home, have rapid access to the hospital, and the ability to obtain frequent blood pressure readings. A home health nurse can often provide frequent home visits and assessments. For preeclampsia without severe features at or beyond 37 weeks' gestation, delivery rather than expectant management (eg watchful waiting or close monitoring) upon diagnosis is recommended. It also is reasonable to deliver patients with gestational hypertension at term.

2. Preeclampsia-eclampsia with severe features—Hospitalization is required for patients with preeclampsia with severe features or those with unpredictable home situations. Regular assessments of blood pressure, urine protein, and fetal heart tones and activity are required. A CBC with platelet count, electrolyte panel, and liver enzymes should be checked regularly, with frequency dependent on severity. A 24-hour urine collection for total protein and creatinine clearance should be obtained on admission and repeated as indicated. Magnesium sulfate should be given for seizure prophylaxis once the diagnosis of severe preeclampsia is made and delivery is planned (see Eclampsia, below); magnesium sulfate is given intravenously, 4- to 6-g load over 15–20 minutes followed by 2–3 g/hour maintenance. A urinary catheter is inserted to monitor urinary output. If hypertension is present with systolic values of ≥ 160 mm Hg or diastolic values ≥110 mm Hg, antihypertensive medications should be administered to reduce the blood pressure to 140–150/90–100 mm Hg. Lower blood pressures than this may induce placental insufficiency through reduced perfusion. Hydralazine, given in 5- to 10-mg increments intravenously every 20 minutes, is frequently used to lower blood pressure. Labetalol, 10–20 mg intravenously, every 20 minutes as needed, can also be used. Immediate-release oral nifedipine 10–20 mg may be administered and then repeated in 20 minutes, followed by 10–20 mg every 4–6 hours for a maximum daily dosage of 180 mg. This medication is helpful if the patient does not have intravenous access. Before term, severe preeclampsia-eclampsia requires delivery with few exceptions. Epigastric pain, seizures, severe range blood pressures, thrombocytopenia, and visual disturbances are strong indications for delivery of the fetus. Marked proteinuria alone can be managed more conservatively.

If the fetus is < 34 weeks' gestation, corticosteroids (betamethasone 12 mg intramuscularly every 24 hours for two doses, or dexamethasone 6 mg intramuscularly every 12 hours for four doses) should be administered to the mother (preeclampsia-eclampsia with or without severe features). *However, when a patient clearly has unstable severe preeclampsia, delivery should not be delayed.* The impetus for delivery should not necessarily preclude the initiation of corticosteroids.

The method of delivery is determined by the maternal and fetal status. A vaginal delivery is preferred because it has less blood loss than a cesarean section and requires less coagulation factors. Cesarean section is reserved for the usual fetal indications.

C. Eclampsia

1. General care—Eclampsia necessitates delivery once the patient is stabilized. It is important, however, that assessment of the status of the patient and fetus take place first. Continuous fetal monitoring must be performed and maternal blood typed and cross-matched quickly. The ACOG recommends that systolic blood pressures > 160 mm Hg be treated within 60 minutes. The use of a semi-autonomous algorithm to treat these severe blood pressures within 60 minutes has demonstrated improved expeditious treatment.

If the patient is eclamptic, she is turned on her side to prevent aspiration and to improve blood flow to the placenta. The seizure may be stopped by giving an intravenous bolus of magnesium sulfate (the preferred agent), 4–6 g over 4 minutes or until the seizure stops. A continuous intravenous infusion of magnesium sulfate is then started at a rate of 2–3 g/hour unless the patient has reduced kidney function (serum creatinine above 1.0 mg/dL). Reducing maintenance dosing to 1 g/hour or temporarily stopping infusion may be necessary to address instances of kidney dysfunction and magnesium toxicity. Magnesium blood levels may be checked every 4–6 hours and ideally the infusion rate adjusted to maintain a therapeutic blood level (4–7 mEq/L). Urinary output is checked hourly, and the patient assessed for signs of possible magnesium toxicity such as loss of deep tendon reflexes or decrease in respiratory rate and depth, which can be reversed with calcium gluconate, 1 g intravenously over 2 minutes. If seizures continue, an additional dose of magnesium sulfate, 2 g intravenously, may be infused. Alternative agents (eg, benzodiazepines and phenytoin) should be used only if magnesium sulfate is unavailable.

2. Delivery—Delivery is mandated once eclampsia has occurred. Vaginal delivery is preferred. Subsequent prolonged fetal heart rate decelerations are frequent after an eclamptic seizure. However, delivery should proceed only after there is maternal hemodynamic stabilization. Furthermore, maternal resuscitation is usually followed by normalization of the fetal tracing. The rapidity with which delivery must be achieved depends on the fetal and maternal status following the seizure and the availability of laboratory data on the patient. Oxytocin, given intravenously and titrated to a dose that results in adequate contractions, can induce or augment labor. Oxytocin should only be administered by a clinician specifically trained in its use. Regional analgesia or general anesthesia is acceptable. Cesarean section is used for the usual obstetric indications.

3. Postpartum—Magnesium sulfate infusion (2–3 g/hour with noted exceptions, see above) should be continued for 24 hours postpartum. Late-onset preeclampsia-eclampsia can occur during the postpartum period. It is usually manifested by either hypertension or seizures. Treatment is the same as before delivery—ie, with hydralazine and magnesium sulfate.

▶ When to Refer

- New onset of hypertension and proteinuria in a pregnant patient > 20 weeks' gestation.
- New onset of seizure activity in a pregnant patient.

▶ When to Admit

- Symptoms of preeclampsia with severe features in a pregnant patient with elevated blood pressure above baseline.
- Evaluation for preeclampsia when severe features of the disease are suspected.
- Evaluation for preeclampsia in a patient with an unstable home environment.
- Evidence of eclampsia.

PRETERM LABOR

ESSENTIALS OF DIAGNOSIS

- ▶ Preterm regular uterine contractions approximately 5 minutes apart.
- ▶ Cervical dilatation, effacement, or both.

General Considerations

Preterm birth is defined as birth between 20 0/7 and 36 6/7 weeks' gestation. Spontaneous preterm labor with or without premature rupture of the fetal membranes causes at least two-thirds of all preterm births. Prematurity is the largest single contributor to infant mortality, and survivors are at risk for a myriad of short- and long-term complications. It is also the most common reason for antepartum hospitalization. Rates of infant death and long-term neurologic impairment are inversely related to gestational age at birth. The cusp of viability in contemporary practice is 23–25 weeks' gestation, and infants born before 23 weeks rarely survive. About two-thirds of the preterm births occur between 34 weeks and 36 weeks and 6 days (termed "late preterm birth"), and good outcomes are expected at these gestational ages. Importantly, however, even these late preterm infants are at significantly increased risk for both morbidity and mortality when compared to those infants born at term.

Major risk factors for spontaneous preterm labor include a past history of preterm birth and a short cervical length as measured by transvaginal ultrasound. Other known risk associations include Black race, multifetal pregnancies, intrauterine infection, substance use, cigarette smoking, periodontal disease, and socioeconomic deprivation. Numerous preterm births are preceded by ruptured membranes.

Clinical Findings

In women with regular uterine contractions and cervical change, the diagnosis of preterm labor is straightforward. However, symptoms such as pelvic pressure, cramping, or vaginal discharge may be the first complaints in high-risk patients who later develop preterm labor. Because these complaints may be vague and irregular uterine contractions are common, distinguishing which patients merit further evaluation can be problematic. In some cases, this distinction can be facilitated by the use of fetal fibronectin measurement in cervicovaginal specimens. This test is most useful when it is negative (< 50 ng/mL) since the negative predictive value for delivery within 7–14 days is 93–97%. A negative test, therefore, usually means the patient can be reassured and discharged home. Because of its low sensitivity, however, fetal fibronectin is not recommended as a screening test in asymptomatic women.

Treatment

A. General Measures

Patients must be educated to identify symptoms associated with preterm labor to avoid unnecessary delay in their evaluation. In patients who are believed to be at increased risk for preterm delivery, randomized trials have failed to demonstrate improved outcomes in women placed on activity restriction. Paradoxically, such recommendations may place a patient at an *increased* risk to deliver preterm. Women with preterm labor at the threshold of viability present unique ethical and obstetric challenges and are best managed in consultation with maternal-fetal medicine and neonatology specialists. The patients in such situations should be actively and continually engaged about decisions regarding the aggressiveness of resuscitative efforts.

B. Corticosteroids

In pregnancies between 24–34 weeks' gestation where preterm birth is anticipated, a single short course of corticosteroids should be administered to promote fetal lung maturity. Between 22–24 weeks' gestation the administration of corticosteroids should be considered. Such therapy has been demonstrated to reduce the frequency of respiratory distress syndrome, intracranial hemorrhage, and even death in preterm infants. Betamethasone, 12 mg intramuscularly repeated once 24 hours later, and dexamethasone, 6 mg intramuscularly repeated every 12 hours for four doses, both cross the placenta and either is the preferred treatment. A single repeat course of antenatal corticosteroids should be considered in women who are at risk for preterm delivery within the next 7 days, and whose prior dose of antenatal corticosteroids was administered > 14 days previously. Rescue course corticosteroids could be provided as early as 7 days from the prior dose, if indicated by the clinical scenario. The Society for Maternal-Fetal Medicine (SMFM) Consult Series recommends offering a single course of antenatal corticosteroids (two doses of 12 mg of intramuscular betamethasone, 24 hours apart) to patients who meet the inclusion criteria of the Antenatal Late Preterm Steroids trial (those with a singleton pregnancy between 34 0/7 and 36 6/7 weeks of gestation who are at high risk for preterm birth within the next 7 days and before 37 weeks of gestation).

C. Antibiotics

Despite the finding that preterm labor is associated with intrauterine infection in certain cases, there is no evidence that antibiotics forestall delivery in women with preterm labor and intact membranes. However, women in preterm labor should receive antimicrobial prophylaxis against group B *Streptococcus* unless a single standard culture of the distal vagina and anorectum has been negative for the organism in the preceding 5 weeks. Notably, there is usually not enough time in this clinical setting to culture and test isolates. The recommended regimen for antimicrobial prophylaxis against group B *Streptococcus* is penicillin G, 5 million units intravenously as a loading dose and then 2.5–3 million units intravenously every 4 hours until delivery. In penicillin-allergic patients not at high risk for anaphylaxis, 2 g of cefazolin can be given intravenously as an initial dose and then 1 g intravenously every 8 hours until delivery. In patients at high risk for anaphylaxis, vancomycin, 20 mg/kg intravenously every 8 hours until delivery, can be used. Clindamycin, 900 mg intravenously every 8 hours until delivery, can also be used after a group B streptococcal isolate has been confirmed to be susceptible.

D. Tocolytic Agents

First-line tocolytic treatment to forestall delivery is with β-adrenergic receptor agonists, calcium channel blockers, or indomethacin. This treatment can prolong pregnancy in the short-term (up to 48 hours) to allow for the administration of antenatal corticosteroids, and (if appropriate), transport the patient to a facility better equipped to care for premature infants. Maintenance therapy (continuation of treatment beyond 48 hours) is not effective at preventing preterm birth and is not recommended.

Before attempts are made to prevent preterm delivery with tocolytic agents, the patient should be assessed for conditions in which delivery would be indicated. Severe preeclampsia, lethal fetal anomalies, placental abruption, and intrauterine infection are all examples of indications for preterm delivery. In such cases, attempts to forestall delivery are inappropriate.

1. β-Adrenergic receptor agonist—Terbutaline can be given every 30 minutes as an intravenous infusion starting at 2.5 mcg/min or as a subcutaneous injection starting at 250 mcg. Oral terbutaline is not recommended because of the lack of proven efficacy and concerns about maternal safety. Serious maternal side effects from terbutaline include tachycardia, pulmonary edema, arrhythmias, metabolic derangements (such as hyperglycemia and hypokalemia), and even death. Pulmonary edema occurs with increased frequency with concomitant administration of corticosteroids, large-volume intravenous fluid infusion, maternal sepsis, or prolonged tocolysis. Because of these safety concerns, the US FDA warns that terbutaline be administered exclusively in a hospital setting and discontinued after 48–72 hours of treatment.

2. Nifedipine and indomethacin—Nifedipine, 20 mg orally every 6 hours, and indomethacin, 50 mg orally once then 25 mg orally every 6 hours up to 48 hours, have been used with limited success.

3. Magnesium sulfate—This commonly used medication (but no longer recommended as a first-line agent) for tocolysis may also be protective against cerebral palsy in infants born from 24–32 weeks' gestation when given at time of birth. Magnesium sulfate is given intravenously as a 4- to 6-g bolus followed by a continuous infusion of 2 g/hour. Magnesium levels are not typically checked but should be monitored if there is any concern for toxicity. Magnesium sulfate is entirely cleared by the kidney and must, therefore, be used with caution in women with any degree of kidney disease.

Preterm Birth Prevention

The US FDA withdrew approval of 17-α hydroxyprogesterone caproate as an agent to reduce the risk of recurrent spontaneous preterm birth in 2023 because of lack of evidence for its efficacy. Although the issue has not been settled, there is evidence that progesterone therapy may decrease rates of preterm birth in nulliparous women who have a shortened cervix as measured by transvaginal ultrasound. The ACOG does not recommend universal transvaginal cervical length screening but acknowledges that this strategy may be considered.

There is also evidence that women with a previous spontaneous preterm birth and a shortened cervix (< 25 mm before 24 weeks' gestation) may benefit from placement of a cervical cerclage. Incidentally detected short cervical length in the second trimester in the absence of a prior singleton preterm birth is not diagnostic of cervical insufficiency, and cerclage is not indicated in this setting. In twin and triplet gestations progesterone administration has not been effective at prolonging pregnancy, and this therapy is not recommended. Cervical cerclage is not recommended for prevention of preterm birth if the sole indication is multiple gestations.

When to Refer

- Symptoms of increased pelvic pressure or cramping in high-risk patients.
- Regular uterine contractions.
- Rupture of membranes.
- Vaginal bleeding.

When to Admit

- Cervical dilation of 2 cm or more before 34 weeks' gestation.
- Contractions that cause cervical change.
- Rupture of membranes.

THIRD-TRIMESTER BLEEDING

Five to 10 percent of women have vaginal bleeding in late pregnancy. The clinician must distinguish between placental causes (placenta previa, placental abruption, vasa previa) and nonplacental causes (labor, infection, disorders of the lower genital tract, systemic disease). The approach to bleeding in late pregnancy depends on the underlying cause, the gestational age at presentation, the degree of blood loss, and the overall status of the mother and her fetus. The cause of antepartum bleeding after mid-pregnancy is unknown in one-third of cases.

Treatment

A. General Measures

The patient should initially be observed closely with continuous fetal monitoring to assess for fetal distress. A CBC with platelets and an INR should be obtained and repeated serially if the bleeding continues. If hemorrhage is significant or if there is evidence of acute hypovolemia, the need for transfusion should be anticipated and an appropriate volume of red cells prepared with cross-matching. Ultrasound examination should be performed to determine placental location. Digital pelvic examinations are done only after ultrasound examination has ruled out placenta previa. Administration of anti-D immune globulin may be required for women who are Rh negative.

B. Placenta Previa

Placenta previa occurs when the placenta implants over the internal cervical os. Risk factors for this condition include previous cesarean delivery, increasing maternal age, multiparity, and cigarette smoking. If the diagnosis is initially made in the first or second trimester, the ultrasound should be repeated in the third trimester. Persistence of placenta previa is an indication for cesarean as the route of delivery. Painless vaginal bleeding is the characteristic symptom in placenta previa and can range from light spotting to profuse hemorrhage. Hospitalization for extended evaluation is the appropriate initial management approach. For pregnancies that have reached 37 weeks' gestation or beyond with continued bleeding, cesarean delivery is generally indicated. Pregnancies at 36 weeks or earlier are candidates for expectant management (eg, watchful waiting or close monitoring) provided the bleeding is not prodigious, and a subset of these women can be discharged if the bleeding and contractions completely subside.

C. Morbidly Adherent Placenta

Morbidly adherent placenta is a general term describing an abnormally adherent placenta that has invaded into the uterus. The condition can be further classified depending on whether the depth of invasion is limited to the endometrium (*accreta*), extends into the myometrium (*increta*), or invades beyond the uterine serosa (*percreta*). The most important risk factor for a morbidly adherent placenta is a prior uterine scar—typically from one or more prior cesarean deliveries. The focus of invasion usually involves the scar itself, and *placenta previa* is commonly associated with morbid adherence. The incidence of these syndromes has increased dramatically over the last 50 years commensurate with the increasing cesarean delivery rate.

After delivery of the infant, almost always in a repeat cesarean section, the morbidly adherent placenta does not separate normally, and the bleeding that results can be torrential. Emergency hysterectomy is usually required to stop the hemorrhage, and transfusion requirements are often massive. Because of the considerable increase in both maternal morbidity and mortality associated with this condition, careful preoperative planning is imperative when the diagnosis is suspected antenatally. Ultrasound findings such as intraplacental lacunae, bridging vessels into the bladder, and loss of the retroplacental clear space suggest placental invasion in women who have placenta previa. The 2021 SMFM Placenta Accreta Task Force consensus document contains standardized ultrasound markers for the identification of placenta accreta spectrum. *Importantly, however, even if ultrasound findings are subtle, an abnormally adherent placenta should be suspected in any patient with one or more prior cesarean deliveries and an anterior placenta previa*. Ideally, delivery planning should involve a multidisciplinary team, and the surgery should take place at an institution with appropriate personnel and a blood bank equipped to handle patients requiring massive transfusions. A systematic approach to management with a multidisciplinary team improves patient outcomes. Evidence-based recommendations regarding delivery timing are lacking, but the goal is to have a planned, late-preterm cesarean delivery. As such, delivery at 34–36 weeks in a stable patient seems a reasonable approach.

D. Placental Abruption

Placental abruption is the premature separation of the placenta from its implantation site before delivery. Risk factors for abruption include hypertension, multiparity, cocaine use, cigarette smoking, previous abruption, and thrombophilias. Classic symptoms are vaginal bleeding, uterine tenderness, and frequent contractions, but the clinical presentation is highly variable. There is often concealed hemorrhage when the placenta abrupts, which causes increased pressure in the intervillous space. Excess amounts of thromboplastin escape into the maternal circulation and defibrination occurs. Profound coagulopathy and acute hypovolemia from blood loss can occur in the mother, especially when the abruption is severe enough to kill the fetus. Ultrasound may be helpful to exclude placenta previa, but failure to identify a retroplacental clot does not exclude abruption. In most cases, abruption is an indication for immediate cesarean delivery because of the high risk of fetal death. Quantification of maternal blood loss, as described in statewide quality improvement bundles, has been advocated to reduce maternal hemorrhage associated morbidity.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 183: postpartum hemorrhage. Obstet Gynecol. 2017;130:e168. [Reaffirmed 2024] [PMID: 28937571]

OBSTETRIC COMPLICATIONS OF THE PERIPARTUM PERIOD

PUERPERAL MASTITIS

Postpartum mastitis occurs sporadically in nursing mothers, usually with symptom onset after discharge from the hospital. *Staphylococcus aureus* is usually the causative agent. Women nursing for the first time and those with difficulty breastfeeding appear to be at greatest risk. Rarely, inflammatory carcinoma of the breast can be mistaken for puerperal mastitis (see also Chapter 19). Unfortunately, strategies aimed at preventing mastitis in breastfeeding women have been unsuccessful.

Mastitis frequently begins within 3 months after delivery and may start with an engorged breast and a sore or fissured nipple. Cellulitis is typically unilateral with the affected area of breast being red, tender, and warm. Fever and chills are common complaints as well. Treatment consists of antibiotics effective against penicillin-resistant staphylococci (dicloxacillin 500 mg orally every 6 hours or a cephalosporin for 10–14 days) and regular emptying of the breast by nursing or by using a mechanical suction device. Although nursing from the infected breast is safe for the infant, local inflammation of the nipple may complicate latching. Failure to respond to usual antibiotics within 2 days may represent an organizing abscess or infection with a resistant organism. The risk for abscess formation is increased when the causative organism is methicillin-resistant *S aureus* (MRSA), compared with infection from nonresistant staphylococcal species. If an abscess is suspected, ultrasound of the breast can help confirm the diagnosis. In these cases, aspiration or surgical evacuation is usually required. Changing antibiotics based on culture sensitivity (to vancomycin or trimethoprim-sulfamethoxazole, for example) is helpful, especially if the clinical course is not improving appropriately.

CHORIOAMNIONITIS & METRITIS

ESSENTIALS OF DIAGNOSIS

- Fever not attributable to another source.
- Uterine tenderness.
- Tachycardia in the mother, fetus, or both.

General Considerations

Pelvic infections are relatively common problems encountered during the peripartum period. Chorioamnionitis is an infection of the amnion and chorion (fetal parts), usually occurring during labor. Uterine infection after delivery is often called endometritis or endomyometritis, but the term “metritis” is probably most accurate to emphasize that the infection extends throughout the uterine tissue. These infections are polymicrobial and are most commonly attributed to urogenital pathogens. The single most important risk factor for puerperal infection is cesarean delivery, which increases the risk 5- to 20-fold. Other recognized risk factors include prolonged labor, use of internal monitors, nulliparity, multiple pelvic examinations, prolonged rupture of membranes, and lower genital tract infections. Although maternal complications such as dysfunctional labor and postpartum hemorrhage are increased with clinical chorioamnionitis, the principal reason to initiate treatment is to prevent morbidity in the offspring. Neonatal complications such as sepsis, pneumonia, intraventricular hemorrhage, and cerebral palsy are increased in the setting of chorioamnionitis. Intrapartum initiation of antibiotics, however, significantly reduces neonatal morbidity.

Clinical Findings

Puerperal infections are diagnosed principally by the presence of fever (≥ 38°C) in the absence of any other source and one or more of the following signs: maternal or fetal tachycardia (or both), and uterine tenderness. Foul-smelling lochia may be present but is an insensitive marker of infection as many women without infection may experience an unpleasant odor. Likewise, some life-threatening infections such as necrotizing fasciitis are typically odorless. Cultures are typically not done because of the polymicrobial nature of the infection.

Treatment

Treatment is empiric with broad-spectrum antibiotics that will cover gram-positive and gram-negative organisms if still pregnant and gram-negative organisms and anaerobes if postpartum. A common regimen for chorioamnionitis is ampicillin, 2 g intravenously every 6 hours, and gentamicin, 2 mg/kg intravenous load then 1.5 mg/kg intravenously every 8 hours. A common regimen for metritis is gentamicin, 2 mg/kg intravenous load then 1.5 mg/kg intravenously every 8 hours, and clindamycin, 900 mg intravenously every 8 hours. Antibiotics are stopped in the mother when she has been afebrile and asymptomatic for 24 hours. No oral antibiotics are subsequently needed. Patients with metritis who do not respond in the first 24–48 hours may have an enterococcal component of metritis and require additional gram-positive coverage (such as ampicillin) to the regimen.

MEDICAL CONDITIONS COMPLICATING PREGNANCY

ANEMIA

Normal pregnancy is characterized by an increase in maternal plasma volume of about 50% and an increase in red cell volume of about 25%. Because of these changes, the mean hemoglobin and hematocrit values are lower than in the nonpregnant state. Anemia in pregnancy is considered when the hemoglobin measurement is < 11 g/dL in the first trimester, 10.5 g/dL in the second trimester, and 11 g/dL in the third trimester. By far, the most common causes are iron deficiency and acute blood loss anemia, the latter usually occurring in the peripartum period. Symptoms such as fatigue and dyspnea that would otherwise suggest the presence of anemia in nonpregnant women are common in pregnant women; therefore, periodic measurement of hematocrits in pregnancy is essential so that anemia can be identified and treated. In addition to its impact on maternal health, untoward pregnancy outcomes such as low birthweight and preterm delivery have been associated with second- and third-trimester anemia.

A. Iron Deficiency Anemia

The increased requirement for iron over the course of pregnancy is appreciable to support fetal growth and expansion of maternal blood volume. Dietary intake of iron generally cannot meet this demand, and all pregnant women should receive about 30 mg of elemental iron per day in the second and third trimesters. Oral iron therapy is commonly associated with GI side effects, such as nausea and constipation, and these symptoms often contribute to noncompliance. If supplementation is inadequate, anemia often becomes evident by the third trimester of pregnancy. Because iron deficiency is by far the most common cause of anemia in pregnancy, treatment is usually empiric and consists of 60–100 mg of elemental iron per day and a diet containing iron-rich foods. Iron studies can confirm the diagnosis, if necessary (see Chapter 15), and further evaluation should be considered in patients who do not respond to oral iron. Intermittent iron supplementation (eg, every other day) has been associated with fewer side effects and may be reasonable for women who cannot tolerate daily therapy.

During the third trimester of pregnancy for women with severe and demonstrated iron deficiency anemia, some experts recommend the administration of intravenous ferric carboxymaltose (injectafer), 1000 mg, over 15 minutes and then repeated in 7 days. Intravenous iron administration has been shown to be more effective than oral iron, which some patients cannot tolerate due to side effects or do not take as prescribed. With severe anemia (hematocrit < 25%), intravenous infusion of iron can reduce the need for blood transfusions.

B. Folic Acid Deficiency Anemia

Megaloblastic anemia in pregnancy is almost always caused by folic acid deficiency, since vitamin B_{12} deficiency is uncommon in the childbearing years. Folate deficiency is usually caused by inadequate dietary intake of fresh leafy vegetables, legumes, and animal proteins.

The diagnosis is made by finding macrocytic red cells and hypersegmented neutrophils on a blood smear (see Chapter 15). However, blood smears in pregnancy may be difficult to interpret since they frequently show iron deficiency changes as well. With established folate deficiency, a supplemental dose of 1 mg/day and a diet with increased folic acid will generally correct the anemia.

C. Sickle Cell Anemia

Women with sickle cell anemia are subject to serious complications in pregnancy. The anemia becomes more severe, and acute pain crises often occur more frequently. When compared with women who do not have hemoglobinopathies, women with hemoglobin SS are at increased risk for infections (especially pulmonary and urinary tract), thromboembolic events, pregnancy-related hypertension, transfusion, cesarean delivery, preterm birth, and fetal growth restriction. There also continues to be an increased rate of maternal mortality, despite an increased recognition of the high-risk nature of these pregnancies. Intensive medical treatment may improve the outcomes for both mother and fetus. Prophylactically transfusing packed red cells to lower the level of hemoglobin S and elevate the level of hemoglobin A is a controversial practice without clear benefit. Most women with sickle cell disease will not require iron supplementation, but folate requirements can be appreciable due to red cell turnover from hemolysis.

D. Other Anemias

Although many of the inherited or acquired causes of anemia are relatively rare in women of childbearing age, they can be encountered in pregnancy. The implications for the mother and her offspring vary widely depending on the etiology of anemia. For example, mild microcytic anemia may be caused by iron deficiency, but it could also represent anemia of chronic disease because of previously undiagnosed malignancy. As such, women who have anemia caused by a disorder besides a nutritional deficiency are best managed in conjunction with a maternal-fetal medicine specialist and a hematologist. Additionally, women who have an inherited form of anemia (hemoglobinopathies and thalassemia syndromes, for example) should be offered genetic counseling; prenatal diagnosis, if available, should be discussed if the mother wishes to know whether the fetus is affected.

ANTIPHOSPHOLIPID SYNDROME

The antiphospholipid syndrome is characterized by autoantibodies, notably in association with arterial and venous thrombosis and adverse pregnancy outcomes (see Chapter 23).

THYROID DISEASE

Thyroid disease is relatively common in pregnancy, and in their overt states, both hypothyroidism and hyperthyroidism have been consistently associated with adverse pregnancy outcomes. There are gestational age-specific effects that pregnancy has on thyroid function tests; failure to recognize these physiologic alterations can cause misclassification or misdiagnosis. Women who have a history of a thyroid disorder or symptoms that suggest thyroid dysfunction should be screened with thyroid function tests. Screening asymptomatic pregnant women, however, is of unproven benefit and is not recommended.

The most common etiology of hypothyroidism during pregnancy is autoimmune (Hashimoto) thyroiditis. Many of the symptoms of hypothyroidism mimic those of normal pregnancy, making its clinical identification difficult. Maternal hypothyroidism has consistently been associated with an increase in complications such as spontaneous pregnancy loss, preterm birth, preeclampsia, placental abruption, and impaired neuropsychological development in the offspring; the fetus is at least partially dependent on maternal T_4 for its CNS development—particularly in the second trimester. For women who are already taking levothyroxine, one should anticipate a 25% dose increase at pregnancy confirmation. Pregnant women with overt hypothyroidism or myxedema should be treated immediately with levothyroxine at full replacement doses of 1.6 mcg/kg/day (about 100–150 mcg daily). For titration, the levothyroxine dosage may be increased according to clinical response and serum TSH, measured every 4–6 weeks and trying to keep the serum TSH level in a trimester-specific gestational reference range. An increase in the dose of levothyroxine may be required in the second and third trimesters, as well. By mid-pregnancy, women require an average of 47% increase in their levothyroxine dosage.

1. Overt hypothyroidism—An elevated serum TSH level with a depressed FT_4 level define overt hypothyroidism. During pregnancy, several factors occur that affect maternal thyroid hormones: (1) Rising estrogen levels increase thyroxine binding globulin serum concentrations, reducing FT_4 levels. (2) Placental deiodinase promotes the turnover of T_4. (3) Supplemental iron and prenatal multivitamins containing iron can bind to oral T_4 and reduce its intestinal absorption.

2. Subclinical hypothyroidism—This is defined as an increased serum TSH with a normal FT_4 level. Although some studies have found associations with untoward pregnancy outcomes such as miscarriage, preterm birth, and preeclampsia, others have failed to confirm these findings. There is no evidence that treatment of subclinical hypothyroidism will prevent any of these outcomes. The ACOG and the American Association of Clinical Endocrinologists recommend against universal screening for thyroid disease in pregnancy.

3. Overt hyperthyroidism—There is excessive production of thyroxine with a depressed (usually undetectable) serum TSH level in overt hyperthyroidism, which is also associated with increased risks in pregnancy. Spontaneous pregnancy loss, preterm birth, preeclampsia, and maternal HF occur with increased frequency with untreated thyrotoxicosis. Thyroid storm, although rare, can be a life-threatening complication. Medical treatment of thyrotoxicosis is usually accomplished with the antithyroid drugs propylthiouracil or methimazole. Although teratogenicity has not been clearly established, in utero exposure to methimazole has been associated with aplasia cutis and choanal and esophageal atresia in the offspring. Propylthiouracil is not believed to be teratogenic, but it has been associated with the rare complications of hepatotoxicity and agranulocytosis. Recommendations by the American Thyroid Association are to treat with propylthiouracil in the first trimester and convert to methimazole for the remainder of the pregnancy. The therapeutic target for the FT_4 level is the upper limit of the normal reference range. The TSH levels generally stay suppressed even with adequate treatment. A β-blocker can be used for such symptoms as palpitations or tremors. Fetal hypothyroidism or hyperthyroidism is uncommon but can occur with maternal Graves disease, which is the most common cause of hyperthyroidism in pregnancy. *Radioiodine ablation is absolutely contraindicated in pregnancy because it may destroy the fetal thyroid.*

4. Postpartum thyroiditis—This is discussed in Chapter 29; see Thyroiditis.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 223: thyroid disease in pregnancy. Obstet Gynecol. 2020;135:e261 [Reaffirmed 2023] [PMID: 32443080]

DIABETES MELLITUS

Normal pregnancy can be characterized as a state of increased insulin resistance that helps ensure a steady stream of glucose delivery to the developing fetus. Thus, both mild fasting hypoglycemia and postprandial hyperglycemia are physiologic.

A. Gestational Diabetes Mellitus

Gestational diabetes mellitus is abnormal glucose tolerance in pregnancy and is generally believed to exaggerate the pregnancy-induced physiologic changes in carbohydrate metabolism. Alternatively, pregnancy may unmask an underlying propensity for glucose intolerance, which will be evident in the nonpregnant state at some future time if not in the immediate postpartum period. Indeed, at least 50% of women with gestational diabetes will have an overt diabetes diagnosis in their lifetime. During pregnancy, the principal concern in women with gestational diabetes is excessive fetal growth, which can cause increased maternal and perinatal morbidity. Shoulder dystocia occurs more frequently in infants born to mothers with diabetes because of fetal overgrowth and increased fat deposition on the shoulders. Cesarean delivery and preeclampsia are also significantly increased in women with diabetes, both gestational and overt.

All asymptomatic pregnant women should undergo laboratory screening for gestational diabetes after 24 weeks' gestation. The diagnostic thresholds for glucose tolerance tests in pregnancy are not universally agreed upon, and importantly, adverse pregnancy outcomes appear to occur along a continuum of glucose intolerance even if the diagnosis of gestational diabetes is not formally assigned. A two-stage testing strategy is recommended by the ACOG, starting with a 50-g screening test offered to all pregnant women at 24–28 weeks' gestation. If this test is abnormal, the diagnostic test is a 100-g oral glucose tolerance test (Table 22–3).

Women in whom gestational diabetes is diagnosed should undergo nutrition counseling, and medications are typically initiated for those with persistent fasting hyperglycemia. Insulin remains the standard of care to achieve glycemic control. Oral hypoglycemic agents, principally glyburide and metformin, have been evaluated in short-term clinical trials and appear to achieve similar degrees of

Table 22–3. Screening and diagnostic criteria for gestational diabetes mellitus.

Screening for gestational diabetes mellitus

1. 50-g oral glucose load, administered between 24 and 28 weeks, without regard to time of day or time of last meal.
2. Venous plasma glucose measured 1 hour later.
3. Value ≥ 140 mg/dL (7.8 mmol/L) in venous plasma indicates the need for a diagnostic glucose tolerance test.

Diagnosis of gestational diabetes mellitus

1. 100-g oral glucose load, administered in the morning after overnight fast lasting at least 8 hours but not more than 14 hours, and following at least 3 days of unrestricted diet (> 150 g carbohydrate) and physical activity.
2. Venous plasma glucose is measured fasting and at 1, 2, and 3 hours. Patient should remain seated and should not smoke throughout the test.
3. The diagnosis of gestational diabetes is made when two or more of the following venous plasma concentrations are met or exceeded: fasting, 95 mg/dL (5.3 mmol/L); 1 hour, 180 mg/dL (10 mmol/L); 2 hours, 155 mg/dL (8.6 mmol/L); 3 hours, 140 mg/dL (7.8 mmol/L).

glycemic control to insulin without increasing maternal or neonatal morbidity. These medications, however, have not been approved by the US FDA for this indication; the long-term safety of oral agents has not been adequately studied in the women or in their offspring, thus insulin is first-line therapy unless circumstances preclude its use. In those cases, metformin is a reasonable choice. Insulin regimens commonly include multiple daily injections of a split-dose mix of intermediate-acting and short-acting agents that do not cross the placenta (eg, regular and NPH insulins, insulin lispro and aspart) (see Chapter 32 for a discussion of self-monitoring glucose systems). Once therapy is initiated, blood glucose surveillance is important to assess for adequacy of glycemic control. Capillary blood glucose levels should be checked four times per day, once fasting and three times after meals. Euglycemia is considered to be 60–95 mg/dL (3.3–5.3 mmol/L) while fasting and premeal, and < 120 mg/dL (6.7 mmol/L) 2 hours postprandially. Intensive therapy with dietary modifications or insulin, or both, has been demonstrated to decrease rates of macrosomia, shoulder dystocia, and preeclampsia. Because of the increased prevalence of overt diabetes in women identified to have gestational diabetes, they should be screened at 6–12 weeks' postpartum with a fasting plasma glucose test or a 2-hour oral glucose tolerance test (75-g glucose load).

B. Overt Diabetes Mellitus

Overt diabetes is diabetes mellitus that antedates the pregnancy. There is an inverse relationship between glycemic control and fetal malformations, and women whose periconceptional glycosylated hemoglobin levels are at or near normal levels have rates of malformations that approach baseline. In gestational diabetes, fetal overgrowth from inadequately controlled hyperglycemia remains a significant concern because of the increased maternal and perinatal morbidity that accompany macrosomia. In overt diabetes, additional complications are increased frequency of spontaneous pregnancy losses and third-trimester stillbirths. There is also at least a two- to threefold increased risk for fetal malformations (risk in in normal pregnancies is 2–3%), as hyperglycemia during organogenesis is teratogenic. The most common malformations in offspring of women with diabetes are cardiac, skeletal, and neural tube defects. For the mother, the likelihood of infections and pregnancy-related hypertension is increased.

Preconception counseling and evaluation in a patient with diabetes is ideal to maximize the pregnancy outcomes. This provides an opportunity to optimize glycemic control and evaluate for evidence of end-organ damage. The initial evaluation of women with diabetes should include a complete chemistry panel, HbA_{1c} determination, 24-hour urine collection for total protein and creatinine clearance, funduscopic examination, and an ECG. Hypertension is common and may require treatment. Optimally, euglycemia should be established before conception and maintained during pregnancy with daily home glucose monitoring by the patient. A well-planned dietary program is a key component, with an intake of 1800–2200 kcal/day divided into three meals and three snacks. Insulin is given subcutaneously in a split-dose regimen as described above for women with gestational diabetes. The use of continuous insulin pump therapy may be helpful for some patients (see Chapter 32).

Throughout the pregnancy, women with diabetes should be assessed every 2–3 weeks and more frequently depending on the clinical condition. Adjustments in the insulin regimen may be necessary as the pregnancy progresses to maintain optimal glycemic control. A specialized ultrasound is often performed around 20 weeks to screen for fetal malformations. Symptoms and signs of infections should be evaluated and promptly treated. In the third trimester, fetal surveillance is indicated, and women with diabetes should receive serial antenatal testing (usually in the form of a nonstress test or biophysical profile). The timing of delivery is dictated by the quality of diabetic control, the presence or absence of medical complications, and fetal status. The goal is to reach 39 weeks (38 completed weeks) and then proceed with delivery. Confirmation of lung maturity may be appropriate if preterm delivery is contemplated.

CHRONIC HYPERTENSION

Chronic hypertension is estimated to complicate up to 5% of pregnancies. To establish this diagnosis, hypertension should antedate the pregnancy or be evident before 20 weeks' gestation to differentiate it from pregnancy-related hypertension. This distinction can be problematic when the initial presentation is after 20 weeks, but chronic hypertension is confirmed if the blood pressure remains elevated beyond 12 weeks postpartum. Risk factors for chronic hypertension include older maternal age, Black race, and obesity.

Women with chronic hypertension are at increased risk for adverse maternal and perinatal outcomes. Superimposed preeclampsia develops in up to 20% of women with mild hypertension, but the risk increases up to 50% when there is severe baseline hypertension (≥ 160/110 mm Hg) and may be even higher when there is evidence of end-organ damage. When preeclampsia is superimposed on chronic hypertension, there is a tendency for it to occur at an earlier gestational age, be more severe, and impair fetal growth. Women with chronic hypertension are also at increased risk for placental abruption, cesarean delivery, preterm birth, and perinatal mortality.

Ideally, women with chronic hypertension should undergo a preconceptional evaluation to detect end-organ damage, assess the need for antihypertensive therapy, and discontinue teratogenic medications. The specific tests ordered may vary depending on the severity of the hypertension, but an evaluation of liver, kidney, and cardiac function (eg, 24-hour urine protein and maternal echocardiogram if mother has underlying renal or cardiac disease may be appropriate).

Based on findings from the 2022 Chronic Hypertension and Pregnancy study, the ACOG recommends utilizing 140/90 mm Hg as the threshold for initiation or titration of medical therapy for chronic hypertension in pregnancy, rather than the previously recommended threshold of 160/110 mm Hg. Although methyldopa has the longest record of safety in pregnancy, nifedipine (see Tables 13–7 and 13–8) and labetalol (see Table 13–10) are also acceptable, and these three agents are recommended above all others when initiating therapy in pregnancy. Care must be taken not to excessively reduce the blood pressure, as this may decrease uteroplacental perfusion. The goal is a modest reduction in blood pressure and avoidance of severe hypertension.

If a patient with mild chronic hypertension is stable on a medical regimen when she becomes pregnant, it is usually appropriate to continue this therapy, although the benefits of doing so are not well established. *ACE inhibitors and ARBs, however, are contraindicated in all trimesters of pregnancy*. These medications are teratogenic in the first trimester and cause fetal hypocalvaria and AKI in the second and third trimesters. These medications should be discontinued when pregnancy is diagnosed, and the patient should be counseled about potential teratogenicity.

When there is sustained *severe* hypertension despite multiple medications or significant end-organ damage from hypertensive disease, pregnancy is not likely to be tolerated well. In these situations, therapeutic abortion may be appropriate. Clinicians need to be aware of laws regarding availability of abortion in the jurisdiction of their practice. If the pregnancy is continued, the patient must be counseled that the maternal and perinatal risks are appreciable, and complications such as superimposed preeclampsia and fetal growth restriction should be anticipated.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 203: chronic hypertension in pregnancy. Obstet Gynecol. 2019;133:e26. [Reaffirmed 2024] [PMID: 30575676]

HEART DISEASE

Normal pregnancy physiology is characterized by cardiovascular adaptations in the mother. Cardiac output increases markedly because of both augmented stroke volume and an increase in the resting heart rate, and the maternal blood volume expands by up to 50%. These changes may not be tolerated well in women with functional or structural abnormalities of the heart. Thus, although only a small number of pregnancies are complicated by cardiac disease, these contribute disproportionately to overall rates of maternal morbidity and mortality. Most cardiac disease in women of childbearing age in the United States is caused by congenital heart disease and not rheumatic heart disease. Ischemic heart disease, however, is seen increasingly in pregnant women due to rising rates of comorbid conditions, such as diabetes mellitus, hypertension, and obesity.

For practical purposes, the best single measurement of cardiopulmonary status is defined by the New York Heart Association Functional Classification. Most pregnant women with cardiac disease have class I or II functional disability, and although good outcomes are generally anticipated in this group, complications such as preeclampsia, preterm birth, and low birth weight appear to occur with increased frequency. Women with more severe disability (class III or IV) are rare in contemporary obstetrics; however, the maternal mortality is markedly increased in this setting and is usually the result of HF. Because of these risks, therapeutic abortion for maternal health should be considered in women who are severely disabled from cardiac disease. Clinicians need to be aware of laws regarding availability of abortion in the jurisdiction of their practice. Specific conditions that have been associated with a high risk for maternal death include Eisenmenger syndrome, primary pulmonary hypertension, Marfan syndrome with aortic root dilatation, and severe aortic or mitral stenosis. In general, these conditions should be considered contraindications to pregnancy.

The importance of preconceptional counseling for women with heart disease cannot be overstated. A thorough evaluation before pregnancy provides an opportunity for comprehensive risk assessment and detailed planning. Once pregnant, women with cardiac disease are best treated by a team of clinicians experienced in caring for such patients. HF and arrhythmias are the most common cardiovascular complications associated with heart disease in pregnancy, and adverse maternal and fetal outcomes are increased when they occur. Volume overload should therefore be evaluated and treated promptly. Labor management depends on the underlying cardiac lesion and the degree of disability. Women with a history of arrhythmia should have continuous cardiac monitoring throughout labor, delivery, and the immediate postpartum period. Cesarean delivery is generally reserved for obstetric indications but may be appropriate for women in whom Valsalva maneuvers are contraindicated. The early postpartum period is a critical time for fluid management. Patients who are predisposed to HF should be monitored closely during the puerperium.

Infective endocarditis prophylaxis is not recommended for most vaginal or cesarean deliveries in the absence of infection, except in the small subset of women at highest risk for adverse outcomes from endocarditis (eg, those with cyanotic heart disease, prosthetic valves, or both). Prophylactic antibiotics for endocarditis, if required, should be given intravenously. If infection is present, such as chorioamnionitis, the underlying infection should be treated with the usual regimen and additional agents are not needed specifically for endocarditis prophylaxis.

ASTHMA

(**See also Chapter 9.**)

Asthma is one of the most common medical conditions encountered in pregnancy. Women with mild to moderate asthma can generally expect excellent pregnancy outcomes, but severe or poorly controlled asthma has been associated with several pregnancy complications, including preterm birth, small-for-gestational-age infants, and preeclampsia. The effects of pregnancy on asthma are likely minimal as asthma severity in the pregnancy is generally similar to its severity during the year preceding the pregnancy. Strategies for treatment are similar to those in nonpregnant women. Patients should be educated about symptom management and avoidance of asthma triggers. Baseline PFTs can objectively assess lung function and may help the patient with self-monitoring of her asthma severity using a peak flow meter. As in nonpregnant women, treatment algorithms generally follow a stepwise approach, and commonly used medications, particularly those for mild to moderate asthma symptoms, are generally considered safe in pregnancy. Concerns about teratogenicity and medication effects on the fetus should be thoroughly discussed with the patient to decrease noncompliance rates. Inhaled β_2-agonists are indicated for all asthma patients, and low to moderate dose inhaled corticosteroids are added for persistent symptoms when a rescue inhaler alone is inadequate. Systemic corticosteroid administration is reserved for severe exacerbations but should not be withheld, if indicated, irrespective of gestational age. Cromolyn, leukotriene receptor antagonists, and theophylline are appropriate alternative therapies if first-line management is ineffective. The primary goals of management in pregnancy include minimizing symptoms and avoiding hypoxic episodes to the fetus. Prostaglandin F2a and ergonovine—medications frequently used to treat postpartum uterine atony—should be avoided because they can precipitate bronchospasm in women with asthma.

SEIZURE DISORDERS

Epilepsy is one of the most frequent serious neurologic disorders in pregnant women. Many of the commonly used antiepileptic drugs are known human teratogens. Therefore, the principal objectives in managing pregnancy in women with epilepsy are achieving adequate control of seizures while minimizing exposure to medications that can cause congenital malformations. Certain women who are contemplating pregnancy and have been seizure-free for 2–5 years may be considered candidates for discontinuation of antiseizure medication before pregnancy. For those who continue to require treatment, however, therapy with one medication is preferred. Selecting a regimen should be based on the type of seizure disorder and the risks associated with each medication. Valproic acid should not be considered first-line therapy because it has consistently been associated with higher rates of fetal malformations than most other commonly used antiepileptic drugs, and it may be associated with impaired neurocognitive development in the offspring. Phenytoin and carbamazepine both have established patterns of associated fetal malformations. Concerns about teratogenicity have prompted increasing use of the newer antiepileptic drugs such as lamotrigine, topiramate, oxcarbazepine, and levetiracetam. Experiences from ongoing registries and large, population-based studies suggest that in utero exposure to the newer antiepileptic drugs in the first trimester of pregnancy carries a lower risk of major malformations than older medications. Lamotrigine and levetiracetam are considered the least teratogenic. One birth registry, however, found an increase in oral clefts among women taking lamotrigine. Several small studies have found an association between levetiracetam and low birth weight. Some studies suggest that topiramate is associated with a slightly increased risk of oral clefts. Although it is recommended that pregnant women with epilepsy be given supplemental folic acid, it is unclear if supplemental folate decreases rates of fetal malformations in women taking antiepileptic medications. Serum levels of antiepileptic medications should be followed, when appropriate, because they may be affected by volume of distribution changes in pregnancy.

BREAST CANCER OCCURRING DURING PREGNANCY OR LACTATION

(See Chapter 19.)

INFECTIOUS CONDITIONS COMPLICATING PREGNANCY

URINARY TRACT INFECTION

The urinary tract is especially vulnerable to infections during pregnancy because the altered secretions of steroid sex hormones and the pressure exerted by the gravid uterus on the ureters and bladder cause hypotonia and congestion and predispose to urinary stasis. Labor and delivery and urinary retention postpartum also may initiate or aggravate infection. *Escherichia coli* is the offending organism in over two-thirds of cases.

From 2% to 10% of pregnant women have asymptomatic bacteriuria, which some believe to be associated with an increased risk of preterm birth. It is estimated that pyelonephritis will develop in 20–40% of these women if untreated.

An evaluation for asymptomatic bacteriuria at the first prenatal visit is recommended for all pregnant women.

If a urine culture is positive, treatment should be initiated. Nitrofurantoin (100 mg orally twice daily), amoxicillin (500 mg orally three times daily), and cephalexin (250 mg orally four times daily) are acceptable medications for 5–7 days. Sulfonamides should be avoided in the third trimester because they may interfere with bilirubin binding and thus impose a risk of neonatal hyperbilirubinemia and kernicterus. Fluoroquinolones are also contraindicated because of their potential teratogenic effects on fetal cartilage and bone. Patients with recurrent bacteriuria should receive suppressive medication (once daily dosing of an appropriate antibiotic) for the remainder of the pregnancy. Acute pyelonephritis requires hospitalization for intravenous antibiotics and crystalloids until the patient is afebrile; this is followed by a full course of oral antibiotics.

ACOG Clinical Consensus No. 4. American College of Obstetricians and Gynecologists. Urinary tract infections in pregnant individuals. Obstet Gynecol. 2023;142:435. [PMID: 39601712]

GROUP B STREPTOCOCCAL INFECTION

Group B streptococci frequently colonize the lower female genital tract, with an asymptomatic carriage rate in pregnancy of 10–30%. This rate depends on maternal age, gravidity, and geographic variation. Vaginal carriage is asymptomatic and intermittent, with spontaneous clearing in approximately 30% and recolonization in about 10% of women. Adverse perinatal outcomes associated with group B streptococcal colonization include UTI, intrauterine infection, premature rupture of membranes, preterm delivery, and postpartum metritis.

Women with postpartum metritis due to infection with group B streptococci, especially after cesarean section, develop fever, tachycardia, and abdominal pain, usually within 24 hours after delivery. Approximately 35% of these women are bacteremic.

Group B streptococcal infection is a common cause of neonatal sepsis. Transmission rates are high, yet the rate of neonatal sepsis is surprisingly low at < 1:1000 live births. Unfortunately, the mortality rate associated with early-onset disease can be as high as 20–30% in premature infants. In contrast, it is approximately 2–3% in those at term. Moreover, these infections can contribute markedly to chronic morbidity, including developmental delays and neurologic disabilities. Late-onset disease develops through contact with hospital nursery personnel. Up to 45% of these health care workers can carry the bacteria on their skin and transmit the infection to newborns.

The 2022 ACOG recommendations for screening and prophylaxis for group B streptococcal colonization, are available at https://www.acog.org/clinical/clinical-guidance/committee-opinion/articles/2020/02/prevention-of-group-b-streptococcal-early-onset-disease-in-newborns.

VARICELLA

Commonly known as chickenpox, primary varicella-zoster virus (VZV) infection during pregnancy may cause serious illness to the mother and to the fetus. Approximately 95% of women born in the United States have VZV antibodies by the time they reach reproductive age. Infection results in lifelong immunity. The incidence of primary VZV infection during pregnancy has been reported as up to 7:10,000. *The vaccine is contraindicated in pregnancy because the effects of the vaccine on the fetus are unknown.* Nonpregnant women who are vaccinated should avoid pregnancy for 3 months after injection. Inadvertent vaccination in early pregnancy or within a month of pregnancy is not an indication for termination, although women should be counseled about theoretical risks.

Clinical Findings

A. Symptoms and Signs

The incubation period for this infection is 10–20 days. A primary infection follows and is characterized by a flu-like syndrome with malaise, fever, and development of a pruritic maculopapular rash on the trunk, which becomes vesicular and then crusts. Pregnant women are prone to the development of VZV pneumonia, often a fulminant infection sometimes requiring respiratory support. After primary infection, the virus becomes latent, ascending to dorsal root ganglia. Subsequent reactivation can occur as zoster, often under circumstances of immunocompromise, although this is rare during pregnancy.

Two types of fetal infection have been documented. The first is congenital VZV syndrome, which typically occurs in 0.4–2% of fetuses exposed to primary VZV infection during the first trimester. Anomalies include limb and digit abnormalities, microphthalmos, and microcephaly.

Infection during the second and third trimesters is less threatening. Maternal IgG crosses the placenta, protecting the fetus. The only infants at risk for severe infection are those born after maternal viremia but before development of maternal protective antibody. Maternal infection manifesting 5 days before or up to 2 days after delivery is the time period believed to be most hazardous for transmission to the fetus.

B. Laboratory Findings

Diagnosis is commonly made on clinical grounds. Laboratory verification is made by ELISA, fluorescent antibody, and hemagglutination inhibition antibody techniques. Vesicular fluid can be sent for qualitative varicella PCR assay.

Treatment

Varicella-zoster immune globulin (VZIG) has been shown to prevent or modify the symptoms of infection in exposed persons. Treatment success depends on identification of susceptible women at or just following exposure. Exposed women with a questionable or negative history of chickenpox should be checked for antibody, since the overwhelming majority will have been previously exposed. If the antibody is negative, VZIG (625 units intramuscularly) should ideally be given within 96 hours of exposure for greatest efficacy, but the CDC reports it can be given for up to 10 days. There are no known adverse effects of VZIG administration during pregnancy, although the incubation period for disease can be lengthened. Infants born to women in whom symptoms develop in the period from 5 days before delivery to 2 days after delivery should also receive VZIG (125 units).

Pregnant women with varicella may benefit from treatment with oral acyclovir, 800 mg orally four times daily for 5 days, if started within 24 hours of rash onset. Treatment has been shown to improve maternal symptoms but does not prevent congenital varicella. Infected pregnant women should be closely observed and hospitalized at the earliest signs of pulmonary involvement. Intravenous acyclovir (10 mg/kg intravenously every 8 hours) is recommended in the treatment of VZV pneumonia.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 151: cytomegalovirus, parvovirus B19, varicella zoster, and toxoplasmosis in pregnancy. Obstet Gynecol. 2015;125:1510. [Reaffirmed 2024] [PMID: 26000539]

TUBERCULOSIS

Women at high risk for tuberculosis include those from endemic areas, those infected with HIV, those with substance use disorder, health care workers, and close contacts of people with tuberculosis. Both tuberculin skin testing and interferon gamma release assays are acceptable tests in pregnancy. Screening CXRs should only be obtained in pregnant patients who have a positive test or with suggestive findings in the history and physical examination. Abdominal shielding must be used if a CXR is obtained.

Decisions on treatment depend on whether the patient has active disease or is at high risk for progression to active disease. Pregnant women with active disease or who are high risk for progression should be treated during pregnancy as the risks of complications from tuberculosis outweigh the risks of treatment. Pregnant women with latent disease not at high risk for disease progression can receive treatment postpartum, which does not preclude breastfeeding. The concentration of medication in breast milk is neither toxic nor adequate for treatment of the newborn. Isoniazid, ethambutol, and rifampin are used to treat tuberculosis (see Chapters 9 and 38). Because isoniazid therapy may cause vitamin B_6 deficiency, supplemental vitamin B_6, 50 mg orally daily, should be given simultaneously. There is concern that isoniazid, particularly in pregnant women, can cause hepatitis. Liver biochemical tests should be performed monthly in pregnant women who receive treatment. Streptomycin, ethionamide, and most other antituberculosis drugs should be avoided in pregnancy. If adequately treated, tuberculosis in pregnancy has an excellent prognosis.

Hui SYA et al. Tuberculosis in pregnancy. Best Pract Res Clin Obstet Gynaecol. 2022;85:34. [PMID: 36002371]

HIV/AIDS DURING PREGNANCY

Asymptomatic HIV infection is associated with a normal pregnancy rate and no increased risk of adverse pregnancy outcomes. There is no evidence that pregnancy causes AIDS progression.

Previously, two-thirds of neonates positive for HIV acquired their infection close to, or during, the time of delivery. Routine HIV screening in pregnancy, including the use of rapid HIV tests in labor and delivery units, and using antiretroviral drugs have markedly reduced this transmission risk to approximately 1%. In a pregnant person who is HIV-positive, a CD4 count, plasma RNA level, creatinine, liver function tests, and resistance testing (if virus is detectable, and the patient has not already had this) should be obtained at the first prenatal visit. Treatment should not be delayed while waiting for the results of resistance testing. Prior or current antiretroviral use should be reviewed. The patient should be tested for HLA-B*5701 if abacavir may be prescribed; HLA-B*5701 positivity puts the patient at risk for a serious hypersensitivity reaction and its use is contraindicated.

A person already taking and tolerating an acceptable antiretroviral regimen need not discontinue it in the first trimester. Patients should also be tested for hepatitis A, hepatitis C, tuberculosis, and toxoplasmosis.

Women not taking medication should be offered combination antiretroviral therapy (commonly a dual nucleoside reverse transcriptase inhibitor combination and either a ritonavir-boosted protease inhibitor or an integrase strand transfer inhibitor) after counseling regarding the potential impact of therapy on both mother and fetus (see Chapter 36). *Antiretroviral therapy should be offered regardless of viral load and CD4 count.* Whether to start in the first or second trimester should be determined on a case-by-case basis, but it should be started as early as reasonably possible. It can be started in the first trimester after explanation of risks and benefits, provided the mother is not experiencing nausea and vomiting. Most medications used to treat HIV/AIDS have thus far proven to be safe in pregnancy with an acceptable risk/benefit ratio. The physiologic changes that occur during pregnancy may alter the effect of some medications. Before starting any regimen, the safety and efficacy of the medications selected should be reviewed. Standard of care includes zidovudine (2 mg/kg intravenously over 1 hour followed by 1 mg/kg/hour intravenously) begun 3 hours before cesarean delivery and continued through the surgery until cord clamping in women whose viral load near delivery (after 34–36 weeks' gestation or within 4–6 weeks of delivery) is > 1000 copies/mL or unknown. Antiretroviral therapy on the patient's usual schedule should be continued in labor. Intravenous zidovudine is not required for women who have been compliant with their antiretroviral therapy and whose viral load is ≤ 50 copies/mL near delivery; data are limited in cases where the viral load is between 50–1000 copies/mL.

The use of prophylactic elective cesarean section at 38 weeks' gestation (before the onset of labor or rupture of the membranes) to prevent vertical transmission of HIV infection from mother to fetus has been shown to further reduce the transmission rate. In patients with a viral load of < 1000 copies/mL near delivery, there may be no additional benefit of cesarean delivery, and those women can be offered a vaginal delivery. Amniotomy should not be performed in the setting of viremia unless there is a clear obstetric indication. Amniotomy, however, has not been associated with an increased risk of perinatal transmission when the mother is receiving antiretroviral therapy and virologically suppressed. Internal monitors, particularly the fetal scalp electrode, should be avoided as should operative deliveries (forceps-assisted and vacuum-assisted vaginal deliveries). Methergine (used for postpartum hemorrhage) should be avoided, if possible, in patients receiving regimens that include cytochrome P450 (CYP) 3A4 inhibitors and CYP3A4 enzyme inducers. Women with HIV should be advised not to breastfeed their infants.

The Public Health Task Force provides guidelines for the management of HIV/AIDS in pregnancy (https://hivinfo.nih.gov). In addition, there is the National Perinatal HIV Hotline, which provides free consultation regarding perinatal HIV care (1-888-448-8765).

Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission. Recommendations for the use of antiretroviral drugs in pregnant women with HIV infection and interventions to reduce perinatal HIV transmission in the United States. 2024 Jan 31. https://clinicalinfo.hiv.gov/en/guidelines/perinatal/whats-new

MATERNAL HEPATITIS B & C CARRIER STATE

A. Hepatitis B Virus

There are an estimated 300 million chronic carriers of hepatitis B virus worldwide. In the United States, up to 1.8 million people are infected, with the highest rate among Asian American people. All pregnant women should be screened for HBsAg during every pregnancy. If not previously done, the patient should have a triple-panel screen (HBsAg, Anti-HBs, and total antibody to hepatitis B core antigen (total anti-HBc). Transmission of the virus to the baby is likely if both surface antigen and e antigen are positive. Vertical transmission can be blocked by the immediate postdelivery administration to the newborn of hepatitis B immunoglobulin and hepatitis B vaccine intramuscularly. The vaccine dose is repeated at 1 and 6 months of age. Third trimester administration of tenofovir disoproxil fumarate, 300 mg orally once daily starting at 28–32 weeks and continuing through delivery (first-line), lamivudine, or telbivudine to women with a viral load of $> 10^6–10^8$ copies/mL has been shown to reduce vertical transmission, particularly if the viral load is $< 10^6$ copies/mL at delivery. This therapy appears safe in pregnancy, although long-term follow-up data are lacking. Pregnant women with chronic hepatitis B should have liver biochemical tests and viral load testing during the pregnancy. Hepatitis B infection is not a contraindication to breastfeeding if the baby has received immunoprophylaxis. Maternal antiviral therapy, if given, need not be continued postpartum.

B. Hepatitis C Virus

This infection is the most common chronic blood-borne infection in the United States. Because risk-based screening misses approximately 50% of cases and postpartum treatment is highly effective, universal screening in pregnancy is recommended. The average rate of hepatitis C virus (HCV) infection among infants born to women positive for HCV and negative for HIV is 5–6%. However, the average infection rate increases to 10–11% when mothers are coinfected with HCV and HIV. The principal factor associated with transmission is HCV RNA in the mother at the time of birth. Treatment is not recommended in pregnancy. Interferon and ribavirin have been considered contraindicated. Ledipasvir/sofosbuvir (Harvoni) has been shown to be safe in animal studies. Direct-acting antiviral regimens should only be initiated during pregnancy if in the setting of a clinical trial. Cesarean section is not recommended solely for a maternal history of hepatitis C. During labor, early rupture of membranes and placement of a fetal scalp electrode should be avoided if safe to do so because of the unknown risk of increased vertical transmission. Breastfeeding is not contraindicated.

HERPES GENITALIS

Infection of the lower genital tract by herpes simplex virus type 2 (HSV-2) (see also Chapter 6) is a common STI with potentially serious consequences to pregnant women and their newborn infants. Although up to 25% of pregnant women may have antibodies to HSV-2, a history of the infection is unreliable, and the incidence of neonatal infection is not known. There are estimated to be 1200–1500 cases of neonatal infection annually in the United States. Many infected neonates are born to women with no history, symptoms, or signs of infection.

Women who have had *primary* herpes infection late in pregnancy are at high risk for shedding virus at delivery; however, it can be difficult to differentiate primary from nonprimary infection. Women with a primary infection or nonprimary first outbreak and women with a clinical history of genital herpes should be offered prophylactic acyclovir, 400 mg orally three times daily, starting at 36 weeks' gestation, to decrease the likelihood of active lesions at the time of labor and delivery. For treatment, see Chapter 37.

Women with a history of *recurrent* genital herpes have a lower neonatal attack rate than women infected during the pregnancy, but they should still be monitored with clinical observation and culture of any suspicious lesions. Since asymptomatic viral shedding is unpredictable by antepartum cultures, recommendations do not include routine cultures in individuals with a history of herpes without active disease. However, when labor begins, vulvar and cervical inspection should be performed. Cesarean delivery is indicated at the time of labor if there are prodromal symptoms or active genital lesions.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 220: management of genital herpes in pregnancy. Obstet Gynecol. 2020;135:e193. [Reaffirmed 2023] [PMID: 32332414]

SYPHILIS, GONORRHEA, & *CHLAMYDIA TRACHOMATIS* INFECTION

These STIs have significant consequences for mother and child (see also Chapters 38 and 39). Untreated syphilis in pregnancy can cause late pregnancy loss, stillbirth, transplacental infection, and congenital syphilis. Gonorrhea can produce large-joint arthritis by hematogenous spread as well as ophthalmia neonatorum. Maternal chlamydial infections are largely asymptomatic but are manifested in the newborn by inclusion conjunctivitis and, at age 2–4 months, by pneumonia. Because of increasing rates of congenital syphilis, all women should be tested for syphilis as part of their routine prenatal care at their initial visit, in the third trimester, and at delivery. Pregnant women younger than 25 years and those at increased risk for *C trachomatis* should be screened for chlamydia at their first prenatal visit. Repeat testing depends on risk factors, prevalence, and state laws. A pregnant person treated for *C trachomatis* should be tested for cure 4 weeks later and then retested 3 months later because of high reinfection rates. Women who remain at high risk should be tested in the third trimester. Women younger than 25 years and those at increased risk should be tested for gonorrhea at their first prenatal appointment. Women with positive tests for gonorrhea should be treated and then retested 3 months later. Women who remain at high risk should be tested in the third trimester. The sexual partners of women with STIs should be identified and treated if possible; the local health department can assist with this process.

GASTROINTESTINAL, HEPATIC, & BILIARY DISORDERS OF PREGNANCY

Complications involving the GI tract, liver, and gallbladder are common in pregnancy. Nausea and vomiting in the first trimester affect most pregnant women to some degree (see Obstetric Complications of the First & Second Trimesters). *Nausea and vomiting in the last half of pregnancy, however, are never normal;* a thorough evaluation of such complaints is mandatory. Some of these conditions are incidental to pregnancy (eg, appendicitis), while others are related to the gravid state and tend to resolve with delivery (eg, acute fatty liver of pregnancy). Importantly, the myriad anatomic and physiologic changes associated with normal pregnancy must be considered when assessing for a disease state. Likewise, interpretation of laboratory studies must consider the pregnancy-associated changes in hepatic protein production.

For conditions in which surgery is clinically indicated, operative intervention should never be withheld based solely on a person being pregnant. While purely elective surgery is avoided during pregnancy, women who undergo surgical procedures for an urgent or emergent indication during pregnancy do not appear to be at increased risk for adverse outcomes. Obstetric complications, when they occur, are more likely to be associated with the underlying maternal illness. Recommendations are that the optimal time for semi-elective surgery is the second trimester to avoid exposure to anesthesia in the first trimester and the enlarged uterus in the third. Importantly, however, there is no convincing evidence that general anesthesia induces malformations or increases the risk for spontaneous pregnancy loss.

CHOLELITHIASIS & CHOLECYSTITIS

Cholelithiasis is common in pregnancy as physiologic changes such as increased cholesterol production and incomplete gallbladder emptying predispose to gallstone formation. The diagnosis is usually suspected based on classic symptoms of nausea, vomiting, and right upper quadrant pain, usually after meals, and is confirmed with right upper quadrant ultrasound. Symptomatic cholelithiasis without cholecystitis is usually managed conservatively, but recurrent symptoms are common. Cholecystitis results from obstruction of the cystic duct and often is accompanied by bacterial infection. Medical management with antibiotics is reasonable in selected cases, but definitive treatment with cholecystectomy will help prevent complications such as gallbladder perforation and pancreatitis. Cholecystectomy has successfully been performed in all trimesters of pregnancy and should not be withheld based on the stage of pregnancy if clinically indicated. Laparoscopy is preferred in the first half of pregnancy after the first trimester but becomes more technically challenging in the last trimester due to the enlarged uterus and cephalad displacement of abdominal contents.

Obstruction of the common bile duct, which can lead to cholangitis, is an indication for surgical removal of gallstones and establishment of biliary drainage. Endoscopic retrograde cholangiopancreatography (ERCP) with or without sphincterotomy is a nonsurgical alternative. ERCP should only be undertaken when there is therapeutic intent. Pregnant women can safely undergo ERCP provided that precautions are taken to minimize fetal exposure to radiation. There does, however, appear to be a slightly higher rate of post-procedure pancreatitis in pregnant women who undergo ERCP. Magnetic resonance cholangiopancreatography (MRCP) can also be of use in patients with suspected common bile duct obstruction. This study is useful for those women in whom the etiology of common duct dilatation is unclear on ultrasound. MRCP can provide detailed evaluation of the entire biliary system and the pancreas while avoiding ionizing radiation.

The most common cause of acute pancreatitis in pregnancy is gallstone disease. The diagnosis can be confirmed with an appropriate history and an elevated serum amylase or lipase. Although pregnancy is associated with a rise in serum amylase, a value of at least two times the upper limit of normal suggests pancreatitis with the appropriate clinical scenario. Management is conservative, including bowel rest, intravenous fluids, supplemental nutrition if necessary, and analgesics. CT imaging should be avoided unless severe complications such as necrosis, abscess, or hemorrhage are suspected.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy, a disorder limited to the gravid state, occurs in the third trimester of pregnancy and causes acute hepatic failure. With improved recognition and immediate delivery, the maternal mortality rate in contemporary reports is about 4%. The disorder is usually seen after the 35th week of gestation and is more common in primigravidas and those with twins. The incidence is about 1:10,000 deliveries.

The etiology of acute fatty liver of pregnancy is likely poor placental mitochondrial function. Many cases may be due to a homozygous fetal deficiency of long-chain acyl coenzyme A dehydrogenase.

Clinical Findings

Clinical onset is gradual, with nausea and vomiting being the most common presenting symptoms. Varying degrees of flu-like symptoms are also typical. Eventually, symptoms progress to those of fulminant hepatic failure: jaundice, encephalopathy, disseminated intravascular coagulation, and death.

Laboratory findings include marked elevation of alkaline phosphatase but only moderate elevations of ALT and AST. Hypocholesterolemia and hypofibrinogenemia are typical, and hypoglycemia can be extreme. Coagulopathy is also frequently seen with depressed procoagulant protein production. Kidney function should be assessed for hepatorenal syndrome. The WBC count is elevated, and the platelet count is depressed. Liver biopsy is usually not needed for diagnosis.

Differential Diagnosis

The differential diagnosis is that of fulminant hepatitis. Liver aminotransferases for fulminant hepatitis are higher (> 1000 U/mL) than those for acute fatty liver of pregnancy (usually 500–1000 U/mL). Preeclampsia may involve the liver but rarely causes jaundice; the elevations in liver biochemical tests in patients with preeclampsia rarely reach the levels seen in patients with acute fatty liver of pregnancy.

Treatment

Diagnosis of acute fatty liver of pregnancy mandates immediate delivery. Intensive supportive care with ICU-level observation is essential and typically includes administration of blood products and glucose and correction of acidemia. Vaginal delivery is preferred. Resolution of encephalopathy and laboratory derangements occurs over days with supportive care, and recovery is usually complete. Some have found plasma exchange therapy to be helpful. Rare cases of liver transplantation have been reported.

Li L et al. The assessment in patients with acute fatty liver of pregnancy (AFLP) treated with plasma exchange: a cohort study of 298 patients. BMC Pregnancy Childbirth. 2023;23:171. [PMID: 36915067]

Nelson DB et al. Acute fatty liver of pregnancy. Clin Obstet Gynecol. 2020;63:152. [PMID: 31725416]

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis of pregnancy is characterized by incomplete clearance of bile acids in genetically susceptible women. The principal symptom is pruritus, which can be generalized but tends to have a predilection for the palms and soles. Presentation is typically in the third trimester, and women with multifetal pregnancies are at increased risk. The finding of an elevated serum bile acid level, ideally performed in the fasting state, confirms the diagnosis. Associated laboratory derangements include modest elevations in hepatic transaminase levels and mild hyperbilirubinemia. Although rare, the bilirubin level may be sufficiently elevated to result in clinical jaundice. The symptoms and laboratory abnormalities resolve quickly after delivery but can recur in subsequent pregnancies or with exposure to combination oral contraceptives.

Adverse fetal outcomes, particularly preterm birth, nonreassuring fetal status, meconium-stained amniotic fluid, and stillbirth, have consistently been reported in women with cholestasis of pregnancy. The risk for adverse perinatal outcomes appears to correlate with disease severity as measured by the degree of bile acid elevation, and women with fasting bile acids > 40 mcmol/L have been reported to be at greatest risk. Because of the risks associated with cholestasis of pregnancy, many clinicians recommend antenatal testing in the third trimester, and if cholestasis is present, elective early delivery to reduce the risk of stillbirth. The diagnosis of cholestasis of pregnancy is made when the level of bile salts is 10 mcmol/L or more (not necessarily fasting) with maternal symptoms. The 2021 SMFM recommendations are for early delivery (36 weeks' gestation) when the patient's bile acid level is > 100 mcmol/L and other fetal tests are normal; in the symptomatic patient whose bile acid level is below 100 mcmol/L, the SMFM suggests delivery between 36–39 weeks' gestation. The ACOG endorses ursodeoxycholic acid as the first-line agent for the treatment of maternal symptoms of intrahepatic cholestasis of pregnancy.

Girling J et al. Intrahepatic cholestasis of pregnancy: Green-top guideline No. 43 June 2022. Royal College of Obstetricians and Gynaecologists. BJOG. 2022;129:e95. [PMID: 35942656]

Lee RH et al. Society for Maternal-Fetal Medicine Consult Series No. 53: intrahepatic cholestasis of pregnancy: replaces Consult No. 13. Am J Obstet Gynecol. 2021;224:B2. [PMID: 33197417]

APPENDICITIS

Appendicitis occurs in about 1 of 1500 pregnancies. The diagnosis is more difficult to make clinically in pregnant women where the appendix is displaced cephalad from McBurney point. Furthermore, nausea, vomiting, and mild leukocytosis occur in normal pregnancy, so with or without these findings, any complaint of right-sided pain should raise suspicion. Imaging can help confirm the diagnosis if clinical findings are equivocal. Abdominal sonography is a reasonable initial imaging choice, but nonvisualization of the appendix is common in pregnancy. CT scanning is more sensitive than ultrasound, and with proper shielding, the radiation exposure to the fetus is minimized. MRI in pregnant women is a reasonable alternative to CT scanning.

An operative approach to appendicitis, rather than a conservative nonoperative approach, is indicated for pregnant patients. Conservative management is associated with increases in maternal morbidity, including septic shock, peritonitis, and VTE. Some experts, however, find conservative management acceptable for uncomplicated appendicitis.

Unfortunately, the diagnosis of appendicitis is not made until the appendix has ruptured in at least 20% of obstetric patients. Peritonitis in these cases can lead to preterm labor or spontaneous pregnancy loss. With early diagnosis and appendectomy, the prognosis is good for mother and baby.

RHEUMATOLOGIC DISORDERS

Diagnosis & Evaluation

A. Examination of the Patient

Two helpful clinical clues for diagnosing arthritis are the joint pattern and the presence or absence of extra-articular manifestations. The joint pattern is defined by the answers to three questions: (1) Is inflammation present? (2) How many joints are involved? and (3) What joints are affected? Joint inflammation manifests as warmth, swelling, and morning stiffness of at least 30 minutes' duration. Overlying erythema occurs with the intense inflammation of crystal-induced and septic arthritis. Both the number of affected joints and the specific sites of involvement affect the differential diagnosis (Table 23–1). Some diseases—gout, for example—are characteristically monoarticular, whereas other diseases, such as rheumatoid arthritis (RA), are usually polyarticular. The location of joint involvement can also be distinctive. Only two diseases frequently cause prominent involvement of the distal interphalangeal (DIP) joint: osteoarthritis and psoriatic arthritis. Extra-articular manifestations such as fever (eg, gout, Still disease, endocarditis, vasculitis, SLE), rash (eg, SLE, psoriatic arthritis, inflammatory myositis), nodules (eg, RA, gout), or neuropathy (eg, vasculitis) narrow the differential diagnosis further.

B. Arthrocentesis and Examination of Joint Fluid

If the diagnosis is uncertain, synovial fluid should be examined whenever possible (Table 23–2). Most large joints are easily aspirated, and contraindications to arthrocentesis are few. The aspirating needle should never be passed through an overlying cellulitis or psoriatic plaque because of the risk of introducing infection. For patients who are receiving DOACs or long-term anticoagulation therapy with warfarin, joints can be aspirated with a small-gauge needle (eg, 22F); the INR should be < 3.0 for patients taking warfarin.

1. Types of studies—

a. Gross examination—Clarity is an approximate guide to the degree of inflammation. Noninflammatory fluid is transparent, mild inflammation produces translucent fluid, and purulent effusions are opaque. Traumatic taps, trauma, and bleeding disorders are the most common causes of bloody effusions.

b. Cell count—Normal synovial fluid contains < 200 white cells/mcL (0.2 × 10^9/L). Higher synovial fluid white cell counts can discriminate between noninflammatory (< 2000 white cells/mcL [2.0 × 10^9/L]), inflammatory (2000–75,000 white cells/mcL [2.0–75 × 10^9/L]), and purulent (> 100,000 white cells/mcL [100 × 10^9/L]) joint effusions. Synovial fluid glucose and protein levels add little information and should not be ordered.

c. Microscopic examination—Compensated polarized light microscopy distinguishes monosodium urate (gout, negatively birefringent) and calcium pyrophosphate (pseudogout, positive birefringent) crystals. Gram stain has specificity but limited sensitivity (50%) for septic arthritis.

d. Culture—Bacterial cultures and special studies for gonococci, tubercle bacilli, or fungi are ordered as appropriate.

2. Interpretation—Synovial fluid analysis is diagnostic in infectious or microcrystalline arthritis. Although the severity of inflammation in synovial fluid can overlap among various conditions, the synovial fluid white cell count is a helpful guide to diagnosis (Table 23–3).

OSTEOARTHRITIS & CRYSTAL-INDUCED ARTHRITIS

OSTEOARTHRITIS

ESSENTIALS OF DIAGNOSIS

- A progressive joint disorder with minimal articular inflammation.
- No systemic symptoms.
- Pain relieved by rest; morning stiffness brief.
- Radiographic findings: narrowed joint space, osteophytes, increased subchondral bone density, bony cysts.

Table 23–1. Diagnostic value of the joint pattern.

Characteristic	Status	Representative Disease
Inflammatory[1] synovial fluid	Present	Rheumatoid arthritis, SLE, gout
	Absent	Osteoarthritis
Number of involved joints	Monoarticular	Gout, trauma, septic arthritis, Lyme disease, osteoarthritis
	Oligoarticular (2–4 joints)	Reactive arthritis, psoriatic arthritis, IBD
	Polyarticular (≥ 5 joints)	Rheumatoid arthritis, SLE
Site of joint involvement	Distal interphalangeal	Osteoarthritis, psoriatic arthritis (not rheumatoid arthritis)
	Metacarpophalangeal, wrists	Rheumatoid arthritis, SLE, calcium pyrophosphate deposition disease (not osteoarthritis)
	First metatarsal phalangeal	Gout, osteoarthritis

[1] See text.

General Considerations

Osteoarthritis, the most common form of joint disease, is chiefly a disease of aging. Ninety percent of all people have radiographic features of osteoarthritis in weight-bearing joints by age 40. Symptomatic disease increases with age. Sex is a risk factor; osteoarthritis develops in women more frequently than in men.

This arthropathy is characterized by degeneration of cartilage and by hypertrophy of bone at the articular margins. Inflammation is usually minimal. Hereditary and mechanical factors may be involved in the pathogenesis.

Obesity is a risk factor for osteoarthritis of the knee, hand, and probably hip. Recreational running does not increase the incidence of osteoarthritis, but participation in competitive contact sports (eg, football) does. Jobs requiring frequent bending and carrying increase the risk of knee osteoarthritis; arthroscopic meniscal procedures and prior joint injuries are also linked to osteoarthritis (see Chapter 46).

Clinical Findings

A. Symptoms and Signs

Osteoarthritis is divided into two types: (1) primary, which most commonly affects some or all of the following: the DIP and the proximal interphalangeal (PIP) joints of the fingers, the carpometacarpal joint of the thumb, the hip, the knee, the metatarsophalangeal (MTP) joint of the big toe, and the cervical and lumbar spine; and (2) secondary, which may occur in any joint as a sequela to articular injury. The injury may be acute, as in a fracture; or chronic, as from occupational overuse of a joint or metabolic disease (eg, hyperparathyroidism, hemochromatosis, ochronosis) or joint inflammation (eg, RA).

The onset is insidious. Initially, there is articular stiffness, seldom lasting > 15 minutes; this develops later into pain on motion of the affected joint and is made worse by activity or weight bearing and relieved by rest. Flexion contracture or varus deformity of the knee is not unusual, and bony enlargements of the DIP (Heberden nodes) and PIP (Bouchard nodes) are occasionally prominent (Figure 23–1). There is no ankylosis, but limitation of motion of the affected joint or joints is common. Crepitus may often be felt over the knee. Joint effusion and other articular signs of inflammation are mild. However, in some cases a one-way valve effect between the knee joint and gastrocnemius-semimembranosus bursa can lead to accumulation of synovial fluid, called a popliteal (Baker) cyst. There are no systemic manifestations.

B. Laboratory Findings

Osteoarthritis does not cause elevation of the ESR or other laboratory signs of inflammation. Synovial fluid is noninflammatory (Table 23–2).

Table 23–2. Examination of joint fluid.

Measure	(Normal)	Group I (Noninflammatory)	Group II (Inflammatory)	Group III (Purulent)
Volume (mL) (knee)	< 3.5	Often > 3.5	Often > 3.5	Often > 3.5
Clarity	Transparent	Transparent	Translucent to opaque	Opaque
Color	Clear	Yellow	Yellow to opalescent	Yellow to green
WBC per mcL	< 200 (0.2×10^9/L)	< 2000 (2.0×10^9/L)	2000–75,000[1] ($2.0–75.0 \times 10^9$/L)	> 100,000[2] (100×10^9/L)
Polymorphonuclear leukocytes	< 25%	< 25%	≥ 50%	≥ 75%
Culture	Negative	Negative	Negative	Usually positive[2]

[1] Gout, rheumatoid arthritis, and other inflammatory conditions occasionally have synovial fluid WBC counts > 75,000/mcL (75×10^9/L) but rarely > 100,000/mcL (100×10^9/L).

[2] Most purulent effusions are due to septic arthritis. Septic arthritis, however, can present with group II synovial fluid, particularly if infection is caused by organisms of low virulence (eg, *Neisseria gonorrhoeae*) or if antibiotic therapy has been started.

Table 23–3. Differential diagnosis by joint fluid groups.

Noninflammatory (< 2000 white cells/mcL [< 2 × 10^9/L])	Inflammatory (2000–75,000 white cells/mcL [2.0–75.0 × 10^9/L])	Purulent (> 100,000 white cells/mcL [> 100 × 10^9/L])	Hemorrhagic

C. Imaging

Radiographs can support the clinical diagnosis of osteoarthritis but are not routinely required. Findings include narrowing of the joint space; osteophyte formation and lipping of marginal bone; and thickened, dense subchondral bone. Bone cysts may also be present.

Differential Diagnosis

Because articular inflammation is minimal and systemic manifestations are absent, osteoarthritis should seldom be confused with other arthritides. The distribution of joint involvement in the hands also helps distinguish osteoarthritis from RA. Osteoarthritis chiefly affects the DIP and PIP joints and spares the wrist and metacarpophalangeal (MCP) joints; RA involves the wrists and MCP joints and spares the DIP joints. Furthermore, the joint enlargement is bony-hard and cool in osteoarthritis but spongy and warm in RA. Degenerative changes in joints—especially in the spine—may cause coexistent metastatic neoplasia, osteoporosis, plasma cell myeloma, or other bone disease to be overlooked.

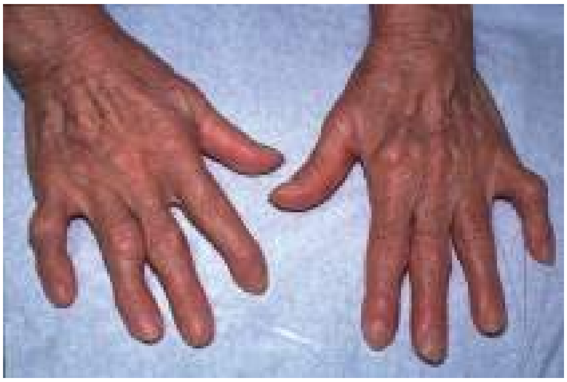

Figure 23–1. Bony enlargement of some distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints consistent with Heberden (DIP) and Bouchard (PIP) nodes. Prevention

Weight reduction reduces the risk of developing symptomatic knee, hip, and hand osteoarthritis. Correcting leg length discrepancy of > 1 cm with shoe modification may prevent knee osteoarthritis from developing in the shorter leg.

Treatment

A. General Measures

Patients with osteoarthritis of the hand may benefit from assistive devices and instruction on techniques for joint protection; splinting is beneficial for those with symptomatic osteoarthritis of the first carpometacarpal joint. Patients with mild to moderate osteoarthritis of the knee or hip should participate in a regular exercise program (eg, a supervised walking program, hydrotherapy classes) and, if overweight, should lose weight. An RCT of individuals with knee osteoarthritis found that physical therapy was more effective at reducing pain and disability at 1 year than intra-articular glucocorticoid injections. Reduction in pain with weight loss can be significant; one study showed that loss of ≥ 10% of body weight resulted in a 50% reduction in pain scores of knee osteoarthritis. In a randomized, double-blind trial of individuals with obesity and pain from knee osteoarthritis, semaglutide resulted in greater reductions in body weight and pain compared to placebo. Using assistive devices (eg, a cane on the contralateral side) can improve functional status.

B. Medical Management

1. Topical therapies—Topical NSAIDs (eg, 4 g of diclofenac gel 1% applied to the affected joint four times daily) are effective for knee and hand osteoarthritis. Because they have lower rates of systemic side effects than oral NSAIDs, topical NSAIDs are preferable for patients with one or a few painful joints, particularly knee or hand osteoarthritis, and for those with risk factors for NSAID-induced GI toxicity. Topical NSAIDs are preferred for patients 75 years of age or older. Topical capsaicin may be of benefit for osteoarthritis of the hand or the knee.

2. Oral NSAIDs—Oral NSAIDs (see Table 5–4) can be considered for patients with involvement of multiple joints, those with hip osteoarthritis, or those with inadequate pain relief from topical agents. Oral NSAIDs are more effective than acetaminophen for osteoarthritis but have greater toxicity. NSAIDs inhibit cyclooxygenase (COX), the enzyme that converts arachidonic acid to prostaglandins. COX exists in two isomers—COX-1, which is expressed continuously in many cells and is responsible for the homeostatic effects of prostaglandins, and COX-2, which is induced by cytokines and expressed in inflammatory tissues. Most NSAIDs are nonselective since they inhibit both isomers. Celecoxib is the only selective COX-2 inhibitor available in the United States. Whenever possible, limiting the duration of oral NSAIDs to control osteoarthritis pain is preferred to minimize the risk of adverse events.

GI toxicity, such as gastric ulceration, perforation, and GI hemorrhage, are the most common serious side effects of NSAIDs. The overall rate of bleeding with NSAID use in the general population is low (1:6000 users or less) but is increased by the risk factors of long-term use; higher NSAID dose; concomitant corticosteroids, anticoagulants, or SSRIs; presence of RA; history of peptic ulcer disease; alcohol use disorder; and age over 70. *PPIs (eg, esomeprazole 20–40 mg orally daily) reduce the incidence of serious GI toxicity and should be used in combination with oral NSAIDs for patients with risk factors for NSAID-induced GI toxicity.* Patients who have recently recovered from an NSAID-induced bleeding gastric ulcer appear to be at high risk for rebleeding (about 5% in 6 months) when an NSAID is reintroduced, even if prophylactic measures (such as PPIs) are used. Compared with nonselective NSAIDs, celecoxib is less likely to cause upper GI tract adverse events, including bleeding.

All of the NSAIDs, including aspirin and celecoxib, can produce renal toxicity, including interstitial nephritis, nephrotic syndrome, prerenal azotemia, and aggravation of hypertension. Hyperkalemia due to hyporeninemic hypoaldosteronism is seen rarely. Renal toxicity is uncommon but is increased by the following risk factors: CKD, volume depletion from diuretic use or GI loss, HF, cirrhosis, or use of ACE inhibitors or ARBs.

All NSAIDs, except the nonacetylated salicylates (eg, salsalate, sodium salicylate) and celecoxib, interfere with platelet function and prolong bleeding time. Aspirin irreversibly inhibits platelet function, so the bleeding time effect resolves only as new platelets are made. In contrast, the effect of nonselective NSAIDs on platelet function is reversible and resolves as the drug is cleared. Concomitant administration of a nonselective NSAID can interfere with the ability of aspirin to acetylate platelets and thus may interfere with the cardioprotective effects of low-dose aspirin. *All NSAIDs are associated with a small increase in the absolute risk of MI and stroke in patients with or without risk factors for heart disease or known heart disease.* While the cardiovascular risk is related to the dose and duration of treatment, stroke and MI can occur within the first week of treatment. Cardiovascular risks associated with naproxen, ibuprofen, and moderate dose celecoxib (200 mg orally daily) are comparable.

3. Acetaminophen, opioids, and supplements—Acetaminophen is not recommended because its impact on pain is frequently negligible and hepatotoxicity can occur from high doses. Opioids are generally not appropriate for the long-term management of pain from osteoarthritis. Chondroitin sulfate and glucosamine, alone or in combination, fish oil, and vitamin D are no better than placebo in reducing the pain of knee or hip osteoarthritis.

4. Intra-articular injections—Intra-articular injections of corticosteroids, hyaluronate, or platelet-rich plasma have not convincingly produced long-term benefits in reducing pain or preserving function in osteoarthritis. A 2-year controlled trial demonstrated that injecting the knee with triamcinolone every 12 weeks was no more effective than injecting saline in reducing knee pain and resulted in more cartilage volume loss. Similarly, platelet-rich plasma injections were no better than saline injections in improving knee pain or slowing disease progression in a meta-analysis of RCTs.

5. Duloxetine—For patients with osteoarthritis in multiple joints who either have not responded to or cannot use NSAIDs, duloxetine, 30–60 mg orally daily, can reduce pain. Nausea occurs in 6–15% of patients.

6. Physical therapy—Physical therapy is modestly beneficial for knee osteoarthritis. An RCT of 156 patients with knee osteoarthritis compared intra-articular glucocorticoid injections to physical therapy; those receiving physical therapy had less pain and functional disability after 1 year compared to those receiving injections. High-intensity strength training offers no benefits over low-intensity training.

C. Surgical Measures

Total hip and knee replacements provide excellent symptomatic and functional improvement when involvement of that joint severely restricts walking or causes pain at rest, particularly at night. Patients should not be excluded from referral for joint replacement based on age, sex, smoking status, comorbidities, or obesity since positive outcomes are achievable in most groups. Arthroscopic surgery for knee osteoarthritis is ineffective. Severe first carpometacarpal osteoarthritis can be treated surgically when other treatments are inadequate.

Prognosis

Symptoms may be severe and limit activity (especially with involvement of the hips, knees, and cervical spine).

When to Refer

Refer patients to an orthopedic surgeon when recalcitrant symptoms or functional impairment, or both, warrant consideration of joint replacement of the hip, knee, or thumb.

CRYSTAL DEPOSITION ARTHRITIS

1. Gouty Arthritis

ESSENTIALS OF DIAGNOSIS

- Acute, monoarticular arthritis, often of the first MTP joint; recurrence is common.
- Polyarticular involvement more common with long-standing disease.
- Identification of urate crystals in joint fluid or tophi is diagnostic.
- Dramatic response to NSAIDs.
- With chronicity, urate deposits in subcutaneous tissue, bone, cartilage, joints, and other tissues.

General Considerations

Gout is a heterogeneous metabolic disease, often familial, associated with abnormal deposits of urate in tissues and characterized initially by a recurring acute arthritis, usually monoarticular, and later by chronic deforming arthritis. Urate deposition occurs when serum uric acid is supersaturated (ie, at levels > 6.8 mg/dL [404.5 mcmol/L]). Hyperuricemia is due to overproduction or underexcretion of uric acid—sometimes both. The disease is more common in Asian-Pacific populations, eg, a prevalence of over 10% has been reported in the Māori people. Primary gout has a heritable component, and genome-wide surveys have linked the risk of gout to genes whose products regulate urate handling by the kidney. Secondary gout, which also may have a heritable component, is related to acquired causes of hyperuricemia, eg, medication use (especially diuretics, low-dose aspirin, cyclosporine, and niacin), myeloproliferative disorders, CKD, and lead poisoning. Alcohol ingestion promotes hyperuricemia by increasing urate production and decreasing the renal excretion of uric acid. Uric acid is created from the metabolism of organic compounds (purines) contained in purine-rich foods or beverages. Beer is particularly high in purines and its ingestion is a common precipitant of gout. Finally, hospitalized patients frequently suffer attacks of gout because of changes in diet (including fasting before procedures), fluid intake, or medications that lead either to rapid reductions or increases in the serum urate level.

About 90% of patients with primary gout are men, usually over 30 years of age. In women, the onset is typically postmenopausal. The characteristic lesion is the tophus, a nodular deposit of monosodium urate monohydrate crystals with an associated foreign body reaction. Tophi are found in cartilage, subcutaneous and periarticular tissues, tendon, bone, the kidneys, and elsewhere. The precise relationship of hyperuricemia to gouty arthritis is still obscure, since chronic hyperuricemia is found in people who never develop gout or uric acid stones. Rapid fluctuations in serum urate levels, either increasing or decreasing, are important factors in precipitating acute gout. The mechanism of the late, chronic stage of gouty arthritis is better understood. This is characterized pathologically by tophaceous invasion of the articular and periarticular tissues, with structural derangement and secondary osteoarthritis.

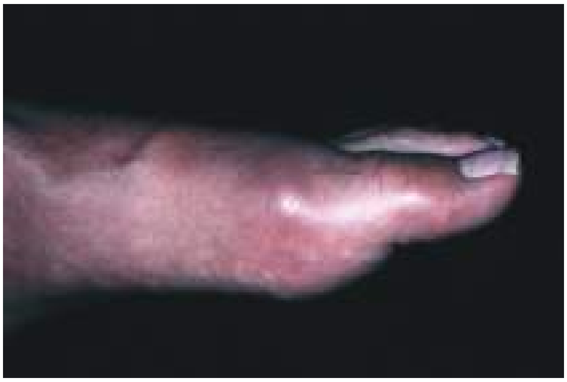
Uric acid kidney stones are present in 5–10% of patients with gouty arthritis. Hyperuricemia correlates highly with the development of stones, with the risk of stone formation reaching 50% in patients with a serum urate level > 13 mg/dL. Chronic urate nephropathy is caused by the deposition of monosodium urate crystals in the renal medulla and pyramids. Although progressive CKD occurs in a substantial percentage of patients with chronic gout, the role of hyperuricemia in causing this outcome is controversial because many patients with gout have numerous confounding risk factors for CKD (eg, hypertension, NSAID use, alcohol use, diabetes). In a randomized trial in patients with CKD and a high risk of its progression, urate-lowering treatment with allopurinol did not slow the decline in eGFR.

Clinical Findings

A. Symptoms and Signs

Acute gouty arthritis is sudden in onset and frequently nocturnal. It may develop without apparent precipitating cause or may follow rapid increases or decreases in serum urate levels. The MTP joint of the great toe is the most susceptible joint ("podagra"), although others, especially those of the feet, ankles, and knees, are commonly affected (Figure 23–2). Gouty attacks may develop in periarticular soft tissues such as the olecranon or prepatellar bursae. Hips and shoulders are rarely affected. More than one joint may occasionally be affected during the same attack; in such cases, the distribution of the arthritis is usually asymmetric. As the attack progresses, the pain becomes intense. The involved joints are swollen and exquisitely tender and the overlying skin tense, warm, and dusky red. Fever is common and may reach 39°C. Tophi may be found in the pinna of the ears, around the joints and extensor tendons of the hands and feet, in the olecranon and prepatellar bursae, and along the Achilles tendon. Tophi usually develop years after the initial attack of gout.

Asymptomatic periods of months or years commonly follow the initial acute attack. After years of untreated hyperuricemia and recurrent severe monoarthritis attacks of the lower extremities, gout can evolve into a chronic,



▲ **Figure 23–2.** Typical inflammatory changes of gout at first metatarsophalangeal joint (podagra). (Used, with permission, from Richard P. Usatine, MD in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 2nd ed. McGraw-Hill, 2013.)

deforming polyarthritis of upper and lower extremities that mimics RA.

Chronic lead intoxication may cause attacks of gouty arthritis (saturnine gout).

B. Laboratory Findings

Although serial measurements of the serum uric acid detect hyperuricemia in 95% of patients, a single uric acid determination during an acute flare of gout is normal in ≥ 25% of cases. A normal serum uric acid level, therefore, does not exclude gout, especially in patients taking urate-lowering drugs. During an acute attack, the peripheral WBC count (neutrophilia) is frequently elevated. The joint fluid is inflammatory (Table 23–2). Identification of sodium urate crystals in joint fluid or material aspirated from a tophus establishes the diagnosis. The crystals, which may be extracellular or found within neutrophils, are needle-like and negatively birefringent when examined by polarized light microscopy.

C. Imaging

Early in the disease, radiographs show no changes. Later, punched-out erosions with an overhanging rim of cortical bone ("rat bite") develop. When these are adjacent to a soft tissue tophus, they are diagnostic of gout. Ultrasonography and dual-energy CT can be used to confirm the diagnosis of gout; tophi that are too small to appreciate on physical examination and smaller deposits of urate crystals can frequently be detected by these imaging modalities.

Differential Diagnosis

Acute gout is often confused with cellulitis. Bacteriologic studies usually exclude acute pyogenic arthritis, but rarely, acute gout and pyogenic arthritis can coexist. Pseudogout is distinguished by the identification of calcium pyrophosphate crystals (positive birefringence) in the joint fluid, usually normal serum uric acid, and the radiographic appearance of chondrocalcinosis.

Tophaceous arthritis may resemble chronic RA; gout is suggested by an earlier history of monoarthritis and is established by the demonstration of urate crystals in a suspected tophus. Likewise, hips and shoulders are generally spared in tophaceous gout. Biopsy may be necessary to distinguish tophi from rheumatoid nodules.

Treatment

A. Asymptomatic Hyperuricemia

As a general rule, uric acid–lowering drugs should not be instituted until gout, renal calculi, or tophi have become apparent.

B. Acute Attack

Treatment of the acute attack focuses on reducing inflammation, not lowering serum uric acid. If a patient is taking long-term urate-lowering therapies like allopurinol or febuxostat, these drugs should be continued. There is no contraindication to starting urate-lowering therapy during an acute gout attack; however, one of the following therapies is needed to treat the acute attack:

1. NSAIDs—Oral NSAIDs in full dose (eg, naproxen 500 mg twice daily or indomethacin 25–50 mg every 8 hours; see Table 5–4) are effective treatment for acute gout and should be continued until the symptoms have resolved (usually 7–10 days). Contraindications include active peptic ulcer disease, impaired kidney function, cirrhosis, and a history of adverse reaction to NSAIDs.

2. Colchicine—Oral colchicine is an appropriate treatment option for acute gout, provided the duration of the attack is < 36 hours. For acute gout, colchicine should be administered orally as follows: a loading dose of 1.2 mg followed by a dose of 0.6 mg 1 hour later for a total dose of 1.8 mg the first day; thereafter 0.6 mg twice per day is used until resolution. Patients who are already taking prophylactic doses of colchicine and have an acute flare of gout may receive the full loading dose (1.2 mg) followed by 0.6 mg 1 hour later (before resuming the usual 0.6 mg once or twice daily) provided they have not received this regimen within the preceding 14 days (in which case, NSAIDs or corticosteroids should be used). Higher doses of colchicine should be avoided, given a high prevalence of adverse events such as diarrhea. Colchicine dose should be reduced or avoided altogether if there is significant kidney or liver impairment and in patients who are taking a drug that strongly reduces CYP3A4 or that is a P-glycoprotein (P-gp) inhibitor, such as verapamil or clarithromycin. Using oral colchicine during the intercritical period to prevent gout attacks is discussed below.

3. Corticosteroids—Corticosteroids often give dramatic symptomatic relief in acute episodes of gout and will control most attacks. They are especially useful in patients with contraindications to NSAIDs. Corticosteroids may be given intravenously (eg, methylprednisolone, 40 mg/day) or orally (eg, prednisone, 40–60 mg/day). Corticosteroids can be given at the suggested dose for 5–10 days and then simply discontinued or given at the suggested initial dose for 2–5 days and then tapered over 7–10 days. If the patient's gout is monoarticular or oligoarticular, intra-articular administration of the corticosteroid (eg, triamcinolone, 10–40 mg depending on the size of the joint) is very effective. Because gouty and septic arthritis can coexist, albeit rarely, joint aspiration and Gram stain with culture of synovial fluid should be performed when intra-articular corticosteroids are given.

4. Interleukin-1 inhibitors—Anakinra (an interleukin-1 receptor antagonist) and canakinumab (a monoclonal antibody against interleukin-1-β) can be used to treat acute gout in hospitalized patients in whom comorbidities prevent the use of NSAIDs, colchicine, or glucocorticoids (Table 23–4). Anakinra has a short half-life (6 hours) and may be preferred in patients in whom infection is a concern; canakinumab is FDA-approved for the treatment of gout flares in patients unable to use other therapies.

Table 23–4. Biologic and targeted synthetic agents (selected list).[1]

Agent	Recommended Regimen[2]	Indication
B-cell–Depleting Agents		
Inebilizumab	Induction: 300 mg intravenously days 1 and 15 Maintenance: 300 mg intravenously every 6 months	IgG_4-related disease
Rituximab	Induction: 375 mg/m^2 intravenously once weekly for 4 weeks or 1000 mg days 1 and 15 Maintenance: varies but typically 500 mg–1000 mg intravenously every 4–6 months	Granulomatosis with polyangiitis
	Induction: 1000 mg intravenously once every 2 weeks for 2 doses Maintenance: 1000 mg intravenously every 2 weeks for 2 doses every 16–24 weeks	RA Doses vary for other diseases (eg, Sjögren disease, microscopic polyangiitis, hepatitis C–associated cryoglobulinemic vasculitis, SLE, APS, systemic sclerosis, inflammatory myositis)
Obinutuzumab	Induction: 1000 mg intravenously days 1 and 15 Maintenance: doses vary	SLE
Calcineurin Inhibitors		
Tacrolimus	Doses vary but typically 2 mg orally twice daily	Lupus nephritis
Voclosporin	23.7 mg orally twice daily	Lupus nephritis
Complement Component C5 Inhibitor		
Eculizumab	Induction: 900 mg intravenously weekly for 4 weeks Maintenance: 1200 mg intravenously every 4 weeks	APS, complement-mediated TMA
IL-1 Inhibitors		
Anakinra	100 mg subcutaneously daily	Gout, adult-onset Still disease
Canakinumab	150 mg subcutaneously as a single dose at gout flare	Gout, adult-onset Still disease
IL-6 Inhibitors		
Sarilumab	200 mg subcutaneously once every 2 weeks	RA, adult Still disease, PMR
Tocilizumab	162 mg subcutaneously once weekly or 4 mg/kg intravenously every 4 weeks followed by an increase to 8 mg/kg intravenously every 4 weeks based on clinical response	RA Doses vary for other diseases (eg, adult Still disease, systemic sclerosis, giant cell arteritis)
IL-12/23 Inhibitors		
Ustekinumab	45 mg subcutaneously at weeks 0, 4, then every 12 weeks (Doses vary based on indication)	Psoriatic arthritis, Crohn disease
IL-17 Inhibitors		
Bimekizumab	160 mg subcutaneously every 4 weeks	Psoriatic arthritis, spondyloarthritis
Brodalumab	Induction: 210 mg subcutaneously at weeks 0, 1, and 2 Maintenance: 210 mg subcutaneously every 2 weeks	Psoriatic arthritis
Ixekizumab	Induction: 160 mg subcutaneously at week 0 Maintenance: 80 mg subcutaneously every 4 weeks	Psoriatic arthritis, axial spondyloarthritis
Secukinumab	Induction: 6 mg/kg intravenously at week 0 Maintenance: 1.75 mg/kg (max 300 mg) intravenously every 4 weeks *or* Induction: 150 mg subcutaneously at weeks 0, 1, 2, 3, and 4 Maintenance: 150 mg subcutaneously every 4 weeks (can be increased to 300 mg if lower dose ineffective)	Psoriatic arthritis, axial spondyloarthritis

(*continued*)

Table 23–4. Biologic and targeted synthetic agents (selected list).[1] (continued)

Agent	Recommended Regimen[2]	Indication
IL-23 Inhibitors		
Guselkumab	100 mg subcutaneously at weeks 0, 4, then every 8 weeks	Psoriatic arthritis, ulcerative colitis
Risankizumab	150 mg subcutaneously at weeks 0, 4, then every 12 weeks	Psoriatic arthritis, Crohn disease, ulcerative colitis
Janus Kinase Inhibitors		
Baricitinib	2 mg orally daily	RA
Tofacitinib	IR Tablet: 5 mg orally twice daily ER Tablet: 11 mg orally once daily	RA, axial spondyloarthritis, IBD-associated spondyloarthritis, psoriatic arthritis
Upadacitinib	15 mg orally daily	RA, axial spondyloarthritis, IBD-associated spondyloarthritis, psoriatic arthritis, atopic dermatitis
Monoclonal Antibody Type I Interferon Receptor		
Anifrolumab	300 mg intravenously every 4 weeks	SLE
Monoclonal Antibody BAFF Inhibitors		
Belimumab	Induction: 10 mg/kg intravenously every 2 weeks for 3 doses Maintenance: 10 mg/kg intravenously every 4 weeks *or* 200 mg subcutaneously once weekly	SLE and lupus nephritis
Multiple Tyrosine Kinases Inhibitor		
Nintedanib	150 mg orally twice daily	Systemic sclerosis
T-cell Costimulation Modulator		
Abatacept	125 mg weekly subcutaneously *or* Weight-based intravenous dosing: < 60 kg: 500 mg, 60–100 kg: 750 mg, 100 kg: 1000 mg at weeks 0, 2, 4, then every 4 weeks	RA, psoriatic arthritis
TNF Inhibitors		
Adalimumab	40 mg subcutaneously every other week	RA, Behçet disease
Certolizumab pegol	400 mg subcutaneously at week 0, 2, and 4 followed by 200 mg subcutaneously every other week	RA, axial spondyloarthritis
Etanercept	50 mg subcutaneously once weekly *or* 25 mg subcutaneously twice weekly	RA, axial spondyloarthritis
Golimumab	50 mg subcutaneously once monthly *or* 2 mg/kg intravenously at weeks 0, 4 and then every 8 weeks thereafter	RA, axial spondyloarthritis
Infliximab	3–5 mg/kg intravenous infusion; repeat infusions after 2 and 6 weeks, then every 8 weeks 5 mg/kg intravenously at 0, 2, and 6 weeks followed by 5 mg/kg intravenously every 6 weeks thereafter	RA, Behçet disease Axial spondyloarthritis

[1] To be used with active participation of a rheumatologist.
[2] Consult for dose modification for weight and for disorders that require dose adjustment (eg, kidney injury, liver disease).
APS, antiphospholipid syndrome; PMR, polymyalgia rheumatica; RA, rheumatoid arthritis; TMA, thrombotic microangiopathy.

C. Management Between Attacks

Treatment during symptom-free periods is intended to minimize urate deposition in tissues and to reduce the frequency and severity of recurrences. Potentially reversible causes of hyperuricemia are a high-purine diet, obesity, alcohol consumption, and use of certain medications. Patients with a single episode of gout who have normal kidney function and are able to lose weight and stop drinking alcohol are at low risk for another attack and may not require long-term medical therapy. In contrast, patients with mild CKD or a history of multiple attacks of gout will likely benefit from pharmacologic treatment. In general, the higher the uric acid level and the more frequent the attacks, the more likely that long-term medical therapy will be beneficial. All patients with tophaceous gout should receive urate-lowering therapy.

1. Diet and alcohol—Excessive consumption of alcohol, particularly beer, can precipitate attacks and should be avoided. Although dietary purines usually contribute only 1 mg/dL to the serum uric acid level, moderation in eating foods with high purine content is advisable. Sugar-sweetened beverages and foods sweetened with high fructose corn syrup increase serum urate and the risk of gout. A high liquid intake and, more importantly, a daily urinary output of ≥ 2 L will aid urate excretion and minimize urate precipitation in the kidney.

2. Avoidance of hyperuricemic medications—Thiazide and loop diuretics inhibit renal excretion of uric acid and, if possible, should be avoided in patients with gout. Similarly, niacin can raise serum uric acid levels and should be discontinued if there are therapeutic alternatives. Low doses of aspirin also aggravate hyperuricemia.

3. Colchicine prophylaxis—Colchicine can be used when urate-lowering therapy is started to suppress attacks precipitated by abrupt changes in the serum uric acid level. The usual dose is 0.6 mg orally either once or twice a day. Colchicine is renally cleared. Patients with moderate CKD should take colchicine only once a day or once every other day to avoid peripheral neuromyopathy and other complications of colchicine toxicity. In patients with concomitant CAD, chronic colchicine use can reduce major cardiovascular events.

4. Canakinumab prophylaxis—In exceptional situations where alternative preventive treatments are not possible, canakinumab can be used for prophylaxis.

5. Reduction of serum uric acid—Indications for urate-lowering therapy in a person with gout include frequent acute arthritis (two or more episodes per year), tophaceous deposits, or CKD (stage 2 or worse). The American College of Rheumatology (ACR) guidelines recommend treating to a target uric acid of 6 mg/dL (357 mcmol/L) so that urate crystals can begin to solubilize. In some cases, particularly in patients with tophi or frequent attacks, control of gout may require lowering serum uric acid to < 5 mg/dL or 297.4 mcmol/L. Lowering serum uric acid levels does not benefit an acute gout flare. Patients with a high serum uric acid who have *not* had gout, renal calculi or tophi generally do not need urate-lowering medications. Exceptions include patients undergoing treatment for myeloproliferative disorders. Three classes of agents may lower the serum uric acid—xanthine oxidase inhibitors (allopurinol or febuxostat), uricosuric agents, and uricase (pegloticase).

A. XANTHINE OXIDASE INHIBITORS—Allopurinol and febuxostat are the preferred first-line agents for lowering urate and have similar efficacy. They reduce plasma uric acid levels by blocking the final enzymatic steps in the production of uric acid. Allopurinol and febuxostat should not be used together, but they can be tried sequentially if the initial agent fails to lower serum uric acid to the target level or if it is not tolerated. The most frequent adverse effect with either medication is the precipitation of an acute gouty attack; thus, patients generally should be receiving prophylactic doses of colchicine.

Hypersensitivity to allopurinol occurs in 2% of cases, usually within the first few months of therapy, and it can be life-threatening. The most common initial sign of hypersensitivity is a pruritic rash that may progress to toxic epidermal necrolysis, particularly if allopurinol is continued; vasculitis and hepatitis are other manifestations. *Patients should be instructed to stop allopurinol immediately if a rash develops.* CKD and concomitant thiazide therapy are risk factors. There is a strong association between allopurinol hypersensitivity and HLA-B*58:01, which is a prevalent allele in certain populations. *It is recommended to screen for HLA-B*58:01 before initiating allopurinol in all persons of Chinese, Thai, and Korean descent, as well as in Black persons.*

The initial daily dose of allopurinol is 100 mg/day orally (50 mg/day for those with stage 4 or worse CKD), titrating upward every 2–5 weeks to achieve the target serum uric acid level. A typical dose of allopurinol is 300 mg, but many patients require > 300 mg daily to achieve the target uric acid level. The maximum daily dose is 800 mg.

Allopurinol interacts with other drugs including azathioprine and 6-MP.

Febuxostat can also rarely cause hypersensitivity reactions, and those with previous hypersensitivity to allopurinol appear to have slightly higher risk. It can be given without dose adjustment to patients with mild to moderate kidney disease. However, abnormal liver tests may develop in 2–3% of patients taking febuxostat. Despite initial concern that febuxostat was associated with more cardiovascular events than allopurinol, a large RCT showed that the two drugs have similar cardiovascular safety. The initial dose of febuxostat is 40 mg/day orally. If the target serum uric acid is not reached in 4 weeks, the dose of febuxostat can be increased to 80 mg/day and then to the maximum dose of 120 mg/day.

B. URICOSURIC DRUGS—Uricosuric drugs lower serum uric acid levels by blocking the tubular reabsorption of filtered urate, thereby increasing uric acid excretion by the kidney. Probenecid is typically started at 250 mg orally twice daily and titrated to a maximum of 3000 mg daily to achieve the target serum urate. Probenecid is typically reserved for patients who cannot achieve a serum uric acid of 6.0 mg/dL or less with allopurinol or febuxostat alone. Probenecid should not be used in patients with a creatinine clearance < 50 mL/min due to limited efficacy; contraindications include a history of nephrolithiasis (uric acid or calcium stones) and evidence of high uric acid excretion (ie, > 800 mg of uric acid in a 24-hour urine collection). To reduce the development of uric acid stones (which occur in up to 11%), patients should be advised to increase their fluid intake and clinicians should consider prescribing an alkalinizing agent (eg, potassium citrate, 30–80 mEq/day orally) to maintain a urinary pH > 6.0.

C. PEGLOTICASE—Pegloticase, a recombinant uricase that must be administered intravenously (8 mg every 2 weeks), is indicated for the rare patient with refractory chronic tophaceous gout. Pegloticase carries an FDA black box warning, which advises administering the drug only in health care settings and by health care professionals prepared to manage anaphylaxis. Methotrexate 15 mg orally per week and folic acid 1 mg orally daily should be started 4 weeks before pegloticase initiation and continued through the end of treatment; use of methotrexate increases response rates and reduces the risk of anaphylaxis. If methotrexate cannot be used, alternative immunosuppressants include mycophenolate mofetil or azathioprine. Pegloticase should be stopped if serum urate levels remain above 6 mg/dL, indicating insufficient uric acid reduction and the development of antidrug antibodies. Pegloticase should be followed by urate-lowering therapy, usually with xanthine oxidase inhibitors.

D. Chronic Tophaceous Arthritis

With rigorous drug adherence, allopurinol, febuxostat, and pegloticase shrink tophi and in time can lead to their disappearance. Resorption of extensive tophi requires maintaining a serum uric acid below 6 mg/dL.

E. Gout in Patients Post Transplant

Hyperuricemia and gout commonly develop in many patients post transplant because they have decreased kidney function and require drugs that inhibit uric acid excretion (especially cyclosporine and diuretics). Often the best approach for monoarticular gout—after excluding infection—is injecting corticosteroids into the joint. For polyarticular gout, drug–drug interactions may limit the use of colchicine and the use of NSAIDs may increase adverse events when there is reduced kidney function; systemic corticosteroids may therefore be the safest alternative for some patients. Since transplant patients often have multiple attacks of gout, long-term relief requires lowering the serum uric acid with allopurinol or febuxostat. Both allopurinol and febuxostat inhibit the metabolism of azathioprine and mercaptopurine and should be avoided in patients taking these medications.

Prognosis

Without treatment, an acute attack may last from a few days to several weeks. The intervals between acute attacks vary up to years, but the asymptomatic periods often become shorter as the disease progresses. Chronic gouty arthritis occurs after repeated attacks of acute gout, but only after inadequate treatment. The younger the patient at the onset of disease, the greater the tendency to a progressive course. Destructive arthropathy is rarely seen in patients whose first attack is after age 50.

Barry A et al. Comparison of gout flares with the initiation of treat-to-target allopurinol and febuxostat: a post-hoc analysis of a randomized multicenter trial. Arthritis Rheumatol. 2024;76:1552. [PMID: 38925627]

2. Calcium Pyrophosphate Deposition

ESSENTIALS OF DIAGNOSIS

- CPPD in fibrocartilage and hyaline cartilage (chondrocalcinosis) can cause:
- An acute crystal-induced arthritis (“pseudogout”).
- A degenerative arthropathy.
- A chronic inflammatory polyarthritis (“pseudorheumatoid arthritis”).
- Asymptomatic chondrocalcinosis detected incidentally on radiographs.

General Considerations

The prevalence of calcium pyrophosphate deposition (CPPD) increases with age. Hyperparathyroidism, familial hypocalciuric hypercalcemia, hemochromatosis, and hypomagnesemia confer risk of CPPD, but most cases have no associated condition.

Clinical Findings

Pseudogout is most often seen in persons aged 60 or older, is characterized by acute, recurrent, and rarely chronic arthritis involving large joints (most commonly the knees and the wrists), and is almost always accompanied by radiographic chondrocalcinosis of the affected joints. Pseudogout, like gout, frequently develops 24–48 hours after major surgery. Identification of weakly positively birefringent calcium pyrophosphate crystals in joint aspirates is diagnostic.

The crowned dens syndrome, caused by pseudogout of the atlantoaxial junction associated with “crown-like” calcifications around the dens, manifests with severe neck pain, rigidity, and high fever that can mimic meningitis or giant cell arteritis.

Degenerative arthropathy associated with CPPD can involve joints not usually affected by osteoarthritis (eg, glenohumeral joint, wrist, patellofemoral compartment of the knee). The “pseudorheumatoid arthritis” of CPPD affects the metacarpophalangeal joints and wrists. Radiographs demonstrate chondrocalcinosis and degenerative changes such as asymmetric joint space narrowing and osteophyte formation.

Treatment

NSAIDs are helpful in the treatment of acute episodes of pseudogout. Colchicine, up to 1.8 mg orally during the first 24 hours of treatment, followed by 0.6 mg once or twice daily until symptoms resolve can be effective. Aspiration of the inflamed joint and intra-articular injection of triamcinolone, 10–40 mg, depending on the size of the joint, can be effective as can oral prednisone started at a dose of 30–50 mg and tapered over 7–10 days.

In patients with contraindications to other therapies, the IL-1 inhibitors anakinra and canakinumab can be used. For three or more attacks per year, prophylaxis with colchicine 0.6 mg orally once or twice daily can reduce flares.

Abhishek A et al. The 2023 ACR/EULAR classification criteria for calcium pyrophosphate deposition disease. Arthritis Rheumatol. 2023;75:1703. [PMID: 37494275]

RHEUMATOID ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Usually insidious onset with morning stiffness and joint pain.
- Symmetric polyarthritis with predilection for small joints of the hands and feet; deformities common with progressive disease.
- Radiographic findings: juxta-articular osteoporosis, joint erosions, and joint space narrowing.
- Rheumatoid factor and antibodies to cyclic citrullinated peptides (anti-CCP) are present in 70–80%.
- Extra-articular disease such as subcutaneous nodules and interstitial lung disease.

General Considerations

RA is a chronic systemic inflammatory disease whose major manifestation is synovitis of multiple joints. It has a prevalence of 1% and is more common in women than men (female:male ratio of 3:1). RA can begin at any age, but the peak onset is in the fourth or fifth decade for women and the sixth to eighth decades for men. Susceptibility to RA is genetically determined with multiple genes contributing. Inheritance of HLA-DRB1 alleles encoding a distinctive five-amino-acid sequence known as the "shared epitope" is the best characterized genetic risk factor. Untreated, RA causes joint destruction with consequent disability and shortens life expectancy.

The pathologic findings in the joint include chronic synovitis with formation of a pannus, which erodes cartilage, bone, ligaments, and tendons. Effusion and other manifestations of inflammation are common.

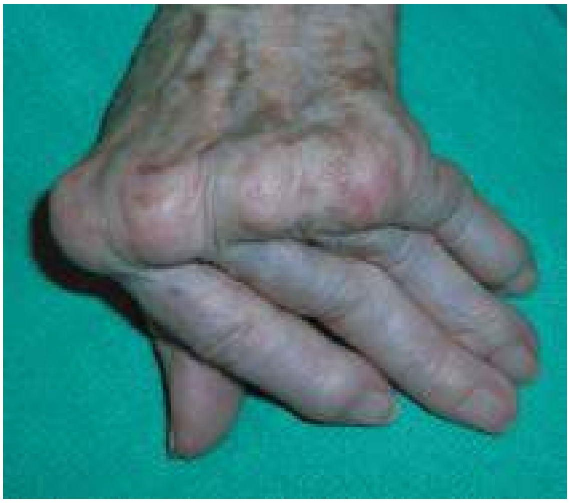
The diagnosis of RA is made using the 2010 ACR/European League Against Rheumatism (EULAR) classification criteria (Table 23–5).

Children with juvenile idiopathic arthritis can have arthritis that persists into adulthood. Although this entity is distinct from RA, the polyarticular form of the disease is often associated with a positive rheumatoid factor and has a similar joint distribution to RA.

Clinical Findings

A. Symptoms and Signs

1. Joint symptoms—The clinical manifestations of RA are highly variable, but joint symptoms usually predominate. Although acute presentations may occur, the onset of articular signs of inflammation is usually insidious, with prodromal symptoms of vague periarticular pain or stiffness. Symmetric swelling of multiple joints with tenderness and pain is characteristic. Monoarticular disease is occasionally seen initially. Stiffness persisting for longer than 30 minutes (and usually many hours) is prominent in the morning. Stiffness may recur after daytime inactivity and be much more severe after strenuous activity. Although any diarthrodial joint may be affected, PIP joints, MCP joints (Figure 23–3), wrists, knees, ankles, and MTP joints are most often involved. Synovial cysts and rupture of tendons may occur. Entrapment syndromes are common—particularly of the median nerve at the carpal tunnel of the wrist. RA can affect the neck but spares the other components of the spine and does not involve the sacroiliac joints. In advanced disease, atlantoaxial (C1–C2) subluxation can lead to myelopathy.



▲ **Figure 23–3.** Ulnar deviation at metacarpophalangeal joints in advanced rheumatoid arthritis. Also note the swelling at the distal interphalangeal joints, seen best on the first finger. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 3rd ed. McGraw-Hill, 2019.)

2. Rheumatoid nodules—Twenty percent of patients have subcutaneous rheumatoid nodules, most commonly situated over bony prominences but also observed in the

Table 23–5. Classification criteria for rheumatoid arthritis.

Patients who have at least one swollen joint that is not better explained by another disease							
Joint Involvement (swollen or tender joints)	Score	Serology	Score	Acute-Phase Reactants	Score	Duration of Symptoms	Score
1 large joint	0	Negative RF; negative anti- CCP Ab	0	Normal CRP and ESR	0	< 6 weeks	0
2–10 large joints	1	Low + RF or anti- CCP Ab	2	Abnormal CRP or ESR	1	≥ 6 weeks	1
1–3 small joints (± large joints)	2	High + RF or anti- CCP Ab	3				
4–10 small joints (± large joints)	3			≥ 6/10 points is definite rheumatoid arthritis			
>10 joints (at least 1 small joint)	5

bursae and tendon sheaths (Figure 23–4). Nodules are occasionally seen in the lungs, the sclerae, and other tissues. Nodules correlate with the presence of rheumatoid factor in serum ("seropositivity"), as do most other extra-articular manifestations.

3. Ocular symptoms—Ocular manifestations include episcleritis, scleritis (Figure 23–5), scleromalacia due to scleral nodules, and peripheral ulcerative keratitis. Dryness of the eyes, mouth, and other mucous membranes is found especially in advanced disease (see Sjögren disease).

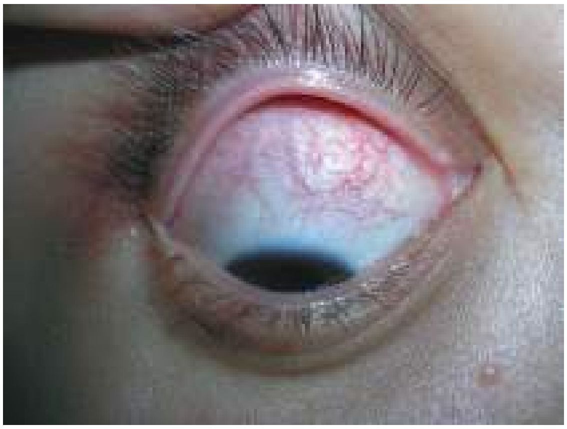

Figure 23–5. Scleritis in a young woman with rheumatoid arthritis. Note the violaceous deep vessel engorgement. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 3rd ed. McGraw-Hill, 2019.)

4. Other symptoms—Interstitial lung disease, often asymptomatic and detected by chest imaging, can be clinically significant in about 10% of patients. Pericarditis and pleural disease are usually silent clinically, but symptomatic effusions can develop. Osteoporosis is common in RA. Patients are at significantly increased risk of cardiovascular disease given a higher prevalence of risk factors such as diabetes, hypertension and obesity, as well as the effects of systemic inflammation. Occasionally, a small-vessel vasculitis develops and manifests as tiny hemorrhagic infarcts in the nail folds or finger pulps. Necrotizing arteritis is rare. A small subset of patients with RA have splenomegaly and neutropenia (Felty syndrome), usually in the setting of untreated severe, destructive arthritis. Felty syndrome must be distinguished from large granular lymphoproliferative disorder, with which it shares many features.

B. Laboratory Findings

Anti-CCP antibodies and rheumatoid factor, an IgM antibody directed against the Fc region of IgG, are present in 70–80% of patients with established RA. Rheumatoid factor has a sensitivity of only 50% in early disease. Anti-CCP antibodies are the most specific blood test for RA (specificity ~95%). Rheumatoid factor can occur in other autoimmune diseases and in chronic infections, including hepatitis C, syphilis, subacute bacterial endocarditis, and tuberculosis. The prevalence of rheumatoid factor positivity also rises with age in healthy individuals. Approximately 20% of patients with RA have antinuclear antibodies.

The ESR and levels of CRP are typically elevated in proportion to disease activity. Anemia of chronic disease is common. Initial joint fluid examination confirms the inflammatory nature of the arthritis (see Table 23–2).

Arthrocentesis is needed to diagnose superimposed septic arthritis, which is a common complication of RA and should be considered whenever a patient with RA has one joint inflamed out of proportion to the rest.

C. Imaging

Characteristic radiographic changes greatly aid in the diagnosis of RA. Radiographs obtained during the first 6 months of symptoms, however, are usually normal. The earliest changes occur in the hands or feet and consist of soft tissue swelling and juxta-articular demineralization. Later, uniform joint space narrowing and erosions develop. The erosions are often first evident at the fifth MTP joint and the ulnar styloid and occur at the juxta-articular margin, where the bony surface is not protected by cartilage. Characteristic changes also occur in the cervical spine, with C1–2 subluxation, but these changes usually take many years to develop. MRI and ultrasonography are more sensitive than radiographs in detecting bony and soft tissue changes in RA and can be considered if synovitis is suspected but difficult to confirm by physical examination.

Differential Diagnosis

In contrast to RA, osteoarthritis spares the wrists and the MCP joints. Osteoarthritis is not associated with constitutional manifestations, and the joint pain is characteristically relieved by rest, unlike the morning stiffness of RA. Signs of articular inflammation, prominent in RA, are usually minimal in osteoarthritis. CPPD disease can cause a degenerative arthropathy of the MCPs and wrists; radiographs are usually diagnostic. Although gouty arthritis is almost always intermittent and monoarticular in the early years, it may evolve with time into a chronic polyarticular process that mimics RA. Gouty tophi can resemble rheumatoid nodules but are not associated with rheumatoid factor, whose sensitivity for rheumatoid nodules approaches 100%. The early history of intermittent monoarthritis and the presence of synovial urate crystals are distinctive features of gout.

Spondyloarthropathies, particularly earlier in their course, can be a source of diagnostic uncertainty; predilection for lower extremities and involvement of the spine and sacroiliac joints point to the correct diagnosis. Chronic Lyme arthritis typically involves only one joint, most commonly the knee, and is associated with positive serologic tests (see Chapter 39). Acute viral infections, most notably with Chikungunya virus and parvovirus B19, can cause a polyarthritis that mimics early-onset RA. However, fever is common, the arthritis usually resolves within weeks, and serologic studies confirm recent infection. Chronic infection with hepatitis C can cause a chronic nonerosive polyarthritis associated with rheumatoid factor; tests for anti-CCP antibodies are negative.

Malar rash, photosensitivity, discoid skin lesions, alopecia, antibodies to double-stranded DNA or Smith, glomerulonephritis, and CNS abnormalities point to SLE. Polymyalgia rheumatica can cause polyarthralgias in patients over age 50, but these patients remain rheumatoid factor–negative and have chiefly proximal muscle pain and stiffness, centered on the shoulder and hip girdles. Joint pain that can be confused with RA presents in a substantial minority of patients with granulomatosis with polyangiitis. This diagnostic error can be avoided by recognizing that, in contrast to RA, the arthritis of granulomatosis with polyangiitis preferentially involves larger joints (eg, hips, ankles, wrists) and usually spares the small joints of the hand. A variety of cancers produce paraneoplastic syndromes, including polyarthritis. One form is hypertrophic pulmonary osteoarthropathy most often produced by lung and GI carcinomas, characterized by a rheumatoid-like arthritis associated with clubbing, periosteal new bone formation, and a negative rheumatoid factor. Diffuse swelling of the hands with palmar fasciitis occurs in a variety of cancers, especially ovarian carcinoma.

Treatment

The primary objectives in treating RA are reduction of inflammation and pain, preservation of function, and prevention of deformity. Early, aggressive treatment is the standard of care. Disease-modifying antirheumatic drugs (DMARDs) should be started as soon as the diagnosis of RA is certain and then adjusted to suppress disease activity. NSAIDs provide some symptomatic relief but do not prevent erosions or alter disease progression. They are not appropriate as monotherapy and should only be used in conjunction with DMARDs, if at all. The ACR recommends using standardized assessments, such as the Disease Activity Score 28 Joints or the Clinical Disease Activity Index, to gauge therapeutic responses, with the target of low disease activity or remission by these measures.

A. Corticosteroids

ACR guidelines recommend avoiding corticosteroids to treat early RA, when possible, given their significant toxicity. In some cases, low-dose corticosteroids (eg, oral prednisone 5–10 mg daily) are necessary to produce a prompt anti-inflammatory effect while waiting for disease control with DMARDs. Corticosteroids should be used for the shortest duration possible and generally for < 3 months. Higher doses are used to manage serious extra-articular manifestations (eg, pericarditis, necrotizing scleritis). When corticosteroids are to be discontinued, they should be tapered gradually on a planned schedule appropriate to the duration of treatment. In the rare patient in whom long-term corticosteroid therapy is needed, measures should be taken to prevent osteoporosis (Table 30–5).

Intra-articular corticosteroids may be helpful for symptom control if one or two joints are the chief source of difficulty. Intra-articular triamcinolone, 10–40 mg depending on the size of the joint to be injected, may be given but not more than four times a year to prevent cartilage loss.

B. DMARDs

1. Synthetic DMARDs—

a. Methotrexate—Methotrexate is the initial synthetic DMARD of choice for patients with RA. It is generally well tolerated and often produces a beneficial effect in 2–6 weeks; about one-third of patients achieve low disease activity on methotrexate monotherapy. The usual initial dose is 7.5 or 10 mg orally once weekly in older patients or those with comorbidities such as mild kidney disease; a starting dose of 15 mg can be used in younger, otherwise healthy individuals. If the patient tolerates methotrexate but has not responded in 1 month, the dose can be increased by 2.5 to 5 mg orally weekly to reach the maximal oral dose of 20 mg weekly. The most frequent side effects are gastric irritation and stomatitis. Cytopenia, most commonly leukopenia or thrombocytopenia but rarely pancytopenia from bone marrow suppression, is an important potential problem of methotrexate therapy. The risk of developing pancytopenia is much higher in patients with GFR < 60 mL/min/1.73 m^2. Hepatotoxicity with fibrosis and cirrhosis is a serious toxic effect that correlates with cumulative dose and is uncommon with appropriate monitoring of liver biochemical tests. Methotrexate is contraindicated in a patient with any form of chronic hepatitis, in pregnant patients, and in any patient with significant kidney dysfunction (estimated GFR < 30 mL/min/1.73 m^2). Heavy alcohol use increases hepatotoxicity, so patients should be advised to drink alcohol in extreme moderation, if at all. Metabolic dysfunction-associated fatty liver disease, diabetes mellitus, obesity, and kidney disease also increase the risk of hepatotoxicity. Liver biochemical tests should be monitored at least every 12 weeks, along with a CBC. The dose of methotrexate should be reduced if aminotransferase levels are elevated, and the drug should be discontinued if abnormalities persist despite dosage reduction. All patients should be prescribed either daily folate (1 mg orally) or weekly leucovorin calcium (2.5–5 mg taken orally 24 hours after the dose of methotrexate) to reduce gastric irritation, stomatitis, cytopenias, and hepatotoxicity. Hypersensitivity to methotrexate can cause an acute or subacute interstitial pneumonitis that can be life-threatening but usually responds to cessation of the drug and corticosteroids. Methotrexate is teratogenic; women of childbearing age must use effective contraception while taking the medication. Methotrexate is associated with a slightly increased risk of B-cell lymphomas, some of which resolve following the discontinuation of the medication as well as all types of skin cancer. The combination of methotrexate and other folate antagonists, such as trimethoprim-sulfamethoxazole, should be used cautiously since pancytopenia can result. Amoxicillin can decrease renal clearance of methotrexate, leading to toxicity.

B. SULFASALAZINE—This drug is often used in combination with methotrexate when methotrexate alone does not adequately control disease activity. It is usually begun at a dosage of 500 mg orally twice daily and then increased each week by 500 mg until the patient improves or the daily dose reaches 3000 mg. Side effects, particularly neutropenia and thrombocytopenia, occur in 10–25% and are serious in 2–5%; nausea is also common. Sulfasalazine causes hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, *so a G6PD level should be checked before initiation*. Patients with aspirin sensitivity should not be given sulfasalazine. Patients taking sulfasalazine should have CBC monitored every 2–4 weeks for the first 3 months, then every 3 months.

C. LEFLUNOMIDE—Leflunomide, a pyrimidine synthesis inhibitor, is an alternative for those who cannot take methotrexate. The dose is 20 mg orally once daily. The most frequent side effects are diarrhea, rash, reversible alopecia, and hepatotoxicity. Some patients experience dramatic unexplained weight loss. The drug is teratogenic and has a half-life of 2 weeks, but active metabolites can be detected for up to 2 years. Thus, it is contraindicated in premenopausal women who wish to bear children.

D. ANTIMALARIALS—Monotherapy with hydroxychloroquine should be reserved for patients with very mild disease because only a small percentage will respond and often only after 3–6 months of therapy. Hydroxychloroquine is often used in combination with other conventional DMARDs, particularly methotrexate and sulfasalazine (so-called “triple therapy”). The advantages of hydroxychloroquine are that it is not immunosuppressive and has comparatively low toxicity, especially at a dosage of 200–400 mg/day orally (not to exceed 5 mg/kg/day). The prevalence of the most important adverse effect, retinal toxicity that can lead to visual loss, is a function of duration of therapy, occurring in < 2% of patients (dosed properly) during the first 10 years of use but rising to 20% after 20 years of treatment. Ophthalmologic examinations at baseline and then every 12 months after 5 years of use are required. Rare reactions include neuropathies and myopathies of both skeletal and cardiac muscle, which usually improve when the drug is withdrawn.

E. JANUS KINASE INHIBITORS—Tofacitinib, baricitinib, and upadacitinib, inhibitors of Janus kinase, are oral agents used to manage severe RA that is refractory to methotrexate or other agents (Table 23–5). Janus kinase inhibitors can be used either as monotherapy or in combination with methotrexate. Janus kinase inhibitors increase the risk of infections. Patients should be screened and treated for latent tuberculosis and vaccinated against varicella prior to receiving these drugs. There is an FDA black box warning for Janus kinase inhibitors related to slightly higher risks of serious heart-related events, cancer, blood clots, and death based on data from a large RCT comparing tofacitinib with TNF inhibitors in patients taking methotrexate.

2. Biologic DMARDs (Table 23–4)—

A. TUMOR NECROSIS FACTOR INHIBITORS—Inhibitors of TNF—a proinflammatory cytokine—are frequently added to the treatment of patients who have not responded adequately to methotrexate and can be used as initial therapy in combination with methotrexate for patients with poor prognostic factors.

Five TNF inhibitors are in use: etanercept, infliximab, adalimumab, golimumab, and certolizumab pegol. Infliximab, etanercept, and adalimumab have biosimilar formulations with demonstrated similar efficacy. Each drug produces substantial improvement in > 60% of patients and is usually well tolerated. Minor irritation at injection sites is the most common side effect of the injectable ant-TNF drugs. TNF inhibitors have been associated with a several-fold increased risk of serious bacterial infections and a striking increase in granulomatous infections, particularly reactivation of tuberculosis. Screening for latent tuberculosis (see Chapter 9) is mandatory before initiating TNF inhibitors. It is prudent to suspend TNF inhibitors when a fever or other manifestations of a clinically significant infection develops. Demyelinating neurologic complications that resemble multiple sclerosis have been reported rarely in patients taking TNF inhibitors, but the true magnitude of this risk—likely small—has not been determined with precision. Most observational studies have not found a higher risk of malignancy with TNF inhibitors. Infliximab was associated with increased morbidity in an HF trial; therefore, TNF inhibitors should be used with extreme caution in patients with moderate or severe HF (New York Heart Association class III/IV). Infliximab can rarely cause anaphylaxis and induce anti-DNA antibodies (and rarely clinically evident drug-induced SLE).

B. ABATACEPT—Abatacept, a recombinant protein made by fusing human IgG with a T-cell inhibitory receptor (CTLA4), blocks T-cell costimulation and produces clinically meaningful responses in approximately 50% of individuals whose disease does not respond to the combination of methotrexate and a TNF inhibitor.

C. RITUXIMAB—Rituximab, a monoclonal antibody that depletes B cells, can be used in combination with methotrexate or leflunomide for patients whose disease has been refractory to treatment with a TNF inhibitor. Because rituximab reduces the humoral immune response, it increases susceptibility to infections. Testing for viral hepatitis is mandatory prior to drug initiation since rituximab and can lead to reactivation of hepatitis B in patients who are surface antigen or core antibody positive.

D. Tocilizumab and sarilumab—Tocilizumab and sarilumab are monoclonal antibodies that block the receptor for IL-6, an inflammatory cytokine involved in the pathogenesis of RA. They are used most often in combination with methotrexate for patients whose disease has been refractory to treatment with a TNF inhibitor. These drugs can cause liver enzyme elevations, neutropenia, lipid elevations, and rarely, GI perforations.

3. Combination DMARDs—DMARDs often have greater efficacy when administered in combination than when used individually. The most commonly used combination is methotrexate with a TNF inhibitor. Still, most patients who require DMARD therapy are given methotrexate monotherapy initially because this regimen is effective in up to one-third of patients and is less expensive and less toxic than combination therapy. The combination of methotrexate, sulfasalazine, and hydroxychloroquine (“triple therapy”) is economical, effective, and not inferior to the combination of methotrexate plus etanercept for those who have not responded to methotrexate monotherapy. The choice of a second-line biologic agent for patients who have not responded to TNF inhibitors is often based on patient and provider preference and insurance coverage since comparative effectiveness data are sparse. *Biologic DMARDs should not be combined.*

Course & Prognosis

After months or years, deformities may occur; the most common are ulnar deviation of the fingers (Figure 23–3), boutonnière deformity (hyperextension of the DIP joint with flexion of the PIP joint), “swan-neck” deformity (flexion of the DIP joint with extension of the PIP joint), valgus deformity of the knee, and volar subluxation of the MTP joints. Screening and management of osteoporosis is important. The excess mortality associated with RA is largely due to CVD. Aggressive management of hypertension, diabetes, obesity, avoidance of cigarette smoking, and control of RA-related inflammation can improve outcomes.

When to Refer

Early referral to a rheumatologist is essential for diagnosis and the timely introduction of effective therapy.

Smolen JS et al. EULAR recommendations for the management of rheumatoid arthritis with synthetic and biological disease-modifying antirheumatic drugs: 2022 update. Ann Rheum Dis. 2023;82:3. [PMID: 36357155]

ADULT STILL DISEASE

Still disease is a systemic form of juvenile chronic arthritis in which high spiking fevers are much more prominent, especially at the outset, than arthritis. This extremely rare syndrome also occurs in adults. Most adults are in their 20s or 30s; onset after age 60 is rare. The fever is dramatic, often with daily spikes to 40°C, associated with sweats and chills, and then plunging to normal or several degrees below normal in the absence of antipyretics. Many patients initially complain of sore throat. An evanescent salmon-colored nonpruritic rash, chiefly on the chest and abdomen, is a characteristic feature. The rash can easily be missed since it often appears only with the fever spike. Many patients have lymphadenopathy and pericardial effusions. Joint symptoms are mild or absent initially, but a destructive arthritis, especially of the wrists, may develop months later. Liver enzyme elevations occur in most patients. Anemia and leukocytosis (predominantly neutrophilia), with peripheral WBC counts often exceeding 15,000/mcL (15×10^9/L), are the rule. Serum ferritin levels are often strikingly elevated (> 3000 mg/mL or 6741 pmol/L). (Other conditions, including viral infections, malignancy, and multiple blood transfusions, can also cause extreme elevations in ferritin levels.) Significant elevations of serum IL-18 or S100 proteins (eg, calprotectin) strongly support the diagnosis, and should be measured if available. The diagnosis of adult Still disease is suggested by the quotidian fever pattern, sore throat, and the classic rash, but it requires exclusion of other causes of fever. About 20% of patients with mild disease respond to NSAIDs. Early use of biologic therapies targeting IL-1 (anakinra or canakinumab) or IL-6 (tocilizumab or sarilumab) improves outcomes and reduces the need for long-term corticosteroids (Table 23–4). The course of adult Still disease can be monophasic, intermittent, or chronic.

Macrophage activation syndrome is a serious, potentially life-threatening complication of Still disease. It manifests as fever; splenomegaly; cytopenia; liver dysfunction; hypertriglyceridemia; hypofibrinogenemia; marked ferritin elevation; elevated soluble CD25; depressed natural cell activity; and hemophagocytosis in bone marrow, spleen, and lymph nodes. Treatment includes high-dose corticosteroids, IL-1 inhibitors, cyclosporine, and interferon-γ inhibitors.

Fautrel B et al. EULAR/PReS recommendations for the diagnosis and management of Still’s disease, comprising systemic juvenile idiopathic arthritis and adult-onset Still’s disease. Ann Rheum Dis. 2024;83:1614. [PMID: 39317417]

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS

- Occurs mainly in young women.
- Rash over areas exposed to sunlight.
- Joint symptoms in 90% of patients.
- Anemia, leukopenia, thrombocytopenia.
- Glomerulonephritis and CNS disease are major sources of disease morbidity.
- Serologic findings: antinuclear antibodies (100%), anti–double-stranded DNA antibodies (approximately two-thirds), and low serum complement levels (particularly during disease flares).

General Considerations

SLE is an inflammatory autoimmune disorder of autoantibodies to nuclear antigens. It can affect multiple organ systems. Many of its clinical manifestations are secondary to inflammation resulting from the trapping of antigen-antibody complexes in capillaries of visceral structures or to autoantibody-mediated destruction of host cells (eg, thrombocytopenia). The clinical course is marked by spontaneous remission and relapses. The severity may vary from mild and episodic to a rapidly fulminant, life-threatening illness.

The incidence of SLE is influenced by many factors, including sex, environmental exposures, and genetics. About 85% of patients are women and most cases develop after menarche and before menopause. Among older individuals, the sex distribution is more equal. SLE occurs in 1 in 400 Black women, 1 in 800 Hispanic women, and 1 in 1100 White women; social determinants of health likely contribute to these disparities. There are familial occurrences of SLE, and the disorder is concordant in 25–70% of identical twins. Positive antinuclear antibody serologies are seen in asymptomatic family members, and the prevalence of other rheumatic diseases is increased among close relatives.

The diagnosis of SLE should be suspected in patients having a multisystem disease with a positive test for antinuclear antibodies. It is imperative to ascertain that the condition has not been induced by a drug (see Drug-Induced Lupus below).

The 2019 European and American criteria require an ANA titer of ≥ 80 (Table 23–6), highlighting that SLE should generally not be diagnosed in the absence of an elevated ANA titer. Criteria are developed as guidelines for the inclusion of patients in research studies and do not supplant clinical judgment in the diagnosis of SLE.

Clinical Findings

A. Symptoms and Signs

Systemic features of SLE include fever, anorexia, fatigue, and weight loss. Many patients have skin lesions at some time; the characteristic “butterfly” (malar) rash affects less than half of patients. Other cutaneous manifestations are panniculitis (lupus profundus), discoid lupus (Figure 23–6), and typical fingertip lesions (periungual erythema, nail fold infarcts, and splinter hemorrhages). Alopecia is common. Mucous membrane lesions tend to occur during periods of exacerbation. Raynaud phenomenon is present in about 20% of patients.

Joint symptoms, with or without active synovitis, occur in over 90% of patients and are often the earliest manifestation. The arthritis can lead to reducible swan-neck deformities, but only 10% of patients develop radiographic erosions that are more typical of RA.

Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see Chapter 25). Some patients may also have interstitial nephritis. With appropriate therapy, the survival rate even for patients with serious kidney disease (proliferative glomerulonephritis) is favorable, although a substantial portion of patients with severe lupus nephritis develop ESKD.

Ocular manifestations include keratoconjunctivitis sicca, retinal vasculitis, episcleritis, scleritis, and optic neuropathy.

Pleurisy and pleural effusion are common. Pneumonitis, interstitial lung disease, and pulmonary hypertension can rarely occur. Alveolar hemorrhage is uncommon but life-threatening.

The pericardium is affected in most patients. HF may result from myocarditis and hypertension. Cardiac arrhythmias can occur. Atypical verrucous endocarditis of Libman-Sacks is usually clinically silent but occasionally can produce acute or chronic valvular regurgitation—most commonly mitral regurgitation, which can be a source of systemic emboli.

GI manifestations can include inflammation of the small intestine (lupus enteritis), which can lead to diarrhea and abdominal pain, as well as peritonitis and lupus hepatitis.

Neurologic complications of SLE include psychosis, cognitive impairment, seizures, peripheral and cranial neuropathies, and strokes. Transverse myelitis in SLE is a medical emergency and can present with weakness, bowel and bladder dysfunction, and a sensory level deficit. Severe depression and psychosis are sometimes exacerbated by the administration of high doses of corticosteroids.

Hematologic manifestations include leukopenia, autoimmune hemolytic anemia, immune thrombocytopenia, and thrombotic thrombocytopenic purpura. Antiphospholipid syndrome (APS) can occur in association with SLE (see Antiphospholipid Syndrome, below).

B. Laboratory Findings

SLE is characterized by the production of many different autoantibodies (Table 23–7). Antinuclear antibody (ANA) tests using HEp-2 cells (a human cell line) as a source of nuclei are nearly 100% sensitive for SLE but not specific—ie, they are positive in low titer in up to 20% of healthy adults and also in many patients with other immune-mediated conditions such as RA, thyroid disease, systemic sclerosis, and Sjögren disease, as well as in some infections and malignancies. False-negative ANA results can occur with tests based on multiplex assays that use specific nuclear antigens rather than cell lines. Antibodies to double-stranded DNA and to Sm are specific for SLE but not sensitive, since they are present in only 60% and 30% of patients, respectively. Depressed serum complement—a finding suggestive of disease activity—often returns toward normal in remission. Anti–double-stranded DNA antibody levels also correlate with disease activity in some patients; anti-Sm levels do not. Other autoantibodies commonly seen in SLE include antibodies to SS-A/Ro, SS-B/La, ribonucleoprotein (RNP), and phospholipid. Antibodies to SS-A/Ro are associated with subacute cutaneous lupus; during pregnancy these autoantibodies can cross the placenta and damage the developing fetal conduction system, producing congenital heart block.

During disease flares, elevations in the ESR are common, but the serum CRP is usually normal unless there is serositis or arthritis. *An elevated CRP in the absence of these manifestations should increase clinical suspicion for infection.* Abnormality of urinary sediment, including hematuria with or without casts, and proteinuria (varying from mild to nephrotic range) can indicate active lupus nephritis and should prompt a renal biopsy.

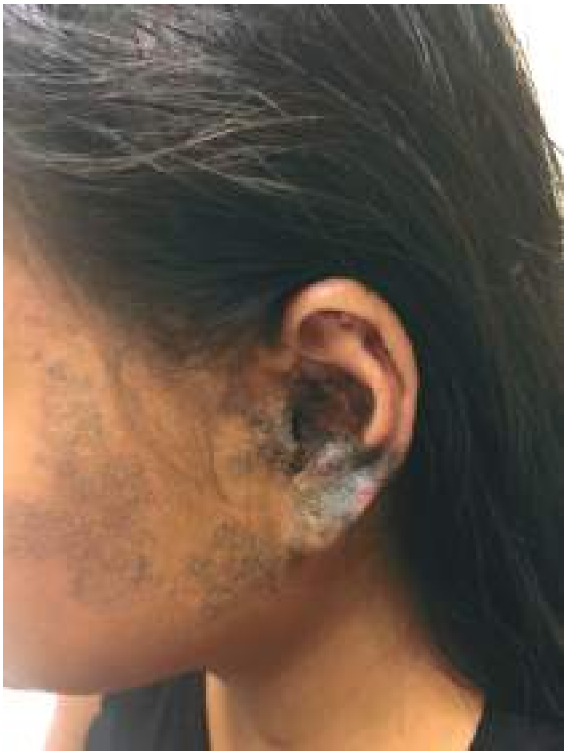
Differential Diagnosis

The differential diagnosis is broad, including drug-induced lupus, RA, systemic vasculitis, systemic sclerosis, primary APS, inflammatory myopathies, viral hepatitis, sarcoidosis, acute drug reactions, and infections or malignancies with multisystem involvement.

Treatment

Since the various manifestations of SLE affect prognosis differently and since SLE activity often waxes and wanes, drug therapy—both the choice of agents and the intensity of their use—must be tailored to match disease severity. Patients should be cautioned against sun exposure and



▲ **Figure 23–6.** Discoid lupus in the ear of a patient. (Used, with permission, from Sarah Goglin, MD.)

should apply broad-spectrum UVA/UVB sunscreen while outdoors. Mild rashes often respond to topical corticosteroids. Minor joint symptoms can usually be alleviated by NSAIDs.

Hydroxychloroquine reduces the incidence of disease flares and prolongs survival in SLE and therefore is recommended for all patients with SLE. Hydroxychloroquine is initial therapy for lupus rashes or joint symptoms. The dose of hydroxychloroquine is 200 or 400 mg/day orally and should generally not exceed 5 mg/kg/day; annual monitoring for retinal toxicity is recommended. Neuropathy and myopathy are rare adverse effects of hydroxychloroquine and may be erroneously ascribed to the underlying disease.

Corticosteroids should be used judiciously in SLE given significant long-term toxicity; they are generally not necessary for minor skin rashes, leukopenia, or the anemia associated with chronic disease. Short courses of prednisone 5–15 mg orally daily can be used to treat flares that are not life-threatening, such as rashes, serositis, or arthritis. Severe manifestations such as proliferative glomerulonephritis, myocarditis, alveolar hemorrhage, CNS involvement, and severe thrombocytopenia or hemolytic anemia all require high-dose corticosteroid treatment combined with other interventions. Methylprednisolone 250–1000 mg given intravenously over 30 minutes daily for 3 days or prednisone 40–60 mg orally is given initially. Corticosteroids should be tapered to the lowest possible dose and eventually stopped if possible (Table 30–5).

Immunosuppressive agents such as mycophenolate mofetil, azathioprine, or methotrexate are used for long-term control of disease; intravenous cyclophosphamide is usually reserved for refractory disease. Belimumab, a monoclonal antibody that inhibits the activity of a B-cell growth factor, is used for active nonrenal and renal lupus that has not responded to standard therapies (eg, antimalarials or immunosuppressive therapies) and is used to permit tapering of prednisone. Voclosporin, a novel calcineurin inhibitor, is approved to treat active lupus nephritis

Table 23–7. Major autoantibody associations in the ANA-positive rheumatic diseases.[1]

Condition	Autoantibodies	Prevalence	Notes
SLE	Anti-dsDNA	50–75%	Correlates with disease activity and lupus nephritis
	Anti-Smith	15–30%	Highly specific for SLE
	Anti-U1 RNP	30–40%	Also seen in MCTD
	Anti-ssA (Ro)	25–50%	Associated with Sjögren disease, neonatal lupus, and SCLE. Both Ro52 and Ro60 are seen in SLE; Ro60 has strong association with skin disease
	Anti-ssB (La)	10–30%	Associated with Sjögren disease and neonatal lupus
	Anti-histone	50–70%	Also seen in drug-induced SLE
Sjögren disease	Anti-ssA (Ro)	40–70%	Associated with sicca symptoms and neonatal lupus. Both Ro52 and Ro60 are seen in Sjögren disease, but Ro52 can be associated with interstitial lung disease
	Anti-ssB (La)	30–60%	Associated with sicca symptoms and neonatal lupus
Mixed connective tissue disease	Anti-U1 RNP	100%	Required to diagnose MCTD
Systemic sclerosis	Anticentromere	30–35%	Associated with limited systemic sclerosis (CREST syndrome)
	Anti-Scl-70	20–60%	Associated with diffuse systemic sclerosis and interstitial lung disease
	RNA polymerase III	< 10%	Associated with diffuse disease, renal crisis, and malignancy
Drug-induced lupus	Anti-histone	75%	Also seen in SLE

MCTD, mixed connective tissue disease.

when used in combination with mycophenolate mofetil. Anifrolumab, a type 1 interferon receptor antagonist, is approved to treat nonrenal lupus that has not responded to standard therapies, and is especially effective for severe lupus skin rashes (Table 23–4).

1. Induction therapy for lupus nephritis—A renal biopsy is recommended to confirm active disease, and urgent immunosuppression is recommended for those with active proliferative or membranous lupus nephritis on pathology. Mycophenolate mofetil (titrated up to 1000 mg or 1500 mg orally twice daily) is usually the first-line treatment for lupus nephritis and is generally given with corticosteroids to achieve disease control. Cyclophosphamide has equivalent efficacy for lupus nephritis and is usually administered using the Euro-Lupus regimen (500 mg intravenously every 2 weeks for six doses) but can also be administered according to the NIH regimen (3–6 monthly intravenous pulses [0.5–1 g/m^2]). When higher doses of cyclophosphamide are required, gonadotropin-releasing hormone analogs can be given to protect against premature ovarian failure in women. The ACR guidelines recommend combination therapy to further improve renal response either by (1) adding a calcineurin inhibitor (voclosporin or tacrolimus) to mycophenolate mofetil in patients with significant proteinuria (≥ 3 g/day) for rapid reduction of proteinuria, or (2) adding belimumab to mycophenolate mofetil or cyclophosphamide in those with lower proteinuria levels. Rituximab is usually reserved for life-threatening or organ-threatening manifestations that have not responded to the above therapies (Table 23–4).

2. Maintenance therapy for lupus nephritis—Either mycophenolate mofetil or azathioprine is typically used for maintenance therapy for lupus nephritis; patients who were induced with combination therapy using belimumab or voclosporin should generally continue these therapies for at least 1–2 years. Prednisone should be tapered to 5 mg or less by 6 months to reduce toxicity. Close follow-up is needed to watch for potential drug side effects; these agents should be administered by clinicians experienced in their use.

Course & Prognosis

Ten-year survival rates exceeding 85% are routine. In most patients, the illness has a relapsing and remitting course. However, there are some in whom the disease pursues a virulent course, leading to serious impairment of vital structures such as lungs, heart, brain, or kidneys, and the disease may lead to death. Mortality in SLE shows a bimodal pattern. In the early years after diagnosis, infections—especially with opportunistic organisms—are the leading cause of death, followed by active SLE, chiefly due to kidney or CNS disease. In later years, accelerated atherosclerosis, linked to chronic inflammation, becomes a major cause of death. Indeed, the incidence of MI is five times higher in persons with SLE than in the general population. Therefore, patients with SLE should avoid cigarette smoking and minimize other conventional risk factors for atherosclerosis.

Fertility is normal in SLE. Women are advised to pursue pregnancy under close supervision and when SLE is well-controlled and no teratogenic medications are being used. Osteoporosis is common; routine screening is recommended for those with corticosteroid exposure. Avascular necrosis of bone, affecting most commonly the hips and knees, is responsible for substantial morbidity.

When to Refer

- Appropriate diagnosis and management of SLE requires the active participation of a rheumatologist.
- The severity of organ involvement dictates referral to other subspecialists, such as nephrologists and pulmonologists.

When to Admit

- Rapidly progressive glomerulonephritis, pulmonary hemorrhage, transverse myelitis, and other severe organ-threatening manifestations of lupus usually require in-patient assessment and management.
- Severe infections, particularly in the setting of immunosuppressant therapy, should prompt admission.

DRUG-INDUCED LUPUS

ESSENTIALS OF DIAGNOSIS

- Symptomatic during exposure to offending drug; symptoms resolve after drug is stopped.
- Unlike in SLE, kidney involvement is unlikely.
- Elevated ANA but unlikely to have anti-DNA antibodies unless secondary to TNF inhibitors.

Drug-induced lupus shares several clinical and serologic features with SLE but is due to ongoing exposure to a drug and resolves when the offending drug is discontinued. In contrast to SLE, the sex ratio is nearly equal. Generally, drug-induced lupus presents with the abrupt onset of fever, arthralgia, myalgia, and serositis but not kidney involvement, neurologic symptoms, or other features of SLE. Serologic testing reveals elevated titers of antinuclear antibodies in all patients, but antibodies to DNA, Sm, RNP, SS-A, and SS-B are rare. Antibodies to histones occur in up to 95% of patients but are also seen in SLE and thus do not distinguish drug-induced lupus from SLE. Complement levels are usually normal. The list of drugs implicated as possible causes of drug-induced lupus is extensive. There are definite associations between the development of drug-induced lupus and the use of hydralazine, isoniazid, and minocycline as well as several less commonly prescribed drugs (procainamide, methyldopa, chlorpromazine). The incidence of drug-induced lupus in patients taking hydralazine for a year or longer is as high as 5–8%; for most other medications, the risk is considerably lower (< 1%). TNF inhibitors can induce antibodies to DNA but usually not anti-histone antibodies; the incidence of lupus-like syndromes resulting from these medications is low (0.5–1%). Drug-induced lupus generally resolves within weeks to months after discontinuing the offending agent.

Subacute cutaneous lupus (SCLE) is a distinct entity and drug-induced in more than one-third of patients. Hydrochlorothiazide is a common cause of SCLE; antifungals (terbinafine), PPIs, antihypertensives (calcium channel blockers, ACE inhibitors), and TNF inhibitors also have been implicated.

ANTIPHOSPHOLIPID SYNDROME

ESSENTIALS OF DIAGNOSIS

- Hypercoagulability; recurrent arterial or VTE.
- Thrombocytopenia is common.
- Recurrent or late fetal loss.
- Anticoagulation with warfarin is recommended over DOACs.

General Considerations

APS can occur alone or in association with other autoimmune diseases such as SLE. The clinical features of APS are venous or arterial occlusions or certain pregnancy complications. Patients have at least one of the following three antiphospholipid antibodies: anticardiolipin antibodies, antibodies to β-2-glycoprotein 1, and lupus anticoagulant.

Catastrophic APS occurs in < 1% of patients with antiphospholipid antibodies. This potentially devastating syndrome leads to diffuse thromboses, thrombotic microangiopathy, and multiorgan system failure. Catastrophic APS has a mortality rate approaching 50%. Triggers of catastrophic APS include infections, surgery, use of estrogen-containing medications, autoimmune disease flares, and discontinuation of anticoagulation.

Clinical Findings

A. Symptoms and Signs

APS can cause thrombotic, microvascular, hematologic, and obstetric complications. Thrombotic events may occur in either the arterial or venous circulations. DVT, PE, and cerebrovascular accidents are typical thrombotic events. Budd-Chiari syndrome, cerebral sinus vein thrombosis, myocardial or digital infarctions, hemorrhagic infarction of the adrenal glands (due to adrenal vein thrombosis), and other thrombotic events also occur. Thrombocytopenia is common in APS. Thromboses can also involve the microvascular circulation, leading to livedo racemosa or vasculopathy, microangiopathic nephropathy, and pulmonary hemorrhage. Cardiac valvular thickening or vegetations can also occur. Obstetric manifestations include ≥ 3 consecutive pregnancy losses before 10 weeks' gestation, fetal deaths between 16–33 weeks' gestation in the absence of preeclampsia or placental insufficiency, or severe preeclampsia or placental insufficiency occurring before 34 weeks with or without fetal death.

The ACR and the EULAR have revised the classification of APS by assigning scores to the results of assay tests and clinical findings; these criteria highlight the far-ranging manifestations of the syndrome and the need to consider APS in the broad spectrum of differential diagnoses (Table 23–8).

B. Laboratory Findings

Thrombocytopenia occurs in 22–42% of patients and is usually moderate (platelet counts > 50,000/mcL [50×10^9/L]). The presence of thrombocytopenia does not reduce the risk of thrombosis.

Three types of antiphospholipid antibodies are associated with this syndrome: (1) IgG or IgM anticardiolipin antibodies, (2) IgG or IgM antibodies to β-2-glycoprotein, and (3) "lupus anticoagulant" that prolongs certain phospholipid-dependent coagulation tests (see below). APS testing is generally done shortly after an event, followed by confirmatory testing after 12 weeks to ensure the antibody was not transient. Anticardiolipin antibodies can produce a biologic false-positive test for syphilis (ie, a positive rapid plasma reagin but negative specific anti-treponemal assay). In general, IgG anticardiolipin antibodies are believed to be more pathologic than IgM. For women younger than 50 years in whom a thrombotic stroke developed, the odds ratio for having the lupus anticoagulant is 43.1. Presence of the lupus anticoagulant is a stronger risk factor for thrombosis or pregnancy loss than is the presence of antibodies to either β_2-glycoprotein 1 or anticardiolipin. A clue to the presence of a lupus anticoagulant, which may occur in individuals who do not have SLE, is prolongation of the partial thromboplastin time (which, paradoxically, is associated with a thrombotic tendency rather than a bleeding risk). Tests for the lupus anticoagulant use phospholipid-dependent functional assays of coagulation, such as the Russell viper venom time (RVVT).

Differential Diagnosis

Other genetic or acquired conditions associated with hypercoagulability such as protein C, protein S, or antithrombin deficiency and factor V Leiden should be excluded. Myeloproliferative cancers, heparin-induced thrombocytopenia, and paroxysmal nocturnal hemoglobinuria are additional considerations. Catastrophic APS has a broad differential, including sepsis, pulmonary-renal

Table 23–8. Criteria for the diagnosis of APS.[1]

Clinical Criteria	Score[2]
Macrovascular	
VTE with high risks for VTE (eg, active malignancy, hospital admission/immobilization, major trauma, obesity, surgery, severe infection, hormonal therapy)	1
VTE without high risks	3

Preeclampsia with severe features (< 34 weeks’ gestation) ***or*** placental insufficiency with severe features (< 34’ weeks gestation) ± fetal death	3
Preeclampsia with severe features (< 34 weeks’ gestation) ***and*** placental insufficiency with severe features (< 34 weeks’ gestation) ± fetal death	4
Cardiac Valve	
Thickening present	2
Vegetations present	4
Hematology	
Thrombocytopenia (lowest 20–130 × 10^9/L)	2
Laboratory Criteria for aPL Tests[3]	
Lupus anticoagulant test Positive (once) Positive (persistent)	 1 5
Anticardiolipin antibody ELISA and/or anti-β_2-glycoprotein-1 antibody Moderate or high positive (IgM) Moderate or positive (IgG) High positive (IgG) High positive (IgG)	 1 4 5 7

[1] When considering the diagnosis of APS, an aPL test needs to be positive within 3 years of the appearance of at least one clinical criterion.

[2] **Scoring:** A diagnosis of APS requires a total of 6 points: 3 points from laboratory criteria for the aPL tests **and** 3 points from clinical criteria.

Use only the highest point value in category if > one criteria applies.

[3] aPL tests are the lupus anticoagulant test, or moderate to high titers of anticardiolipin or anti-β 2-glycoprotein-I antibodies (IgG or IgM).

aPL, antiphospholipid antibody; APS, antiphospholipid syndrome.

syndromes, systemic vasculitis, disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura.

Treatment

Patients who have positive anti-phospholipid antibodies but no history of the clinical events described above should not be treated with anticoagulation.

1. Thrombotic APS—Most individuals with either macro- or microvascular thrombosis require lifelong anticoagulation with warfarin to maintain an INR of 2.0–3.0. DOACs are not recommended because they are less effective than warfarin in APS, especially for arterial thromboses. Patients who have recurrent thrombotic events while taking warfarin may require higher INRs (≥ 3.0), but the bleeding risk increases substantially with this degree of anticoagulation; LMW heparin is used in patients who have thrombotic events while taking warfarin despite INRs being in the therapeutic range.

2. Pregnancy-associated APS—The combination of prophylactic doses of low-molecular-weight heparin (Table 16–14) and low-dose aspirin (81 mg) is the usual approach to prevent pregnancy complications. In pregnant patients with a history of thrombotic events outside of pregnancy, full-dose low-molecular-weight heparin is administered (Table 16–16). Anticoagulation for thromboprophylaxis is typically continued through pregnancy and the early postpartum period; the use of corticosteroids and intravenous immunoglobulin in these patients is not recommended.

3. Catastrophic APS—Either intravenous immunoglobulin or plasmapheresis *plus* intravenous heparin and high doses of corticosteroids are administered for this disorder. Resistant disease may require B-cell depletion (rituximab) or complement component C5 inhibitors (eculizumab), although data to support these therapies are limited to case series (Table 23–4).

RAYNAUD PHENOMENON

ESSENTIALS OF DIAGNOSIS

- Paroxysmal bilateral digital pallor and cyanosis followed by rubor.
- Precipitated by cold or emotional stress; relieved by warmth.
- **Primary form:** benign course; usually affects young women.
- **Secondary form:** more severe, sometimes causing digital ulceration or gangrene.

General Considerations

Raynaud phenomenon (RP) is a syndrome of paroxysmal digital ischemia, most commonly caused by an exaggerated response of digital arterioles to cold or emotional stress. The initial phase of RP, mediated by excessive vasoconstriction, consists of well-demarcated digital pallor or cyanosis; the subsequent (recovery) phase of RP, caused by vasodilation, leads to intense hyperemia and rubor. Although RP chiefly affects fingers, it can also affect toes and other acral areas such as the nose and ears. RP is classified as primary (idiopathic or Raynaud disease) or secondary. Nearly one-third of the population reports being "sensitive to the cold" but does not experience the paroxysms of digital pallor, cyanosis, and erythema characteristic of RP. Primary RP occurs in 2–6% of adults, is especially common in young women, and poses more of a nuisance than a threat to good health. In contrast, secondary RP is less common, is chiefly associated with rheumatic diseases (especially systemic sclerosis), and can be severe enough to cause digital ulceration or gangrene.

Clinical Findings

Early in the course of RP, only one or two fingertips may be affected; as it progresses, all fingers down to the distal palm may be involved. The thumbs are rarely affected. During recovery there may be intense rubor, throbbing, paresthesia, pain, and slight swelling. Attacks usually terminate spontaneously or upon returning to a warm room or putting the extremity in warm water. The patient is usually asymptomatic between attacks. Sensory changes that often accompany vasomotor manifestations include numbness, tingling, diminished sensation, and aching pain.

Primary RP appears more commonly in women between ages 15 and 30, symmetrically involving the fingers of both hands, unlike secondary RP (which may be unilateral and may involve only one or two fingers). It tends to be mildly progressive. Spasm becomes more frequent and prolonged. Unlike secondary RP, primary RP does not cause digital pitting, ulceration, or gangrene.

Nailfold capillary abnormalities are among the earliest clues of secondary rather than primary RP. The nailfold capillary pattern can be visualized by placing a drop of grade B immersion oil at the patient's cuticle and then viewing the area with an ophthalmoscope set to 40 diopters; handheld dermatoscopes also can be used. Dropout of capillaries and dilation of the remaining capillary loops indicate a secondary form of RP, most commonly systemic sclerosis. While highly specific for secondary RP, nailfold capillary changes have a low sensitivity. Digital pitting or ulceration or other abnormal physical findings (eg, skin tightening, loss of extremity pulse, rash, swollen joints) provides evidence of secondary RP.

Primary RP must be differentiated from the numerous causes of secondary RP (Table 23–9). The history and examination may suggest the diagnosis of systemic sclerosis, SLE, RA, or mixed connective tissue disease; RP is often the first manifestation of limited systemic sclerosis (CREST syndrome). The diagnosis of many of these rheumatic diseases is supported with specific serologic tests.

Miscellaneous
Atherosclerosis
Embolic disease
Migraine
Sequela of frostbite

[1] Listed in descending order of frequency.

RP may occur with thoracic outlet syndromes; involvement is generally unilateral, and symptoms referable to brachial plexus compression tend to dominate the clinical picture. Carpal tunnel syndrome should also be considered, and nerve conduction tests are appropriate in selected cases.

Occupations that involve chronic vibration exposure of digits (eg, construction) can result in RP.

Differential Diagnosis

The differentiation from Buerger disease (thromboangiitis obliterans) is usually not difficult, since thromboangiitis obliterans is generally a disease of men, particularly those who smoke cigarettes; peripheral pulses are often diminished or absent; and, when RP occurs in association with thromboangiitis obliterans, it is usually in only one or two digits.

In acrocyanosis, cyanosis of the hands is permanent and diffuse; the sharp and paroxysmal line of demarcation with pallor does not occur with acrocyanosis. Frostbite may lead to chronic RP. Patients with peripheral neuropathy or complex regional pain syndrome can also have vasomotor symptoms.

RP may be mimicked by type I cryoglobulinemia, usually associated with plasma cell myeloma or with lymphoproliferative disorders, in which a monoclonal antibody cryoprecipitates in the cooler distal circulation.

Treatment

A. General Measures

Keeping the body warm is a cornerstone of initial therapy. Patients should wear gloves or mittens whenever in temperatures that precipitate attacks. Warm shirts, coats, and hats will help prevent the exaggerated vasospasm that causes RP and that is not prevented by warming only the hands. The hands should be protected from injury at all times; wounds heal slowly, and infections are consequently hard to control. Softening and lubricating lotion to control fissured dry skin should be applied to the hands frequently. Cigarette smoking should be stopped, and sympathomimetic drugs (eg, decongestants and amphetamines) should be avoided. For most patients with primary RP, general measures alone are sufficient to control symptoms. Medical or surgical therapy should be considered in patients who have severe symptoms or are experiencing tissue injury from digital ischemia.

B. Medications

Calcium channel blockers are first-line therapy for RP. Calcium channel blockers produce a modest benefit and are more effective in primary RP than secondary RP. Slow-release nifedipine (30–120 mg/day orally), amlodipine (5–20 mg/day orally), felodipine, isradipine, and nisoldipine are more effective than verapamil, nicardipine, and diltiazem. In patients with severe, secondary RP refractory to calcium channel blockers, phosphodiesterase inhibitors (eg, sildenafil, tadalafil, and vardenafil) can be added or substituted. Additional therapies include angiotensin II receptor blockers, topical nitrates, or SSRIs (fluoxetine). Bosentan, an endothelin receptor antagonist, can be effective for those with digital ulcerations. Severe or refractory episodes of RP in which there is a threat of digital loss may require treatment with intravenous prostacyclin or prostacyclin analogs (eg, epoprostenol, iloprost, treprostinil).

C. Procedures

Digital sympathectomy may be indicated when ischemia is progressive and other medical measures have failed. RCTs of botulinum toxin injection have not demonstrated efficacy.

Prognosis

Primary RP is benign but bothersome for individuals who are exposed to cold climates or excessive air conditioning. The prognosis of secondary RP depends on the underlying disease; unfortunately, severe pain from ulceration and gangrene is not rare with systemic sclerosis.

When to Refer

Appropriate management of patients with secondary RP often requires consultation with a rheumatologist.

When to Admit

Patients with critical digital ischemia as evidenced by severe pain and demarcation should be admitted for intensive therapy.

SYSTEMIC SCLEROSIS (Scleroderma)

ESSENTIALS OF DIAGNOSIS

- **Limited disease** (CREST syndrome): skin thickening confined to face, neck, and distal extremities.
- **Diffuse disease** (20%): widespread thickening of skin, with areas of increased pigmentation and depigmentation.
- Raynaud phenomenon and antinuclear antibodies are present in virtually all patients.
- **Systemic features:** gastroesophageal reflux, GI hypomotility, pulmonary fibrosis, pulmonary hypertension, renal involvement.

General Considerations

Systemic sclerosis is a rare chronic disorder characterized by diffuse fibrosis of the skin and internal organs. Symptoms usually appear in the third to fifth decades, and women are affected two to three times as frequently as men.

Two forms of systemic sclerosis are generally recognized: limited (80% of patients) and diffuse (20%). Limited or diffuse systemic sclerosis refers specifically to the amount of skin involvement. Both can have multisystem internal organ involvement. In general, patients with limited systemic sclerosis have better outcomes than those with diffuse disease, largely because life-threatening lung or kidney disease is less common. Pulmonary hypertension is more characteristic of limited systemic sclerosis.

Clinical Findings

A. Symptoms and Signs

1. Limited systemic sclerosis—Raynaud phenomenon is usually the initial manifestation and can precede other symptoms by years. Often there is one or more features of the CREST syndrome (calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia). Hardening of the skin (scleroderma) is limited to the face, neck, and skin distal to the elbows and knees. A small group of patients do not have skin hardening (scleroderma-sine scleroderma). Patients with limited disease are more susceptible to digital ischemia, leading to finger loss, and to life-threatening pulmonary hypertension than are patients with diffuse disease. Small and large bowel hypomotility can cause constipation alternating with diarrhea, malabsorption due to bacterial overgrowth, pseudo-obstruction, and severe bowel distention with rupture. Dysphagia and symptoms of reflux due to esophageal dysfunction are common and result from abnormalities in motility and later from fibrosis. Fibrosis and atrophy of the GI tract cause hypomotility. Large-mouthed diverticula occur in the jejunum, ileum, and colon.

2. Diffuse systemic sclerosis—Polyarthralgia, weight loss, and malaise are common early features of diffuse systemic sclerosis but are infrequent in limited disease. The skin changes of diffuse disease can involve the trunk and proximal extremities, in contrast to limited disease. Cutaneous disease usually, but not always, develops before visceral involvement and can manifest initially as non-pitting subcutaneous edema associated with pruritus. With time the skin becomes thickened and hidebound, with loss of normal folds. Telangiectasia, pigmentation, and depigmentation are characteristic. Ulceration of the fingertips and subcutaneous calcification are seen. Tendon friction rubs over the forearms and shins occur uniquely (but not universally) in diffuse systemic sclerosis. Pulmonary fibrosis and pulmonary vascular disease are reflected in restrictive lung physiology and low diffusing capacities. Cardiac abnormalities include pericardial effusions, heart block, myocardial fibrosis, and right HF secondary to pulmonary hypertension. GI manifestations, such as those seen in limited disease, are common. Scleroderma renal crisis, resulting from intimal proliferation of smaller renal arteries and usually associated with acute-onset hypertension and kidney injury, is a life-threatening emergency. Many cases can be treated effectively with ACE inhibitors.

B. Laboratory Findings

Mild anemia is often present. In renal crisis, the peripheral blood smear shows findings consistent with a microangiopathic hemolytic anemia (due to mechanical damage to red cells from diseased small vessels). Mild proteinuria, usually < 2 grams per 24 hours, with few cells or casts can occur in those with renal crisis. Antinuclear antibody tests are nearly always positive, frequently in high titers. The scleroderma antibody (anti-SCL-70), directed against topoisomerase III, is found in one-third of patients with diffuse systemic sclerosis and in 20% of those with limited disease. Anti-SCL-70 antibodies portend a poor prognosis, with a high likelihood of serious internal organ involvement (eg, interstitial lung disease). Anticentromere antibodies are seen in 50% of those with limited systemic sclerosis. Anticentromere antibodies are highly specific for limited systemic sclerosis, but they also occur occasionally in overlap syndromes. Anti-RNA polymerase III antibodies develop in 10–20% of systemic sclerosis patients overall and are associated with rapidly progressive skin disease, renal crisis, and a higher risk of concomitant solid cancers, especially lung and breast cancers (Table 23–7).

C. Special Examinations

Patients should receive pulmonary function testing, HRCT of the chest, and echocardiography at regular intervals to assess cardiopulmonary involvement.

Differential Diagnosis

Early in its course, systemic sclerosis can cause diagnostic confusion with other causes of Raynaud phenomenon, particularly SLE, mixed connective tissue disease, and the inflammatory myopathies. Scleroderma, which is often associated with diabetes or infection, is characterized by skin thickening of the posterior neck, shoulders, and upper back; however, this condition spares the fingers. Eosinophilic fasciitis is a rare disorder presenting with skin hardening that resembles diffuse systemic sclerosis. The inflammatory abnormalities, however, are limited to the fascia rather than the dermis and epidermis. Moreover, patients with eosinophilic fasciitis are distinguished from those with systemic sclerosis by the presence of peripheral blood eosinophilia, the absence of Raynaud phenomenon, a good response to prednisone, and an association (in some cases) with paraproteinemias. Diffuse skin thickening and visceral involvement are features of scleromyxedema; the presence of a paraprotein, the absence of Raynaud phenomenon, and distinct skin histology point to scleromyxedema. Diabetic cheiroarthropathy typically develops in longstanding, poorly controlled diabetes mellitus and can mimic sclerodactyly. Morphea and linear scleroderma cause sclerodermatous changes limited to circumscribed areas of the skin and usually have excellent outcomes.

Treatment

Treatment of diffuse and limited systemic sclerosis focuses on the organ systems involved. Although there is no effective therapy for the underlying disease process, interventions for management of specific organ manifestations have improved substantially. There is little or no role for prednisone in the treatment of systemic sclerosis except in patients with debilitating symptoms that cannot be controlled with other therapies, such as severe myositis or inflammatory arthritis. Doses higher than 15 mg daily have been associated with scleroderma renal crisis. Treatment for Raynaud phenomenon is discussed above.

1. Skin disease—For significant skin involvement, methotrexate (titrated up to 15 or 20 mg orally once weekly) or mycophenolate mofetil (titrated up to 2000 or 3000 mg orally daily), started as early as possible in the disease course, can be modestly effective. Intravenous immunoglobulin, rituximab, and tocilizumab are additional options for refractory disease. The choice of therapy is often driven by other disease manifestations. For example, in patients with arthritis, methotrexate is preferred, while in those with interstitial lung disease, mycophenolate mofetil, rituximab, or tocilizumab is preferred (Table 23–4).

2. Renal crisis—The hypertensive crises in scleroderma renal crisis must be treated urgently and aggressively (in the hospital) with ACE inhibitors, eg, captopril, initiated at 25 mg orally every 6 hours and titrated up as tolerated to a maximum of 100 mg every 6 hours.

3. GI disease—Esophageal reflux can be reduced and the risk of scarring diminished by avoiding late-night meals and using PPIs (eg, omeprazole, 20–40 mg orally once or twice daily), which achieve near-complete inhibition of gastric acid production and are effective for refractory esophagitis. Patients with delayed gastric emptying maintain their weight better if they eat small, frequent meals and remain upright for at least 2 hours after eating. Oral prokinetic agents such as metoclopramide (10 mg four times daily) can improve dysphagia caused by esophageal hypomotility. Erythromycin (250 mg three times daily) can be used if prokinetic agents fail. Malabsorption due to bacterial overgrowth responds to antibiotics, eg, rifaximin, 550 mg three times orally daily, often prescribed cyclically.

4. Lung disease—For patients who require treatment for interstitial lung disease, mycophenolate mofetil (1000–1500 mg orally twice daily) can improve dyspnea and pulmonary function tests modestly. Cyclophosphamide has some efficacy but greater toxicity; this drug should be administered only by physicians familiar with its use. The IL-6 inhibitor tocilizumab slows the rate of decline in pulmonary function and may be used as an alternative for patients who cannot tolerate mycophenolate mofetil. In patients who do not respond to or cannot take mycophenolate or cyclophosphamide, nintedanib (an inhibitor of multiple tyrosine kinases) can slow the progression of systemic sclerosis–associated lung disease and is FDA-approved for this indication. However, the optimal timing and duration of treatment with nintedanib remain under investigation. Azathioprine and rituximab are additional options for treatment of systemic sclerosis–associated lung disease (Table 23–4). Lung transplantation has favorable outcomes in eligible patients.

5. Pulmonary hypertension—Treatment of pulmonary hypertension in systemic sclerosis is largely extrapolated from general trials of pulmonary hypertension. Therapies include calcium channel blockers (amlodipine, nifedipine, extended-release diltiazem), phosphodiesterase type 5 inhibitors (sildenafil, tadalafil), a guanylate cyclase stimulant (riociguat), TGF-β signaling modulator (sotatercept), and endothelin receptor antagonists (bosentan, ambrisentan, macitentan); combinations of two or more drugs from these categories are commonly used. Refractory pulmonary hypertension may require prostacyclin pathway agonists (epoprostenol, treprostinil, iloprost, selexipag) or lung transplantation.

6. Joint and muscle disease—Arthralgias and myalgias commonly occur, and patients can initially try NSAIDs or acetaminophen. Hydroxychloroquine or methotrexate can be used for inflammatory arthritis, while biologic drugs typically used for RA can be used for refractory disease. Significant inflammatory myositis may initially respond to low-dose prednisone or methotrexate; severe cases require therapies for immune-mediated inflammatory myositides.

Prognosis

The 10-year survival rate in systemic sclerosis averages approximately 70%. Lung disease—pulmonary fibrosis or pulmonary arterial hypertension—is the leading cause of mortality. Persons in whom severe internal organ involvement does not develop in the first 3 years have a substantially better prognosis. Small studies conducted in patients with simultaneous onset of cancer and systemic sclerosis have demonstrated that the disease developed due to an immune response directed at the cancer.

When to Refer

- Appropriate management of systemic sclerosis requires frequent consultations with a rheumatologist.
- Severity of organ involvement dictates referral to cardiologists, pulmonologists, gastroenterologists, or nephrologists.

When to Admit

- Critical digital ischemia, severe pulmonary hypertension or interstitial lung disease with cardiopulmonary compromise, renal crisis.
- Serious GI manifestations such as bowel obstruction, GI bleeding, or severe malabsorption.

IMMUNE-MEDIATED INFLAMMATORY MYOPATHIES

ESSENTIALS OF DIAGNOSIS

- Progressive muscle weakness.
- **Dermatomyositis:** characteristic cutaneous manifestations (Gottron papules, heliotrope rash); increased risk of malignancy.
- Elevated creatine kinase, myositis-specific antibodies, diagnostic muscle biopsy.
- Mimics include infectious, metabolic, or drug-induced myopathies.

General Considerations

Immune-mediated inflammatory myopathies are categorized by muscle symptoms and associated autoantibodies. They include antisynthetase syndromes, dermatomyositis, polymyositis, myositis resulting from a rheumatic disease or overlap syndrome, inclusion body myositis (IBM), and immune-mediated necrotizing myopathy. These disorders are characterized by progressive muscle weakness, and most demonstrate an inflammatory infiltrate in muscle tissue.

Antisynthetase syndromes, dermatomyositis, and polymyositis are systemic disorders of unknown cause whose principal manifestation is muscle weakness. Although their clinical presentations (aside from the presence of certain skin findings in dermatomyositis, some of which are pathognomonic) and treatments are similar, the diseases are distinct. They affect persons of any age group, but the peak incidence is in the fifth and sixth decades of life and women are affected twice as commonly as men. There is an increased risk of malignancy in dermatomyositis but not in antisynthetase syndromes. Up to one patient in four with dermatomyositis has an occult malignancy. Malignancies may be evident at the time of presentation with muscle disease or may not be detected until months after diagnosis. The malignancies most commonly associated with dermatomyositis are lung, ovarian, breast, colorectal, cervical, bladder, nasopharyngeal, esophageal, pancreatic, and renal. Patients may have skin disease without overt muscle involvement, a condition termed dermatomyositis sine myositis (or amyopathic dermatomyositis); these patients can have aggressive interstitial lung disease. Polymyositis has become a rarer diagnosis as many cases previously attributed to it are now identified as conditions such as immune-mediated necrotizing myopathy and overlap syndromes. Myositis may overlap with other connective tissue diseases, especially systemic sclerosis, SLE, mixed connective tissue disease, and Sjögren disease.

IBM affects older men and is characterized by more distal weakness in the upper extremities and is generally less symmetric. Immune-mediated necrotizing myopathies include those associated with the signal recognition particle or with anti-3-hydroxy-3-methylglutaryl coenzyme A reductase (anti-HMGCR) autoantibodies, often in the setting of statin use. This latter entity is distinct from the more common statin-induced myopathy, which occurs in about 1% of statin users. Unlike anti-HMGCR necrotizing myopathy, statin-induced myopathy generally resolves within 6 months of drug discontinuation.

Clinical Findings

A. Symptoms and Signs

1. Antisynthetase syndrome—Presenting symptoms are muscle weakness, particularly of the proximal muscles. Weakness can range from mild to severe. Constitutional symptoms are common. Other clinical findings include inflammatory nonerosive arthritis, fever, Raynaud phenomenon, “mechanic’s hands” (hyperkeratosis along the radial and palmar aspects of the fingers), interstitial lung disease, and specific autoantibodies (eg, antibodies to Jo-1, PL-7, PL-12, EJ, OJ, Zo, Ks, Ha, or Ly).

2. Dermatomyositis—Most patients experience symmetric, proximal muscle weakness. There is a characteristic dusky red rash which may appear in a malar distribution, mimicking the classic rash of SLE. Facial erythema beyond the malar distribution (crossing the nasolabial fold) is characteristic of dermatomyositis. Erythema also occurs over other areas of the face, neck, shoulders, and upper chest and back (“shawl sign”). Periorbital edema and a purplish (heliotrope) suffusion over the eyelids are typical signs. Coloration of the heliotrope and other rashes of dermatomyositis can be affected by skin tone. In Black persons, the rashes may appear more hyperpigmented than erythematous or violaceous (Figure 23–7). Periungual

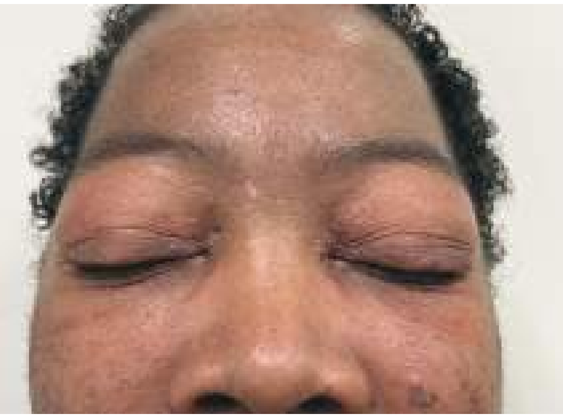

Figure 23–7. Heliotrope rash in a patient who has anti-NXP2 dermatomyositis. (Used, with permission, from Rebecca L. Manno, MD.)

erythema, dilations of nailfold capillaries, Gottron papules (raised violaceous lesions overlying the dorsa of DIP, PIP, and MCP joints), and Gottron sign (erythematous rash on the extensors surfaces of the fingers, elbows, and knees) are highly suggestive of dermatomyositis. Scalp involvement by dermatomyositis may mimic psoriasis and intense scalp pruritus is common. Infrequently, the cutaneous findings of this disease precede the muscle inflammation by weeks or months. Autoantibodies seen in dermatomyositis include anti-Mi2, anti-TIF-1-γ, anti-NXP2, and anti-MDA5. Each of these autoantibodies is associated with specific clinical features. For example, anti-TIF1-γ and anti-NXP2 are strongly associated with malignancy, while anti-MDA5 is associated with punched-out skin ulcerations and rapidly progressive lung disease (Table 23–10).

3. Polymyositis—With current diagnostic testing, many cases previously labeled as polymyositis are now attributed to more precisely defined myositis subtypes. Therefore, other diagnoses, including IBM, immune-mediated necrotizing myopathy, and overlap syndromes should be considered in patients presenting with progressive, symmetrical, proximal muscle weakness without significant skin involvement and negative antibody testing.

4. Inclusion body myositis—IBM is a common cause of misdiagnosed "treatment-resistant polymyositis." The typical patient is a man over the age of 50 years. The onset of IBM is more insidious than that of dermatomyositis (ie, occurring over years rather than months) and is characterized by asymmetric distal motor weakness (especially the wrists and hands). Dysphagia occurs in up to half of patients. Foot-drop from anterior leg muscle weakness can occur. Creatine kinase levels are often minimally elevated and are normal in 25%. Electromyography may show a mixed picture of myopathic and neurogenic abnormalities. The disease is associated with antibodies to cytoplasmic 5′-nucleotidase 1A (cN1A). IBM is unlikely to respond to immunosuppressive therapy.

5. Immune-mediated necrotizing myopathy—This myopathy is characterized by the presence of muscle necrosis. Autoantibodies aid in diagnosis; anti-SRP antibodies are associated with severe muscle weakness, pain, and cardiac involvement. Anti-HMGCR antibodies usually, but not always, occur in the setting of statin use and are associated with profound proximal muscle weakness and marked creatine kinase elevations. Many patients have a severe and unrelenting disease course with persistent weakness, unlike other statin-induced myopathies.

Table 23–10. Myositis-specific antibodies.

Antibody	Clinical Association
Anti-Jo-1, PL-7, PL-12, EJ, OJ	Myositis with antisynthetase syndrome; no increased malignancy risk
Anti-Mi-2	Dermatomyositis with rash more than myositis, good prognosis
Anti-MDA5 (anti-CADM 140)	Dermatomyositis with rapidly progressive lung disease, cutaneous ulcers
Anti-TIF-1 (p155/140)	Dermatomyositis with severe skin manifestations, cancer-associated
Anti-NXP-2	Dermatomyositis with subcutaneous edema, calcinosis, severe muscle weakness, cancer-associated
Anti-SAE	Dermatomyositis with rash and high prevalence of dysphagia, cancer-associated
Anti-SRP	Severe, acute necrotizing myopathy with more cardiac involvement
Anti-HMG-CoA reductase	Necrotizing myopathy related to statin use
PM-Scl, Ro, Ku, U 1-3 RNP	Polymyositis/dermatomyositis overlap syndromes
Anti-cN1A	Inclusion body myositis

MDA5, melanocyte differentiation-associated protein 5; SRP, signal recognition particle

B. Laboratory Findings

Measurement of serum levels of muscle enzymes, especially creatine kinase and aldolase, is useful in diagnosis and in assessment of disease activity. Inflammatory myositis can be misdiagnosed as hepatitis because of elevations in serum levels of muscle-derived ALT and AST levels. Anemia is uncommon. The ESR and CRP are often normal and are not reliable indicators of disease activity. Rheumatoid factor is found in a minority of patients. Antinuclear antibodies can be present, especially when there is an associated connective tissue disease. A number of autoantibodies are seen exclusively in patients with myositis and are associated with distinctive clinical features (Table 23–10). CXRs are usually normal unless there is associated interstitial lung disease. Electromyographic abnormalities can point toward a myopathic, rather than a neurogenic, cause of weakness. MRI can detect early and patchy muscle involvement, can guide biopsies, and often is more useful than electromyography for diagnosis. MRI can also determine the extent of fatty replacement in the muscle, a consequence of long-standing severe disease. The search for an occult malignancy should begin with a history and physical examination, a CBC, comprehensive biochemical panel, UA, and age- and risk-appropriate cancer screening tests. Given the especially strong association of ovarian carcinoma and dermatomyositis, transvaginal ultrasonography, CT scanning, and CA-125 levels may be useful in women. No matter how extensive the initial screening, some malignancies will not become evident for months after the initial presentation of the myopathy.

C. Biopsy

Biopsy of clinically involved muscle is often required if patients do not have characteristic dermatomyositis rashes or myositis-specific antibodies. In dermatomyositis, the cellular infiltrate is mostly perifascicular and perivascular, while in polymyositis, the inflammatory infiltrate involves the fascicle itself. Myofiber HLA-DR expression can be diagnostic of antisynthetase myopathy. Necrosis with a paucity of inflammatory cells suggests an immune-mediated necrotizing myopathy. Muscle biopsy in IBM shows characteristic intracellular rimmed vacuoles by light microscopy and either tubular or filamentous inclusions in the nucleus or cytoplasm by electron microscopy. False-negative muscle biopsies sometimes occur in these disorders because of the patchy distribution of pathologic abnormalities and the absence of the primary inflammatory infiltrate from immunosuppression. Skin biopsy in dermatomyositis will show interface dermatitis and is indistinguishable pathologically from lupus.

Differential Diagnosis

Muscle inflammation may occur as a component of SLE, systemic sclerosis, Sjögren disease, and overlap syndromes. In those cases, associated findings usually permit the precise diagnosis of the primary condition.

Hypothyroidism is a common cause of proximal muscle weakness associated with elevations of serum creatine kinase. Hyperthyroidism and Cushing disease may both be associated with proximal muscle weakness with normal levels of creatine kinase. Patients with polymyalgia rheumatica are over the age of 50 and—in contrast to patients with polymyositis—have pain but no objective weakness; creatine kinase levels are normal. Disorders of the peripheral nervous system and CNS (eg, chronic inflammatory polyneuropathy, multiple sclerosis, myasthenia gravis, Lambert-Eaton disease, and amyotrophic lateral sclerosis) can produce weakness but are distinguished by characteristic symptoms and neurologic signs and often by distinctive electromyographic abnormalities. Muscle weakness associated with some systemic vasculitides (polyarteritis nodosa, microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis, granulomatosis with polyangiitis, and mixed cryoglobulinemia) is typically distal and asymmetric (such as mononeuritis multiplex), at least in the early stages.

Limb-girdle muscular dystrophy can present in early adulthood with a clinical picture that mimics polymyositis: proximal muscle weakness, elevations in serum creatine kinase, and inflammatory cells on muscle biopsy.

Many drugs, including corticosteroids, alcohol, clofibrate, penicillamine, tryptophan, and hydroxychloroquine, can produce proximal muscle weakness. Long-term use of colchicine, even as low as 0.6 mg per day in patients with moderate CKD, can produce a mixed neuropathy-myopathy that mimics polymyositis. Weakness and muscle enzyme elevation reverse with cessation of the drug. HIV-associated myopathy can cause proximal weakness, elevated muscle enzymes, and an inflammatory muscle infiltrate; antiretroviral therapy can result in mitochondrial myopathy presenting as weakness, myalgias, and fatigue.

Statins can cause myalgias, myopathy, and rhabdomyolysis, in addition to the anti-HMGCR myopathy described above. Although only about 0.1% of patients taking a statin drug alone develop myopathy, concomitant administration of other drugs (especially nirmatrelvir with ritonavir [Paxlovid], gemfibrozil, cyclosporine, niacin, macrolide antibiotics, azole antifungals, and protease inhibitors) increases the risk.

The use of immune checkpoint inhibitors to treat cancer can cause rheumatic and musculoskeletal symptoms, including myalgia and myositis.

Treatment

Most patients with immune-mediated inflammatory myopathy respond to corticosteroids. Initially, prednisone, 40–60 mg or more orally daily is often required. The dose is then adjusted downward while monitoring muscle strength and serum levels of muscle enzymes. Long-term use of corticosteroids is often needed, and the disease may recur when they are withdrawn. Patients with an associated neoplasm have a poor prognosis, although remission may follow treatment of the tumor; corticosteroids may or may not be effective in these patients. Immunosuppressive drugs like methotrexate (15–25 mg orally or subcutaneous weekly), azathioprine (1.5–2 mg/kg orally once daily), or mycophenolate mofetil (1–1.5 g orally twice daily) are often started to reduce cumulative corticosteroid exposure. Intravenous immunoglobulin, an FDA-approved therapy for dermatomyositis, is highly effective for skin, muscle and interstitial lung disease associated with immune-mediated inflammatory myopathies. Along with corticosteroids, IVIG is first-line therapy for anti-HMGCR myopathy. Rituximab or tofacitinib may be effective for some inflammatory myositis or skin involvement unresponsive to corticosteroids and other immunosuppressant. Since the rash of dermatomyositis is often photosensitive, patients should limit sun exposure. Immunosuppressive therapy has limited efficacy for IBM.

All patients with immune-mediated inflammatory myopathies should be referred for physical therapy and encouraged to participate in an exercise program. This is a foundational treatment of IBM and a key component of therapeutic interventions for all patients with myositis.

When to Refer

- All patients with myositis should be referred to a rheumatologist or neurologist.
- Severe lung disease may require consultation with a pulmonologist.

When to Admit

- Signs of rhabdomyolysis.
- New onset of dysphagia.
- Respiratory insufficiency with hypoxia or carbon dioxide retention.

Jensen KY et al. High-intensity resistance training improves quality of life, muscle endurance and strength in patients with myositis: a randomised controlled trial. Rheumatol Int. 2024;44:1909. [PMID: 39192022]

MIXED CONNECTIVE TISSUE DISEASE, OVERLAP, & UNDIFFERENTIATED SYNDROMES

Special attention has been drawn to a subset of patients with positive antinuclear antibodies who have high titers of RNP autoantibodies and overlapping features of SLE, systemic sclerosis, RA, and inflammatory myositis. Swollen or puffy hands are a common early feature of this disease, referred to as mixed connective tissue disease. Raynaud phenomenon, arthralgias, and myalgias are common. Unlike patients with SLE, renal or CNS disease is uncommon. A key reason to identify this subset of patients is that pulmonary hypertension and interstitial lung disease are major causes of mortality, and regular screening for these manifestations is required.

Some patients have features of more than one connective tissue disease (eg, RA and SLE, SLE and systemic sclerosis) without high-titer anti-RNP antibodies. This is called "overlap syndrome." Others have only a few features of autoimmunity and cannot yet be classified ("undifferentiated connective tissue disease"). Treatments are guided more by the distribution and severity of patients' organ system involvement than by therapies specific to these overlap syndromes.

Chevalier K et al. Clinical presentation, course, and prognosis of patients with mixed connective tissue disease: a multicenter retrospective cohort. J Intern Med. 2024;295:532. [PMID: 38013625]

SJÖGREN DISEASE

ESSENTIALS OF DIAGNOSIS

- Women (average age 50 years) comprise 90% of patients.
- Dryness of eyes and mouth (sicca) are the most common features, but can be a multisystem disease with neurologic, pulmonary, and renal involvement.
- Rheumatoid factor, SSA (anti-Ro60 and Ro52), SSB (anti-La), and antinuclear antibodies are common.
- Increased incidence of lymphoma.

General Considerations

Sjögren disease is a systemic autoimmune disorder whose clinical presentation is usually dominated by dryness of the eyes and mouth due to immune-mediated dysfunction of the lacrimal and salivary glands. The disorder is predominantly seen in women, with a ratio of 9:1; most cases develop between the ages of 40 and 60 years. In general, it is slowly progressive with symptoms and glandular damage occurring over years. A high incidence of lymphoma is observed. Sjögren disease can occur in isolation ("primary" Sjögren disease) or in association with another rheumatic disease ("secondary" Sjögren disease), most frequently RA but also with SLE, primary biliary cholangitis, systemic sclerosis, and Hashimoto thyroiditis.

Clinical Findings

A. Symptoms and Signs

Keratoconjunctivitis sicca results from inadequate tear production caused by lymphocyte and plasma cell infiltration of the lacrimal glands. For most patients, symptoms of dryness of the mouth (xerostomia) are the most disabling. Patients frequently complain of a "cotton mouth" and difficulty swallowing foods, especially dry foods, like crackers, unless they are washed down with liquids. A few patients have such severe xerostomia that they have difficulty speaking. Persistent xerostomia results in rampant dental caries; caries at the gum line strongly suggest Sjögren disease. Ocular symptoms are directly related to decreased tear production. Burning, itching, and the sensation of having a foreign body or a grain of sand in the eye are common. The initial manifestation in some patients may be the inability to tolerate wearing contact lenses. Photophobia may signal corneal ulceration, a painful complication of severe ocular dryness. Dryness may involve the nose, throat, larynx, bronchi, vagina, and skin. Parotid enlargement, which may be chronic or relapsing, develops in one-third of patients.

Additional systemic autoimmune manifestations of Sjögren disease are rarer than sicca and include inflammatory arthritis, small-vessel vasculitis (often associated with cryoglobulinemia), and lung involvement (interstitial lung disease and pneumonitis). The spectrum of neurologic involvement is broad and can be devastating, including peripheral neuropathy, dysautonomia, and neuromyelitis optica. Renal tubular acidosis (type I, distal) occurs in 20% of patients, and chronic interstitial nephritis may cause impaired kidney function.

B. Laboratory Findings

Laboratory findings include mild anemia, leukopenia, and eosinophilia. Polyclonal hypergammaglobulinemia, rheumatoid factor positivity (70%), and antinuclear antibodies (95%) are all common. Antibodies against SS-A (anti-Ro 60 and Ro52) and SS-B (anti-La) are often present in primary Sjögren disease and tend to correlate with the presence of extraglandular manifestations (Table 23–7). Cryoglobulins are associated with a higher risk of vasculitis and subsequent lymphoma.

Useful ocular diagnostic tests include the Schirmer test, which measures the quantity of tears secreted. Lip biopsy, a simple procedure, reveals characteristic lymphoid foci in accessory salivary glands. Sialometry is an easy bedside test to quantify saliva production with a value ≤ 0.1 mL/min for unstimulated whole salivary flow being common, but not alone diagnostic, in Sjögren disease.

Ultrasound of salivary glands show hyperechoic bands and hypoechoic areas and may be a helpful tool for diagnosis and prognosis.

Differential Diagnosis

Isolated complaints of dry mouth are commonly due to medication side effects. Chronic hepatitis C can cause sicca symptoms and rheumatoid factor positivity; minor salivary gland biopsies reveal lymphocytic infiltrates but not to the extent of Sjögren disease, and tests for anti-SS-A and anti-SS-B are negative. Diffuse infiltration of CD8 T cells producing parotid gland enlargement can develop in patients with HIV. Involvement of the lacrimal or salivary glands, or both, in sarcoidosis can mimic Sjögren disease; biopsies reveal noncaseating granulomas. Rarely, amyloid deposits in the lacrimal and salivary glands produce sicca symptoms. IgG$_4$-related systemic disease can cause lacrimal and salivary gland enlargement.

Treatment & Prognosis

Treatment of mild to moderate sicca symptoms is symptomatic and supportive. Artificial tears applied frequently will relieve ocular symptoms and avert further desiccation. Topical ocular cyclosporine 0.05% or lifitegrast 5% also improve ocular symptoms. The mouth should be kept well lubricated. Sipping water frequently or using sugar-free gums and hard candies usually relieves dry mouth symptoms. Pilocarpine (5 mg orally four times daily) and the acetylcholine derivative, cevimeline (30 mg orally three times daily), may improve xerostomia symptoms. Atropinic (anticholinergic) drugs and decongestants decrease salivary secretions and should be avoided. A program of oral hygiene, including fluoride treatment, is essential to preserve dentition.

Drugs targeting B cells, such as sequential belimumab followed by rituximab, or ianalumab (cecmonoclonal antibody BAFF inhibitor), have shown promise in improving composite outcomes in Sjögren disease (Table 23–4). Nipocalimab, a monoclonal antibody with high affinity to block FcRn and reduce levels of circulating immunoglobulin G, was granted Breakthrough Therapy designation by the FDA in 2024 for patients with moderate to severe Sjögren disease.

Although Sjögren disease may compromise patients' quality of life significantly, the disease is usually associated with a normal life span. Poor prognosis is influenced by the presence and severity of organ involvement (pulmonary, renal, neurologic), vasculitis, and the complication of lymphoma. The patients at greatest risk for developing lymphoma are those with severe exocrine dysfunction, marked parotid gland enlargement, splenomegaly, vasculitis, peripheral neuropathy, anemia, and mixed monoclonal cryoglobulinemia (3–10% of the total Sjögren population).

When to Refer

- Presence of systemic symptoms or signs.
- Ocular dryness not responsive to artificial tears.

When to Admit

Presence of severe systemic signs, such as vasculitis or neurologic, unresponsive to outpatient management.

IgG$_4$-RELATED DISEASE

ESSENTIALS OF DIAGNOSIS

- Mainly affects men older than 50 years.
- Lymphoplasmacytic infiltrates causing tumors or fibrosis in any organ or tissue.
- Subacute onset; constitutional symptoms rare.
- Diagnostic histopathology.

General Considerations

IgG$_4$-related disease is a systemic disorder of unknown cause marked by highly characteristic fibroinflammation that contains IgG$_4$ plasma cells and can infiltrate virtually any organ. The disorder chiefly affects men (75% of patients) over the age of 50 years.

Clinical Findings

A. Symptoms and Signs

IgG$_4$-related disease can affect any organ of the body, can be localized or generalized, demonstrates the same distinctive histopathology at all sites of involvement, produces protean manifestations depending on location and extent of involvement, and causes disease that ranges in severity from asymptomatic to organ- or life-threatening. The inflammatory infiltration in IgG$_4$-related disease frequently produces tumefactive masses that can be found during physical examination or on imaging. Some of the common presenting manifestations include enlargement of salivary or submandibular glands, lymphadenopathy, proptosis from periorbital infiltration, retroperitoneal fibrosis, mediastinal fibrosis, inflammatory aortic aneurysm, and pancreatic mass with autoimmune pancreatitis. IgG$_4$-related disease can also affect the thyroid (formerly Riedel thyroiditis), kidney, meninges, pituitary, sinuses, lung, prostate, breast, and bone. Most symptomatic patients with IgG$_4$-related disease present subacutely; fever and constitutional symptoms are usually absent.

B. Laboratory Findings

Serum IgG$_4$ levels are usually, but not invariably, elevated so this finding cannot be used as the sole diagnostic criterion. The infiltrating lesions in IgG_4-related disease often produce tumors or fibrotic changes that are evident on CT or MRI. However, the cornerstone of diagnosis is histopathology. The key pathological findings are a dense lymphoplasmacytic infiltrate rich in IgG_4 plasma cells, storiform (matted and irregularly whorled) fibrosis, and obliterative phlebitis.

Differential Diagnosis

IgG_4-related disease can mimic many disorders including sarcoidosis, Sjögren disease (lacrimal gland enlargement), pancreatic cancer (pancreatic mass), chronic infections (eg, HIV, hepatitis C), and granulomatosis with polyangiitis (proptosis). Lymphoma shares some histopathologic features of IgG_4-related disease.

Treatment & Prognosis

Patients who are asymptomatic and have no organ-threatening disease can be monitored carefully. Spontaneous resolution can occur. Initial therapy is usually oral prednisone 0.6 mg/kg/day, tapered over weeks or months depending on response. Given that corticosteroid monotherapy may fail to control the disease and can cause significant long-term toxicity, B-cell–depleting therapy, such as rituximab or inebilizumab, is often also used. Azathioprine and mycophenolate are alternative therapies. The degree of fibrosis in affected organs determines the patient's responsiveness to treatment.

When to Refer

- Presence of organ involvement.
- Symptoms or signs not responsive to prednisone.

When to Admit

Presence of severe systemic signs unresponsive to outpatient management.

VASCULITIS SYNDROMES

Vasculitis is a heterogeneous group of disorders characterized by inflammation within the walls of affected blood vessels. The first consideration in classifying cases of vasculitis is the size of the major vessels involved: large, medium, or small. The major forms of primary systemic vasculitis are listed in Table 23–11. The presence of the clinical signs and symptoms shown in Table 23–12 helps distinguish among these three groups. After determining the size of the major vessels involved, other issues that contribute to the classification include the following:

- Does the process involve arteries, veins, or both?
- What are the patient's demographic characteristics (age, sex, ethnicity, cigarette smoking status)?
- Which organs are involved?
- Is there hypocomplementemia or other evidence of immune complex deposition?
- Is there granulomatous inflammation on tissue biopsy?
- Are antineutrophil cytoplasmic antibodies (ANCA) present?

In addition to primary vasculitides, "secondary" forms of vasculitis occur in the setting of chronic infections (eg, hepatitis B or C, subacute bacterial endocarditis), connective tissue disorders, IBD, malignancies, and reactions to

Table 23–11. Classification scheme of primary vasculitides according to size of predominant blood vessels involved.

- **Predominantly large-vessel vasculitides**
  - Takayasu arteritis
  - Giant cell arteritis (temporal arteritis)
  - Behçet disease[1]
- **Predominantly medium-vessel vasculitides**
  - Polyarteritis nodosa
  - Thromboangiitis obliterans
  - Primary angiitis of the CNS
- **Predominantly small-vessel vasculitides**
  - Cutaneous leukocytoclastic angiitis ("hypersensitivity vasculitis")
  - Immune-complex–mediated
    - IgA vasculitis (Henoch-Schönlein purpura)
    - Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)
    - Essential cryoglobulinemia[2]
  - "ANCA-associated" vasculitis[3]
    - Granulomatosis with polyangiitis[2]
    - Microscopic polyangiitis[2]
    - Eosinophilic granulomatosis with polyangiitis[2]

[1] May involve small-, medium-, and large-sized blood vessels.

[2] Frequent overlap of small- and medium-sized blood vessel involvement.

[3] Not all forms of these disorders are always associated with ANCA.

ANCA, antineutrophil cytoplasmic antibodies.

Table 23–12. Typical clinical manifestations of large-, medium-, and small-vessel vasculitis.

Large Vessel	Medium Vessel	Small Vessel
Fever, weight loss, malaise, arthralgias/ arthritis Limb claudication Asymmetric blood pressures Absence of pulses Bruits Aortic dilation	Fever, weight loss, malaise, arthralgias/ arthritis Cutaneous nodules Ulcers Livedo reticularis Digital gangrene Mononeuritis multiplex Microaneurysms	Fever, weight loss, malaise, arthralgias/ arthritis Purpura Vesiculobullous lesions Urticaria Glomerulonephritis, hematuria Alveolar hemorrhage Cutaneous extravascular necrotizing granulomas Splinter hemorrhages Uveitis Episcleritis Scleritis

medications. Only the major primary forms of vasculitis are discussed here.

POLYMYALGIA RHEUMATICA & GIANT CELL ARTERITIS

ESSENTIALS OF DIAGNOSIS

- Age over 50 years.
- Markedly elevated ESR and CRP.
- **Polymyalgia rheumatica:** pain and stiffness in shoulders and hips lasting for several weeks without other explanation.
- **Giant cell arteritis:** headache, jaw claudication, polymyalgia rheumatica; without treatment, permanent blindness may occur.

General Considerations

Polymyalgia rheumatica and giant cell arteritis probably represent a spectrum of one disease. Both affect the same population (patients over the age of 50), and the incidence of the disease increases with each decade of life. Both show preference for the same HLA haplotypes and show similar patterns of cytokines in blood and arteries. Giant cell arteritis is a systemic panarteritis affecting medium-sized and large vessels. Giant cell arteritis was previously called temporal arteritis because the temporal artery is frequently involved, as are other extracranial branches of the carotid artery. However, the aorta and its major branches may be also involved in giant cell arteritis. Polymyalgia rheumatica and giant cell arteritis frequently coexist. Polymyalgia rheumatica alone is not a systemic vasculitis, does not cause blindness, and responds to low-dose (10–20 mg/day orally) prednisone; giant cell arteritis can cause blindness, aortitis, and large artery complications that require high-dose (40–60 mg/day) prednisone.

Clinical Findings

A. Polymyalgia Rheumatica

Polymyalgia rheumatica is a clinical diagnosis based on pain and stiffness of the shoulder and pelvic girdle areas, frequently in association with fever, malaise, and weight loss. In approximately two-thirds of cases, polymyalgia occurs in the absence of giant cell arteritis. Because of profound stiffness and pain in the shoulders, hips, and lower back, patients have trouble combing their hair, putting on a coat, or rising from a chair. In contrast to polymyositis and polyarteritis nodosa, polymyalgia rheumatica does not cause muscular weakness either through primary muscle inflammation or secondary to nerve infarction.

B. Giant Cell Arteritis

The 2022 American and European classification criteria for giant cell arteritis highlight the multiple domains important to making the diagnosis of giant cell arteritis: clinical, laboratory, pathologic (temporal artery biopsy), and imaging.

The mean age at onset of giant cell arteritis is 79 years. The classic cranial symptoms are headache, scalp tenderness, visual symptoms (particularly amaurosis fugax or diplopia), and jaw claudication. Of these symptoms, jaw claudication has the highest positive predictive value. The temporal artery can be normal on physical examination but may be nodular, enlarged, tender, or pulseless. Blindness usually results from anterior ischemic optic neuropathy, caused by occlusive arteritis of the posterior ciliary branch of the ophthalmic artery; there may be no funduscopic findings for the first 24–48 hours after the onset of blindness. About 50% of patients with giant cell arteritis have polymyalgia rheumatica.

Asymmetry of pulses in the arms, a murmur of aortic regurgitation, or bruits near the clavicle resulting from subclavian artery stenoses identify patients in whom giant cell arteritis has affected the aorta or its major branches. Clinically evident large artery involvement—characterized chiefly by aneurysm of the thoracic aorta or stenosis of the subclavian, vertebral, carotid, and basilar arteries—occurs in approximately 25% of patients with giant cell arteritis, sometimes years after the diagnosis. Subclinical large artery disease is the rule: PET scans reveal inflammation in the aorta and its major branches in nearly 85% of untreated patients. Forty percent of patients with giant cell arteritis have nonclassical symptoms at presentation, including large artery involvement causing chiefly aortic regurgitation or arm claudication, respiratory tract problems (most frequently dry cough), mononeuritis multiplex (most frequently with painful paralysis of a shoulder), or fever of unknown origin. Giant cell arteritis accounts for 15% of all cases of fever of unknown origin in patients over the age of 65. Thus, in an older patient with fever of unknown origin, elevated acute-phase reactants, and negative infectious workup, giant cell arteritis must be considered even in the absence of GCA-specific features such as headache or jaw claudication. In some cases, instead of having the well-known symptom of jaw claudication, patients complain of vague pain affecting other locations, including the tongue, nose, or ears. Indeed, unexplained head or neck pain in an older patient may signal the presence of giant cell arteritis.

C. Laboratory Findings

1. Polymyalgia rheumatica—Acute-phase reactants (generally ESR higher than 30 mm/hour and CRP > 0.5 mg/dL) are universally present.

2. Giant cell arteritis—Nearly 90% of patients with giant cell arteritis have ESRs > 50 mm/hour. The ESR in this disorder is often > 100 mm/hour, but cases in which the ESR is lower or even normal do occur. In one series, 5% of patients with biopsy-proven giant cell arteritis had ESRs < 40 mm/hour. Although the CRP is slightly more sensitive, patients with biopsy-proven giant cell arteritis with normal CRP have also been described. Most patients also have a mild normochromic, normocytic anemia and thrombocytosis. The alkaline phosphatase (liver source) is elevated in 20% of patients with giant cell arteritis.

D. Imaging

Ultrasonography of the temporal artery can demonstrate vasculitis (halo sign) with a sensitivity (50–80%) and specificity (80–90%) that is highly operator dependent. For large artery giant cell arteritis (eg, aortitis), magnetic resonance angiography, or CT angiography (sensitivity 73–85%, specificity 85–100%) can establish the diagnosis by demonstrating long stretches of narrowing, thickening, or aneurysmal dilation of the aorta and the subclavian and axillary arteries, or both. PET-CT has a sensitivity 85% and specificity 83% to differentiate between clinically active large-vessel vasculitis and noninflammatory conditions. While these imaging techniques can complement clinical evaluation and, in some cases, reduce the need for temporal artery biopsy, pathologic demonstration of vasculitis remains the gold standard for definitive diagnosis.

Differential Diagnosis

The differential diagnosis of malaise, anemia, and striking acute-phase reactant elevations includes rheumatic diseases (such as RA or other systemic vasculitides), occult malignancies, and chronic infections (such as subacute bacterial endocarditis and osteomyelitis).

Treatment

A. Polymyalgia Rheumatica

Patients with isolated polymyalgia rheumatica (ie, those not having giant cell arteritis symptoms of headache, jaw claudication, scalp tenderness, or visual symptoms) are treated with prednisone, 10–20 mg/day orally. If the patient does not experience a dramatic improvement within 72 hours, the diagnosis should be revisited. Usually after 2–4 weeks of treatment, slow tapering of prednisone can be attempted. Most patients require some dose of prednisone for a minimum of approximately 1 year; 6 months is too short in most cases. Disease flares are common (≥ 50%) as prednisone is tapered, which may necessitate increasing prednisone. Tapering of prednisone should be based on symptoms and not solely on laboratory values because ESR can fluctuate and is not specific for polymyalgia rheumatica disease activity. Sarilumab, a human anti-IL-6Rα antibody, is FDA-approved for treatment of refractory polymyalgia rheumatica and for patients who fail corticosteroid tapering (Table 23–4).

B. Giant Cell Arteritis

The urgency of early diagnosis and treatment in giant cell arteritis relates to the prevention of blindness. Once blindness develops, it is usually permanent. Therefore, when a patient has symptoms and findings suggestive of cranial involvement from giant cell arteritis, therapy with prednisone (1 mg/kg/daily or max 80 mg/day orally) should be initiated immediately, and a temporal artery biopsy or temporal artery ultrasound performed promptly thereafter. For patients who seek medical attention for visual loss, intravenous pulse methylprednisolone (eg, 1 g daily for 3 days) should be started; unfortunately, few patients recover vision no matter what the initial treatment. Although it is prudent to obtain a temporal artery biopsy as soon as possible after instituting treatment, diagnostic findings of giant cell arteritis may still be present 2 weeks (or longer) after starting corticosteroids. An adequate biopsy specimen is essential (at least 2 cm in length), because the disease may be segmental. Obtaining a unilateral biopsy is recommended in 2021 guidelines (positive in approximately 80–85% of patients) since bilateral biopsies only increase the yield by < 15%. The presence of a "halo sign" on temporal artery ultrasonography may obviate the need for temporal artery biopsy, although biopsy remains the gold standard for diagnosis. Temporal artery biopsy is abnormal in only 50% of patients with *large artery* giant cell arteritis (eg, aortitis). In these patients, magnetic resonance angiography or CT angiography will establish the diagnosis by demonstrating long stretches of narrowing, thickening, or aneurysmal dilation of the aorta and the subclavian and axillary arteries, or both. Thoracic aortic aneurysms occur 17 times more frequently in patients with giant cell arteritis than in normal individuals and can cause aortic regurgitation, dissection, or rupture. The aneurysms can develop at any time but typically occur 7 years after the diagnosis of giant cell arteritis is made; hence, routine screening for this complication in cranial and large-vessel giant cell arteritis is recommended.

Prednisone should be continued at a high dose orally for about 1 month before tapering. When tapering and adjusting the dosage of prednisone, the ESR (or CRP) is a useful, but not absolute, guide to disease activity. A common error is treating the ESR rather than the patient. The ESR often rises slightly as the prednisone is tapered, even as the disease remains quiescent. Because older individuals often have baseline ESRs that are above the normal range, mild ESR elevations should not be an occasion for renewed treatment with prednisone in patients who are asymptomatic. Tocilizumab, an inhibitor of the IL-6 receptor, is FDA-approved for giant cell arteritis and can reduce the prolonged use of prednisone and decrease the risk of disease flare. Giant cell arteritis treatment guidelines are to initiate tocilizumab along with glucocorticoids for all patients with new or relapsing giant cell arteritis (Table 23–4).

Pugh D et al. 18F-FDG-PET/MR imaging to monitor disease activity in large vessel vasculitis. Nat Commun. 2024;15:7314. [PMID: 39183340]

TAKAYASU ARTERITIS

Takayasu arteritis is a granulomatous vasculitis of the aorta and its major branches. It primarily affects women, and age of onset is < 60 years. Takayasu arteritis can present with nonspecific constitutional symptoms of malaise, fever, and weight loss with or without manifestations of vascular inflammation and damage: diminished pulses, unequal blood pressures in the arms, carotidynia (tenderness over the carotid arteries), bruits over carotid and subclavian arteries, retinopathy, limb claudication, hypertension, or major ischemic events. There are no specific laboratory abnormalities or autoantibodies, although ESR and CRP are elevated in most cases. The diagnosis is established by imaging and clinical presentation. It is important to visualize the entirety of the aorta given the wide distribution of vascular lesions in Takayasu. MRI can detect inflammatory thickening of affected arteries. CT angiography provides images of the stenoses, occlusions, and dilations characteristic of arteritis. High-dose corticosteroids (eg, oral prednisone, 1 mg/kg) are recommended for newly diagnosed or severely relapsing Takayasu arteritis. The addition of methotrexate, azathioprine, mycophenolate mofetil, or TNF inhibitors is recommended for refractory disease and as corticosteroid-sparing agents; TNF inhibitors are first line. There are limited data for other biologic therapies, such as anti-IL-6 therapy (tocilizumab) and tofacitinib. Antiplatelets therapy is recommended for patients with active Takayasu arteritis or critical cranial or vertebrobasilar involvement. Takayasu arteritis has a chronic relapsing and remitting course that requires ongoing monitoring and adjustment of therapy.

POLYARTERITIS NODOSA

ESSENTIALS OF DIAGNOSIS

- Medium-sized arteries are affected.
- Clinical findings depend on the arteries involved; lungs are spared.
- Common features include fever, abdominal pain, extremity pain, livedo reticularis, mononeuritis multiplex.
- Kidney involvement causes renin-mediated hypertension.
- Associated with hepatitis B (10% of cases).

General Considerations

Polyarteritis nodosa is a necrotizing arteritis of medium-sized vessels that has a predilection for involving the skin, peripheral nerves, mesenteric vessels (including renal arteries), heart, and brain but spares the lungs. Polyarteritis nodosa is rare with a prevalence of 30 per 1 million people. Approximately 10% of cases of polyarteritis nodosa are caused by hepatitis B and most occur within 6 months of hepatitis B infection. Mutations in the gene for adenosine deaminase 2 have been identified in early-onset familial polyarteritis.

Clinical Findings

A. Symptoms and Signs

The clinical onset is usually insidious, with fever, malaise, weight loss, and other symptoms developing over weeks to months. Pain in the extremities is often a prominent early feature caused by arthralgia, myalgia (particularly affecting the calves), or neuropathy. The combination of mononeuritis multiplex (most commonly presenting with foot drop) and features of a systemic illness is one of the earliest specific clues to the presence of an underlying vasculitis. Polyarteritis nodosa is among the forms of vasculitis most commonly associated with vasculitic neuropathy.

In polyarteritis nodosa, the typical skin findings—livedo reticularis (Figure 23–8), subcutaneous nodules, and skin ulcers—reflect the involvement of deeper, medium-sized blood vessels. Digital gangrene is common. The most common cutaneous presentation is lower extremity ulcerations, usually occurring near the malleoli. Involvement of the renal arteries leads to a renin-mediated hypertension (much less characteristic of vasculitides involving smaller blood vessels). For unclear reasons, classic polyarteritis nodosa seldom (if ever) involves the lung, with the occasional exception of the bronchial arteries.

Abdominal pain—particularly diffuse periumbilical pain precipitated by eating—is common but often difficult to attribute to mesenteric vasculitis in the early stages. Nausea and vomiting are frequent symptoms. Infarction compromises the function of major viscera and may lead to acalculous cholecystitis or appendicitis. Some patients present dramatically with an acute abdomen caused by mesenteric vasculitis and gut perforation or with hypotension resulting from rupture of a microaneurysm in the liver, kidney, or bowel.

Subclinical cardiac involvement is common, and overt cardiac dysfunction may occur (eg, MI secondary to coronary vasculitis, or myocarditis).

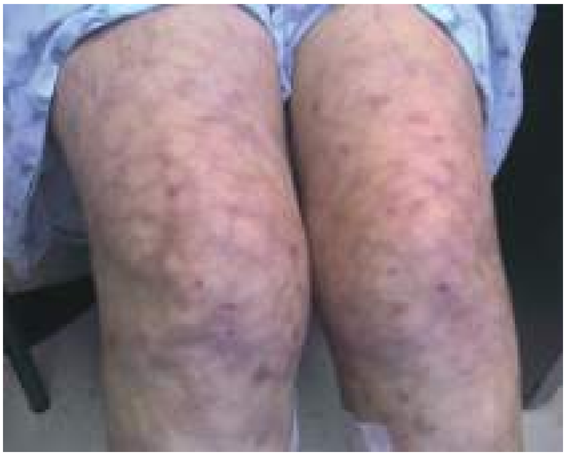

Figure 23–8. Livedo reticularis as a manifestation of antiphospholipid antibody syndrome. (Used, with permission, from Imboden JB et al. *Current Diagnosis & Treatment: Rheumatology,* 3rd ed. McGraw-Hill, 2013.)

B. Laboratory Findings

Most patients with polyarteritis nodosa have anemia and leukocytosis. Acute-phase reactants are often (but not always) strikingly elevated. There is no specific autoantibody for polyarteritis nodosa. Patients with classic polyarteritis nodosa are ANCA-negative but may have low titers of rheumatoid factor or antinuclear antibodies, both of which are nonspecific. Tests for active hepatitis B infection (HBsAg, HBeAg, hepatitis B viral load) should be performed. Patients with childhood onset of polyarteritis nodosa should undergo genetic evaluation for mutations in the genes for adenosine deaminase 2.

C. Biopsy and Angiography

The diagnosis of polyarteritis nodosa requires confirmation with either a tissue biopsy or vascular imaging. Biopsies of symptomatic sites such as skin and nerve and muscle (or both) are essential for diagnosis. A deep biopsy, not a punch biopsy, of skin ulcers or nodules should be made to ensure a medium-size artery is included in the sample. Current guidelines recommend a biopsy of the nerve and muscle (instead of the nerve alone) in patients with neuropathic symptoms. Patients in whom polyarteritis nodosa is suspected—eg, based on mesenteric ischemia or new-onset hypertension occurring in the setting of a systemic illness—may be diagnosed by the angiographic finding of aneurysmal dilations in the renal, mesenteric, or hepatic arteries.

Differential Diagnosis

Genetic collagen vascular disorders (such as Ehlers-Danlos and Loeys-Dietz syndromes), fibromuscular dysplasia, and segmental arterial mediolysis should be considered when imaging findings suggest polyarteritis nodosa in the absence of other clinical features of the disorder.

Treatment

High-dose pulse methylprednisolone (eg, 1 g intravenously daily for 3 days) is recommended as the initial treatment for severe polyarteritis nodosa. Adding cyclophosphamide lowers the risk of death and morbidity in severe disease. Methotrexate or azathioprine are used to maintain remissions induced by cyclophosphamide. For patients with polyarteritis nodosa associated with hepatitis B, the preferred treatment regimen is a short course of prednisone accompanied by anti-HBV therapy and plasmapheresis (three times a week for up to 6 weeks). TNF-α inhibitors are first-line therapy for the polyarteritis associated with deficiency of adenosine deaminase 2.

Prognosis

Without treatment, the 5-year survival rate in this disorder is about 10%. With appropriate therapy, remissions are often possible and the 5-year survival rate has improved to 60–90%. Poor prognostic factors are CKD with serum creatinine > 1.6 mg/dL (141 mcmol/L), proteinuria > 1 g/day, GI ischemia, CNS disease, and cardiac involvement. In the absence of any of these five factors, 5-year survival is nearly 90%. Survival at 5 years drops to 75% with one poor prognostic factor and to about 50% with two or more factors. Substantial morbidity and death may result from adverse effects of cyclophosphamide and corticosteroids (Table 30–5). These therapies require careful monitoring and expert management. In contrast to many other forms of systemic vasculitis, disease relapses in polyarteritis following the successful induction of remission occur in only about 20% of cases.

Chung SA et al. 2021 American College of Rheumatology/Vasculitis Foundation Guideline for the management of polyarteritis nodosa. Arthritis Rheumatol. 2021;73:1384. [PMID: 34235883]

GRANULOMATOSIS WITH POLYANGIITIS

ESSENTIALS OF DIAGNOSIS

- Classic triad of upper and lower respiratory tract disease and glomerulonephritis.
- Suspect if upper respiratory tract symptoms (eg, nasal congestion, sinusitis) are refractory to usual treatment.
- Kidney disease is often rapidly progressive.
- VTE commonly occurs.
- ANCAs (90% of patients), usually directed against proteinase-3 (but may be directed against myeloperoxidase).
- Tissue biopsy usually necessary for diagnosis.

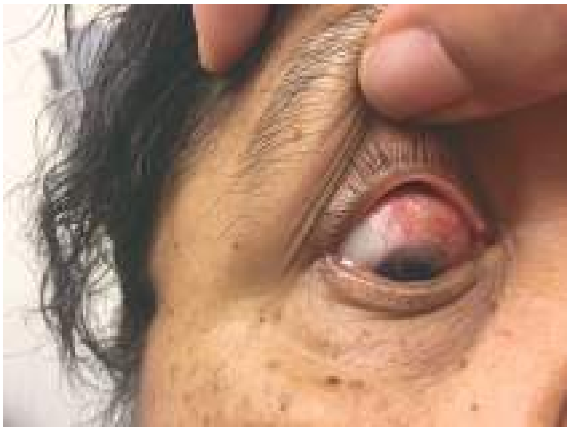
General Considerations

Granulomatosis with polyangiitis (formerly Wegener granulomatosis), which has an estimated incidence of approximately 12 cases per million individuals per year, is one of three vasculitides associated with ANCA. The other "ANCA-associated vasculitides" are microscopic polyangiitis and eosinophilic granulomatosis with polyangiitis. Granulomatosis with polyangiitis is characterized by vasculitis of small arteries, arterioles, and capillaries, necrotizing granulomatous lesions of both upper and lower respiratory tract, glomerulonephritis, and other vasculitic organ manifestations. Without treatment, generalized disease is invariably fatal, with most patients surviving < 1 year after diagnosis. It occurs most commonly in the fourth and fifth decades of life and affects men and women with equal frequency.

Clinical Findings

A. Symptoms and Signs

The disorder usually develops over 4–12 months. Upper respiratory tract symptoms develop in 90% of patients and lower respiratory tract symptoms develop in 60%; some patients may have both upper and lower respiratory tract symptoms. Upper respiratory tract symptoms include nasal



▲ **Figure 23–9.** Nodular scleritis in a patient with granulomatosis with polyangiitis. (Used, with permission, from Dr. Sarah Goglin.)

congestion, sinusitis, otitis media, mastoiditis, inflammation of the gums, or stridor due to subglottic stenosis. Since many of these symptoms are common, the underlying disease is not often suspected until the patient develops systemic symptoms, or the original problem is refractory to treatment. The lungs are affected initially in 40% and eventually in 80%, with symptoms including cough, dyspnea, and hemoptysis. Other early symptoms can include a migratory oligoarthritis with a predilection for large joints; a variety of symptoms related to ocular disease (unilateral proptosis from orbital pseudotumor; red eye from scleritis [Figure 23–9], episcleritis, anterior uveitis, or peripheral ulcerative keratitis); purpura or other skin lesions; and dysesthesia due to neuropathy. Renal involvement, which develops in three-fourths of the cases, may be subclinical until kidney disease is advanced. Fever, malaise, and weight loss are common.

Physical examination can be remarkable for congestion, crusting, ulceration, bleeding, and even perforation of the nasal septum. Destruction of the nasal cartilage with "saddle nose" deformity occurs late. Otitis media, proptosis, scleritis, episcleritis, and conjunctivitis are other common findings. Newly acquired hypertension, a frequent feature of polyarteritis nodosa, is rarely a symptom of granulomatosis with polyangiitis. VTE events (eg, DVT and PE) are a common occurrence in granulomatosis with polyangiitis. Although limited forms of granulomatosis with polyangiitis have been described in which the kidney is spared initially, kidney disease will develop in most untreated patients.

B. Laboratory Findings

1. Serum tests and UA—Most patients have anemia, mild leukocytosis, and elevated acute-phase reactants. If there is kidney involvement, proteinuria occurs and the urinary sediment contains red cells, often with red cell casts.

Serum tests for ANCA help in the diagnosis of granulomatosis with polyangiitis. ANCA levels, however, correlate erratically with disease activity, and changes in titer should not dictate changes in therapy in the absence of supporting clinical data. The two key ANCA subtypes relevant to systemic vasculitis are those directed against proteinase-3 (PR3) and myeloperoxidase (MPO). Antibodies to these two antigens are termed "PR3-ANCA" and "MPO-ANCA," respectively. The cytoplasmic pattern of immunofluorescence (c-ANCA) caused by PR3-ANCA has a high specificity (> 90%) for granulomatosis with polyangiitis but may less commonly be seen in the other forms of ANCA-associated vasculitis. A substantial percentage of patients with "limited" granulomatosis with polyangiitis, disease that does not pose an immediate threat to life and is often confined to the sinus and upper respiratory tract, are ANCA-negative. The perinuclear (p-ANCA) pattern, caused by MPO-ANCA, is more likely to occur in microscopic polyangiitis or eosinophilic granulomatosis with polyangiitis but may be found in granulomatosis with polyangiitis. Approximately 10–25% of patients with classic granulomatosis with polyangiitis have MPO-ANCA. All positive immunofluorescence assays for ANCA should be confirmed by enzyme immunoassays for the specific autoantibodies directed against PR3 or MPO.

2. Histologic findings—Although ANCA testing is helpful, most cases require diagnostic confirmation by tissue biopsy. Histologic features of granulomatosis with polyangiitis include vasculitis, granulomatous inflammation, geographic necrosis, and acute and chronic inflammation. The full range of pathologic changes is usually evident only on thoracoscopic lung biopsy; granulomas, observed only rarely in kidney biopsy specimens, are found much more commonly on lung biopsy specimens. Nasal biopsies often do not show vasculitis but may show chronic inflammation and other changes that rule out nasopharyngeal cancer or infection. Kidney biopsy discloses a segmental necrotizing glomerulonephritis with multiple crescents; this is characteristic but not diagnostic. The kidney lesion of granulomatosis with polyangiitis (and other forms of "ANCA-associated vasculitis") is characterized as a pauci-immune glomerulonephritis because of the relative absence (compared with immune complex–mediated disorders) of IgG, IgM, IgA, and complement proteins within glomeruli.

C. Imaging

Chest CT is more sensitive than CXR; lesions include infiltrates, nodules, masses, and cavities. Pleural effusions are uncommon. Often the radiographs prompt concern about lung cancer. Other common radiographic abnormalities include extensive sinusitis and even bony sinus erosions.

▶ Differential Diagnosis

Due to refractory and severe sinusitis, granulomatosis with polyangiitis may be misdiagnosed as chronic infectious sinonasal disease and treated with antibiotics alone. Initial complaints of joint pain can lead to a misdiagnosis of RA. Lung cancer may be the first diagnostic consideration for middle-aged patients with cough, hemoptysis, and lung masses. Granulomatosis with polyangiitis shares with SLE, anti–glomerular basement membrane disease, and microscopic polyangiitis the ability to cause an acute pulmonary-renal syndrome. Although both granulomatosis with polyangiitis and microscopic polyangiitis may have MPO-ANCA positivity, microscopic polyangiitis does not involve the sinuses or upper respiratory tract and does not have granulomatous inflammation on histopathology. Cocaine use can destroy midline tissues—the nose and palate—that mimics granulomatosis with polyangiitis. Patients using cocaine may have a drug-induced positive result for PR-3-ANCA, and lesional biopsies may demonstrate vasculitis from exposure to the toxin. COPA syndrome, a rare genetic autoinflammatory interferonopathy condition caused by mutations in the coatomer subunit-α gene, has many features of a systemic vasculitis such as diffuse alveolar hemorrhage, glomerulonephritis, and inflammatory arthritis.

Treatment

Early treatment is crucial to preventing the devastating end-organ and catastrophic complications of this disease. Treatment is divided into two phases: induction of remission and maintenance of remission. Plasma exchange is not routinely recommended for the treatment of ANCA-associated vasculitis.

A. Induction of Remission

Choice of induction therapy is dictated by whether the patient has mild disease (ie, no significant kidney dysfunction) or severe disease (ie, life- or organ-threatening disease such as rapidly progressive glomerulonephritis or pulmonary hemorrhage). American College of Rheumatology/Vasculitis Foundation recommendations for the treatment of granulomatosis with polyangiitis favor rituximab (plus corticosteroids) as first-line induction therapy, particularly for patients who are anti-PR3 positive. Cyclophosphamide may also be used for induction therapy in severe disease. Avacopan, an oral C5a receptor inhibitor, is FDA-approved as add-on treatment for severe ANCA-associated vasculitis induction therapy in combination with rituximab or cyclophosphamide plus corticosteroids. Although the standard induction regimen of corticosteroids in ANCA-associated vasculitis is prednisone 1 mg/kg orally daily, faster corticosteroid dose reductions have demonstrated equal efficacy with fewer corticosteroid-related complications, such as infections.

1. Rituximab plus prednisone (plus avacopan)—The B-cell–depleting antibody rituximab is FDA-approved in combination with corticosteroids (prednisone 1 mg/kg orally daily) for the treatment of granulomatosis with polyangiitis and microscopic polyangiitis (Table 23–4). Studies demonstrate that rituximab is as effective as cyclophosphamide for remission induction in these conditions.

2. Cyclophosphamide plus prednisone (plus avacopan)—Remission can be induced in > 90% of patients treated with prednisone (1 mg/kg daily) plus cyclophosphamide (2 mg/kg/day orally or 15 mg/kg intravenously every 2 weeks for three doses, then every 3 weeks for at least three doses with adjustments required for acute or CKD and patients over age 70). To minimize toxicity, patients are treated with cyclophosphamide for only 3–6 months; once remission is achieved, the patient is switched to a non-cyclophosphamide maintenance regimen.

Both rituximab and cyclophosphamide increase the risk of developing life-threatening opportunistic infections (including progressive multifocal leukoencephalopathy [PML]). *Whenever cyclophosphamide or rituximab is used,* Pneumocystis jirovecii *prophylaxis with one single-strength oral trimethoprim-sulfamethoxazole daily is essential.*

3. Methotrexate plus prednisone—For nonsevere disease without life- or organ-threatening manifestations, methotrexate up to 25 mg oral or subcutaneous weekly, plus prednisone up to 1 mg/kg orally daily may be effective induction therapy. If there is an intolerance or contraindication to methotrexate, mycophenolate mofetil can be used as a second-line induction therapy for nonsevere disease.

B. Maintenance of Remission

Options for maintaining remission in patients with normal or near normal kidney function after rituximab or cyclophosphamide induction include azathioprine (up to 2 mg/kg/day orally), methotrexate (20–25 mg/week either orally or subcutaneously), mycophenolate mofetil, or rituximab (Table 23–4). Per treatment guidelines, intravenous rituximab is favored as first-line maintenance treatment.

When to Refer

All patients should be referred to a rheumatologist; other subspecialty consultations may also be appropriate.

When to Admit

Admit for organ- or life-threatening disease, including alveolar hemorrhage or rapidly progressive glomerulonephritis.

Hellmich B et al. EULAR recommendations for the management of ANCA-associated vasculitis: 2022 update. Ann Rheum Dis. 2024;83:30. [PMID: 36927642]

Robson JC et al; DCVAS Study Group. 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for granulomatosis with polyangiitis. Arthritis Rheumatol. 2022;74:393. [PMID: 35106964]

MICROSCOPIC POLYANGIITIS

ESSENTIALS OF DIAGNOSIS

- Necrotizing vasculitis of small- and medium-sized arteries and veins.
- Most common cause of pulmonary-renal syndrome (diffuse alveolar hemorrhage and glomerulonephritis).
- +ANCA in 75% of cases.

General Considerations

Microscopic polyangiitis is a pauci-immune nongranulomatous necrotizing vasculitis that (1) affects small blood vessels (capillaries, venules, or arterioles), (2) often causes glomerulonephritis and pulmonary capillaritis, and (3) is often associated with ANCA. Because microscopic polyangiitis may involve medium-sized as well as small blood vessels and because it tends to affect capillaries within the lungs and kidneys, its spectrum overlaps those of both polyarteritis nodosa and granulomatosis with polyangiitis.

In rare instances, medications, particularly propylthiouracil, hydralazine, allopurinol, penicillamine, minocycline, and sulfasalazine, induce a systemic vasculitis associated with high titers of p-ANCA and features of microscopic polyangiitis.

Clinical Findings

A. Symptoms and Signs

A wide variety of findings suggesting vasculitis of small blood vessels may develop in microscopic polyangiitis. These include "palpable" (or "raised") purpura and other signs of cutaneous vasculitis (ulcers, splinter hemorrhages, vesiculobullous lesions).

Microscopic polyangiitis is the most common cause of pulmonary-renal syndromes, being several times more common than anti–glomerular basement membrane disease. Pulmonary hemorrhage may occur with pathologic findings typically of capillaritis. Interstitial lung fibrosis that mimics usual interstitial pneumonitis may be part of the presenting condition and conveys a poor prognosis.

Vasculitic neuropathy (mononeuritis multiplex) is also common in microscopic polyangiitis.

B. Laboratory Findings

Three-fourths of patients with microscopic polyangiitis are ANCA-positive, usually with anti-myeloperoxidase antibodies (anti-MPO-ANCA) that cause a p-ANCA pattern on immunofluorescence testing. ANCA directed against proteinase-3 (PR3-ANCA) can also be observed.

Elevated acute-phase reactants are typical of active disease. Microscopic hematuria, proteinuria, and RBC casts in the urine may occur. The kidney lesion is a segmental, necrotizing glomerulonephritis, often with localized intravascular coagulation and the observation of intraglomerular thrombi upon renal biopsy.

Differential Diagnosis

Distinguishing this disease from granulomatosis with polyangiitis may be challenging. In microscopic polyangiitis, there is no granulomatous inflammation and it is not associated with the chronic destructive upper respiratory tract disease often found in granulomatosis with polyangiitis. Because their treatments may differ, microscopic polyangiitis must also be differentiated from polyarteritis nodosa. COPA syndrome is a rare, genetic, multisystem, autoinflammatory disorder with recurrent pulmonary hemorrhage that mimics microscopic polyangiitis. There may be autoantibodies. COPA often presents in childhood, usually with a striking family history.

Treatment

Microscopic polyangiitis is usually treated in the same way as granulomatosis with polyangiitis: patients with severe disease, typically involving pulmonary hemorrhage and glomerulonephritis, require urgent induction treatment with corticosteroids and either rituximab or cyclophosphamide. Following successful induction of remission, maintenance treatment should be continued with rituximab, as first line, or azathioprine, methotrexate, or mycophenolate (all second-line maintenance therapy). In cases of drug-induced MPO-ANCA–associated vasculitis, the offending medication should be discontinued; significant organ involvement (eg, pulmonary hemorrhage, glomerulonephritis) requires immunosuppressive therapy.

Prognosis

The key to effecting good outcomes is early diagnosis. Compared with patients who have granulomatosis with polyangiitis, those who have microscopic polyangiitis are more likely to have significant fibrosis on renal biopsy because of later diagnosis.

Gialouri CG et al. Relapses and serious adverse events during rituximab maintenance therapy in ANCA-associated vasculitis: a multicentre retrospective study. Rheumatology (Oxford). 2024 Aug 6:keae409. [PMID: 39107924]

Kronbichler A et al. Diagnosis and management of ANCA-associated vasculitis. Lancet. 2024;403:683. [PMID: 38368016]

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

Eosinophilic granulomatosis with polyangiitis (previously called Churg-Strauss syndrome) is an ANCA-associated vasculitis (along with granulomatosis with polyangiitis and microscopic polyangiitis), although the presence of ANCA occurs in < 50% of patients (usually anti-MPO). It is characterized by peripheral eosinophilia, sinusitis with polyposis, asthma, lung infiltrates, vasculitic skin involvement, glomerulonephritis, and vasculitic neuropathy. Myocarditis can lead to arrhythmias and HF if untreated. Eosinophilic granulomatosis with polyangiitis should be considered in patients with an unexplained peripheral eosinophilia and vasculitis. Laboratory workup for unexplained eosinophilia should include ANCA testing, serum tryptase levels, peripheral flow cytometry for PDGF receptor abnormalities (which can be seen in eosinophilic leukemia), and testing for helminthic infections. Eosinophilic infiltrates on tissue samples strongly suggest the diagnosis of eosinophilic granulomatosis with polyangiitis, especially if accompanied by vasculitis (purpura, glomerulonephritis, vasculitic ulcers, mononeuritis multiplex). Corticosteroids remain first-line treatment with azathioprine and methotrexate demonstrating efficacy for mild to moderate disease. Mepolizumab, an IL-5 inhibitor, is FDA-approved for the treatment of eosinophilic granulomatosis with polyangiitis, although it has not been studied for severe life- or organ-threatening vasculitic disease manifestations (which generally require cyclophosphamide).

Bloom JL et al. Therapeutic advances in eosinophilic granulomatosis with polyangiitis. Rheum Dis Clin North Am. 2023;49:563. [PMID: 37331733]

CRYOGLOBULINEMIA

Cryoglobulinemia can be associated with an immune-complex–mediated, small-vessel vasculitis. The cryoglobulins associated with vasculitis are cold-precipitable immune complexes consisting of rheumatoid factor and IgG (rheumatoid factor is an autoantibody to the constant region of IgG). The rheumatoid factor component can be monoclonal (type II cryoglobulins) or polyclonal (type III cryoglobulins). Type I cryoglobulins are cryoprecipitable monoclonal proteins that lack rheumatoid factor activity; these cause cold-induced hyperviscosity syndromes, not vasculitis, and are associated with B-cell lymphoproliferative diseases. Type II and Type III cryoglobulinemias are associated with chronic infections (hepatitis C, subacute bacterial endocarditis, osteomyelitis, HIV, and hepatitis B) or connective tissue diseases (especially Sjögren disease).

Clinical Findings

Cryoglobulinemic vasculitis typically manifests as recurrent palpable purpura (predominantly on the lower extremities) and peripheral neuropathy. A proliferative glomerulonephritis may develop and can manifest as rapidly progressive glomerulonephritis. Abnormal liver biochemical tests, abdominal pain, digital gangrene, and pulmonary disease may also occur. The diagnosis is based on a compatible clinical picture and a positive serum test for cryoglobulins. The presence of a disproportionately low C4 level or rheumatoid factor or both can be diagnostic clues to the presence of cryoglobulinemia.

Treatment

Antiviral regimens are first-line therapy for hepatitis C–associated cryoglobulinemic vasculitis that is neither life- nor organ-threatening. Interferon-free direct-acting antiviral agents are preferred because of the excellent long-term response in clinical trials. Patients with severe cryoglobulinemic vasculitis (eg, extensive digital gangrene, extensive neuropathy, and rapidly progressive glomerulonephritis) and hepatitis C should receive immunosuppressive therapy with corticosteroids and either rituximab or cyclophosphamide plus antiviral treatment. Plasma exchange may provide additional benefit in selected cases.

IgA VASCULITIS (Henoch-Schönlein Purpura)

IgA vasculitis (Henoch-Schönlein purpura), the most common systemic vasculitis in children, occurs in adults as well. Typical clinical features are palpable purpura, arthritis, and hematuria. Abdominal pain occurs less frequently in adults than in children. Pathologic features on skin biopsy include leukocytoclastic vasculitis with IgA deposition. Biopsy of the kidney reveals segmental glomerulonephritis with crescents and mesangial deposition of IgA. The cause is not known.

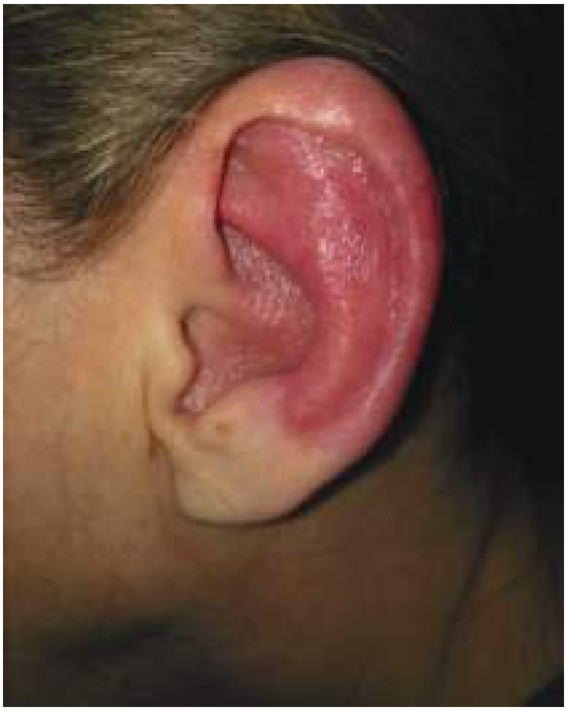
The purpuric skin lesions are typically located on the lower extremities but may also be seen on the hands, arms, trunk, and buttocks. Joint symptoms are present in most patients, with the knees and ankles being most commonly involved. Abdominal pain secondary to vasculitis of the intestinal tract is often associated with GI bleeding. Hematuria is a sign of a renal lesion that is usually reversible, although it may progress to CKD (see Henoch-Schönlein purpura, Chapter 25). Children tend to have more frequent and more serious GI vasculitis, whereas adults more often have glomerulonephritis. Chronic courses with persistent or intermittent skin disease are more likely to occur in adults than in children.

The value of corticosteroids has been controversial. Severe disease in adults is often treated with immunosuppressive agents, such as rituximab or mycophenolate mofetil, but there is no consensus regarding the efficacy of this approach or optimal therapeutic regimen.

Castañeda S et al. IgA vasculitis (Henoch-Schönlein purpura): an update on treatment. J Clin Med. 2024;13:6621. [PMID: 39518760]

RELAPSING POLYCHONDRITIS

This disease is characterized by inflammatory destructive lesions of cartilaginous structures, principally the ears, nose, trachea, and larynx (Figure 23–10). Nearly 40% of cases are associated with another disease, especially other immunologic disorders (ANCA vasculitis, SLE, RA, or Hashimoto thyroiditis), cancers (plasma cell myeloma), or hematologic disorders (myelodysplastic syndrome).



▲ **Figure 23–10.** Chondritis of ear cartilage. (Used, with permission, from Dr. Sarah Goglin.)

Relapsing polychondritis is episodic and affects men and women equally. The cartilage is painful, swollen, and tender during an attack and subsequently becomes atrophic, resulting in permanent deformity. Biopsy of the involved cartilage shows inflammation and chondrolysis. Laryngotracheal and bronchial chondritis can lead to life-threatening airway narrowing and collapse. Noncartilaginous manifestations of the disease include fever, episcleritis, uveitis, deafness, aortic regurgitation, inflammatory arthritis, and rarely, glomerulonephritis. Large-vessel vasculitis is a frequently overlooked but potentially catastrophic complication. Diagnosing this uncommon disease is especially difficult since the signs of cartilage inflammation (such as red ears or nasal pain) may be more subtle than the fever, arthritis, rash, or other systemic manifestations, and there are no serologic markers.

Prednisone, 0.5–1 mg/kg/day orally, is often effective. Dapsone (100–200 mg/day orally) or methotrexate (7.5–20 mg orally per week) may also have efficacy, sparing the need for long-term high-dose corticosteroid treatment. Involvement of the tracheobronchial tree may respond to inhibitors of TNF.

The genetic syndrome VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) is caused by somatic mutations in *UBA1* in hematopoietic progenitor cells. Clinical features include hematologic manifestations (cytopenias, macrocytosis, bone marrow failure) and a spectrum of inflammatory findings such as chondritis, vasculitis, fever, and arthritis. This rare syndrome (predominately in males because it is X-linked) should be considered in the differential diagnosis of chondritis, especially in the presence of an unexplained macrocytosis and evidence of systemic inflammation (ie, high ESR/CRP).

BEHÇET DISEASE

ESSENTIALS OF DIAGNOSIS

- Recurrent, painful oral and genital aphthous ulcers.
- Erythema nodosum–like lesions; follicular rash; pathergy phenomenon.
- Anterior or posterior uveitis. Posterior uveitis may be asymptomatic until significant damage to the retina has occurred.
- Neurologic lesions can mimic multiple sclerosis.

General Considerations

Named after the Turkish dermatologist who first described it, Behçet disease is of unknown cause and most commonly occurs in persons of Asian, Turkish, or Middle Eastern background. The protean manifestations likely result from vasculitis that may involve all types of blood vessels: small, medium, and large, on both the arterial and venous side of the circulation.

Clinical Findings

A. Symptoms and Signs

The hallmark of Behçet disease is painful aphthous ulcerations in the mouth. These lesions, which usually are multiple, may be found on the tongue, gums, and inner surfaces of the oral cavity. Genital lesions, similar in appearance, are common but do not occur in all patients. Other key cutaneous lesions of Behçet disease include tender, erythematous, papular lesions that resemble erythema nodosum, and papulopustular lesions. On biopsy, however, many of these lesions are shown to be secondary to vasculitis rather than septal panniculitis. These erythema nodosum–like lesions tend to ulcerate, which is a major difference between the lesions of Behçet disease and the erythema nodosum seen in sarcoidosis and IBD. An erythematous follicular rash that occurs frequently on the upper extremities may be a subtle feature of the disease. The **pathergy phenomenon** is highly specific for Behcet, although not pathognomonic. In this phenomenon, sterile pustules develop at sites where needles have been inserted into the skin (eg, for phlebotomy).

Nonerosive inflammatory arthritis occurs in about two-thirds of patients most commonly affecting the knees and ankles. Eye involvement is one of the most devastating complications of Behçet disease. Anterior uveitis, associated with the triad of photophobia, blurred vision, and a red eye, is intensely symptomatic. This complication may lead to a hypopyon, the accumulation of pus in the anterior chamber. If not treated properly, anterior uveitis may lead to synechiae formation between the iris and lens, resulting in permanent pupillary distortion. Posterior uveitis, as a retinal venulitis, may lead to the insidious destruction of large areas of the retina before the patient becomes aware of visual problems.

CNS involvement can cause major morbidity. Findings include sterile meningitis (recurrent meningeal headaches associated with a lymphocytic pleocytosis), cranial nerve palsies, seizures, encephalitis, sinus vein thrombosis, and spinal cord lesions. The CNS lesions may mimic multiple sclerosis radiologically. Aphthous ulcerations of the ileum and cecum and other forms of GI involvement develop in approximately a quarter of patients. Large-vessel vasculitis can lead to pulmonary artery aneurysms and life-threatening pulmonary hemorrhage. Finally, patients have a hypercoagulable tendency that may lead to complicated VTE events, particularly DVT, PE, cerebral sinus thrombosis, and other problems associated with clotting.

The clinical course may be chronic but is often characterized by remissions and exacerbations.

B. Laboratory Findings

There are no pathognomonic laboratory features of Behçet disease. Acute-phase reactants are often elevated, and there is no disease specific autoantibody. Behçet disease has a genetic risk factor (HLA B51), but this gene is neither necessary nor sufficient to cause the disease.

Differential Diagnosis

The differential diagnosis for oral ulcerations is broad and includes other forms of vasculitis (ANCA-associated), IBD, celiac disease, IgA deficiency, infections (HIV, histoplasmosis), complex aphthosis, and mucosal skin conditions (pemphigus vulgaris, lichen planus, mucous membrane pemphigoid).

Treatment

Both colchicine (0.6 mg once to three times daily orally) and topical corticosteroids (oral dexamethasone suspension 1 mg twice daily swish and spit of 0.5 mg/5 mL) may ameliorate mucocutaneous ulcerative symptoms. Apremilast, a selective phosphodiesterase-4 inhibitor, is FDA-approved for the treatment of oral ulcers in Behçet disease. Corticosteroids (1 mg/kg/day of oral prednisone) are a mainstay of initial therapy for severe disease manifestations. Azathioprine (2 mg/kg/day orally) may be an effective steroid-sparing agent. TNF-α inhibitors (infliximab, adalimumab) (Table 23–4) or cyclophosphamide are indicated for severe ocular and CNS complications of Behçet disease.

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the CNS is a rare syndrome that produces small- and medium-sized vasculitis limited to the brain and spinal cord. Biopsy-proved cases have predominated in men who have a history of weeks to months of headaches, encephalopathy, and multifocal strokes. Systemic symptoms and signs are absent, and routine laboratory tests, including ESR and CRP, may be normal. MRI of the brain is almost always abnormal, and the spinal fluid often reveals a mild lymphocytosis and a modest increase in protein level. Angiograms classically reveal a "string of beads" pattern produced by alternating segments of arterial narrowing and dilation. However, neither the MRI nor the angiogram appearance is specific for vasculitis. Indeed, in one study, none of the patients who had biopsy-proved CNS vasculitis had an angiogram showing "the string of beads," and none of the patients with the classic angiographic findings had a positive brain biopsy for vasculitis. Review of many studies suggests that the sensitivity of angiography varies greatly (from 40% to 90%) and the specificity is only approximately 30%. Several conditions, including vasospasm, can produce the same angiographic pattern as vasculitis. Definitive diagnosis requires a compatible clinical picture with exclusion of infection (including subacute bacterial endocarditis), neoplasm (especially intravascular lymphoma), or drug exposure (eg, cocaine) that can mimic primary angiitis of the CNS *and* a positive brain biopsy. In contrast to biopsy-proved cases, patients with angiographically defined CNS vasculopathy are chiefly women who have had an abrupt onset of headaches and stroke (often in the absence of encephalopathy) with normal spinal fluid findings. Many patients who fit this clinical profile may have reversible cerebral vasoconstriction rather than true vasculitis. Such cases are best treated with calcium channel blockers (such as nimodipine or verapamil) and possibly a short course of corticosteroids. Biopsy-proven cases of primary angiitis of the CNS usually improve with corticosteroids, but often cyclophosphamide or mycophenolate mofetil is required to induce and maintain remission. Treatment response correlates with the size of arteries involved: vasculitis of small cortical and leptomeningeal vessels is associated with a better response and outcome than vasculitis of larger arteries. Cases of CNS vasculitis associated with cerebral amyloid angiopathy often respond well to corticosteroids, albeit the long-term natural history remains poorly defined.

Salvarani C et al. Primary central nervous system vasculitis. N Engl J Med. 2024;391:1028. [PMID: 39292929]

LIVEDO RETICULARIS & LIVEDO RACEMOSA

Livedo reticularis produces a mottled, purplish discoloration of the skin with reticulated cyanotic areas surrounding paler central cores (Figure 23–8). This distinctive "fishnet" pattern is caused by spasm or obstruction of perpendicular arterioles, combined with pooling of blood in surrounding venous plexuses. Idiopathic primary livedo reticularis is a benign condition that worsens with cold exposure, improves with warming, and primarily affects the extremities. Apart from cosmetic concerns, it is usually asymptomatic. The presence of systemic symptoms or the development of cutaneous ulcerations suggests an underlying disease. Livedo reticularis must be distinguished from erythema ab igne, a benign cutaneous disorder caused by exposure to infrared heat source, such as that generated from a heating pad or laptop computer.

Secondary livedo reticularis, called livedo racemosa, occurs with diseases that cause vascular obstruction or inflammation. Livedo racemosa resembles idiopathic livedo reticularis but has a wider skin distribution, including trunk, buttocks, and extremities. Of particular importance is the link with antiphospholipid antibody syndrome. Livedo racemosa is the presenting manifestation in 25% of patients with antiphospholipid antibody syndrome and is strongly associated with the subgroup that has arterial thromboses. Other underlying causes of livedo racemosa include the vasculitides (particularly polyarteritis nodosa), cholesterol emboli syndrome, thrombocythemia, cryoglobulinemia, cold agglutinin disease, primary hyperoxaluria (due to vascular deposits of calcium oxalate), and disseminated intravascular coagulation.

SERONEGATIVE SPONDYLOARTHROPATHIES

The seronegative spondyloarthropathies include axial spondyloarthropathy (radiographic ankylosing spondylitis and nonradiographic), psoriatic arthritis, reactive arthritis, the arthritis associated with IBD, and undifferentiated spondyloarthropathy. In addition to axial inflammation, these disorders share features of asymmetric oligoarthritis of large peripheral joints, enthesopathy (inflammation of where ligaments, tendons, and joint capsule insert into bone), ocular inflammation, the absence of autoantibodies, and a striking association with HLA-B27. HLA-B27 is positive in up to 90% of patients with ankylosing spondylitis and 75% with reactive arthritis. HLA-B27 also occurs in 50% of patients with psoriatic and IBD who have sacroiliitis. Patients with only peripheral arthritis in these latter two syndromes do not show an increase in HLA-B27.

AXIAL SPONDYLOARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Chronic low backache and stiffness in young adults (onset age < 45 years), worst in the morning.
- Progressive limitation of back motion and chest expansion.
- Transient (50%) or persistent (25%) peripheral arthritis of large joints.
- Anterior uveitis in 20–25%.
- May be radiographic (ankylosing spondylitis) or nonradiographic.
- Negative serologic tests for rheumatoid factor and anti-CCP antibodies.

General Considerations

Axial spondyloarthritis (axSpA) is a chronic inflammatory disease of the joints of the axial skeleton, manifested clinically by pain and progressive fusion of the spine. axSpA can be radiographic (diagnostic changes of sacroiliac joints or spine visible on plain radiograph) or nonradiographic (axial inflammation [sacroiliitis] is only visualized by MRI). This classification more likely represents a spectrum of disease rather than distinct conditions. Radiographic axSpA has historically been named ankylosing spondylitis, although this nomenclature does not distinguish between the radiographic and nonradiographic forms of the disease. The age at onset is usually in the late teens or early 20s. The incidence is greater in males than in females.

Clinical Findings

A. Symptoms and Signs

The onset of axSpA is usually gradual, with intermittent bouts of back pain that may radiate into the buttocks. The back pain has an "inflammatory quality." It is worse in the morning and associated with profound stiffness that lasts hours. Pain and stiffness improve with activity, in contrast to back pain due to mechanical causes, which improves with rest and worsens with activity. As the disease advances, symptoms progress in a cephalad direction and back motion becomes limited, with the normal lumbar curve flattened and the thoracic curvature exaggerated. Chest expansion is often limited due to costovertebral joint involvement. In advanced cases, the entire spine becomes fused, allowing no motion in any direction. Acute arthritis of large peripheral joints occurs in about 50% of cases, and permanent changes in the peripheral joints—most commonly the hips, shoulders, and knees—are seen in about 25%. Enthesopathy, a hallmark of the spondyloarthropathies, can manifest as swelling of the Achilles tendon at its insertion, plantar fasciitis (producing heel pain), or dactylitis, which is fusiform "sausage" swelling of a finger or toe.

Anterior uveitis occurs in up to 25% of cases and may be a presenting feature of axSpA. Cardiac involvement, characterized by atrioventricular conduction defects, aortic regurgitation, or aortic root widening, occurs in 3–5% of patients with long-standing severe disease. Pulmonary fibrosis of the upper lobes, with progression to cavitation and bronchiectasis, mimicking tuberculosis, may rarely occur long after the onset of skeletal symptoms.

B. Laboratory Findings

ESR is elevated in 85% of cases, and autoantibodies are negative. Anemia of chronic inflammation may be present but is often mild. HLA-B27 is found in 90% of White and 50% of Black patients with axSpA. Because this antigen occurs in 8% of healthy White persons and 2% of healthy Black persons, it is not a specific diagnostic test and is most useful when there is intermediate probability of disease.

C. Imaging

The earliest radiographic changes are usually in the sacroiliac joints. Between 10% and 25% of patients with nonradiographic axial spondyloarthropathy will progress to radiographic spondyloarthropathy (erosion and sclerosis of sacroiliac joints on radiograph) within 10 years. The sacroiliitis of ankylosing spondylitis is bilateral and symmetric. Inflammation where the annulus fibrosus attaches to the vertebral bodies initially causes sclerosis ("the shiny corner sign") and then characteristic squaring of the vertebral bodies. The term "bamboo spine" describes the late radiographic appearance of the spinal column in which the vertebral bodies are fused by vertically oriented, bridging syndesmophytes formed by the ossification of the annulus fibrosus and calcification of the anterior and lateral spinal ligaments.

Differential Diagnosis

Low back pain due to mechanical causes, disk disease, and degenerative arthritis is very common. RA predominantly affects multiple, small, peripheral joints of the hands and feet. RA spares the sacroiliac joints and only affects the cervical component of the spine. Bilateral sacroiliitis indistinguishable from ankylosing spondylitis is seen with spondyloarthropathy associated with IBD. Sacroiliitis associated with reactive arthritis and psoriasis is often asymmetric or even unilateral. Osteitis condensans ilii (sclerosis on the iliac side of the sacroiliac joint) is an asymptomatic, postpartum radiographic finding that is occasionally mistaken for sacroiliitis. Diffuse idiopathic skeletal hyperostosis (DISH) causes exuberant osteophytes ("enthesophytes") of the spine that may be difficult to distinguish from the syndesmophytes of ankylosing spondylitis.

Treatment

NSAIDs remain first-line treatment of axSpA (Table 5–4). TNF inhibitors have well-established efficacy for NSAID-resistant axial disease; responses are often substantial and durable. TNF inhibitors may also have disease-modifying effects and slow radiographic progression. Etanercept, adalimumab, infliximab, golimumab, or certolizumab pegol is reasonable for patients whose symptoms are refractory to NSAIDs (Table 23–4). Secukinumab and ixekizumab (monoclonal antibodies against soluble IL-17A) and tofacitinib and upadacitinib (small-molecule JAK inhibitors) are highly effective and FDA-approved for the treatment of radiographic and nonradiographic axSpA. Sulfasalazine (1000 mg orally twice daily) may be useful for peripheral arthritis but lacks effectiveness for spinal and sacroiliac joint disease. Corticosteroids have minimal impact in ankylosing spondylitis and can worsen osteopenia. All patients should be referred to a physical therapist for instruction in postural exercises and a safe exercise program.

Prognosis

Most patients have persistent symptoms over decades; rare individuals experience long-term remissions. The severity of disease varies greatly, with about 10% of patients having work disability after 10 years. Developing hip disease within the first 2 years of disease onset presages a worse prognosis. Biologic agents provide symptomatic relief, improve quality of life, and may slow disease progression for many patients with ankylosing spondylitis.

When to Refer

- Early referral to a rheumatologist is essential for diagnosis and the timely introduction of effective therapy to prevent joint damage.
- Refer to an ophthalmologist for symptoms of uveitis.

All patients should be referred to a physical therapist for instruction in postural exercises and a safe exercise program.

PSORIATIC ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Psoriasis precedes arthritis in 80% of cases.
- **Arthritis:** usually asymmetric, with "sausage" appearance of fingers and toes (dactylitis); polyarthritis that may resemble RA.
- Sacroiliac joint involvement common.
- **Radiographic findings:** osteolysis; pencil-in-cup deformity; relative lack of osteoporosis; bony ankylosis; asymmetric sacroiliitis and atypical syndesmophytes.

General Considerations

Although psoriasis usually precedes the onset of arthritis, arthritis may precede skin disease by up to 2 years or occur simultaneously in approximately 20% of cases.

Clinical Findings

A. Symptoms and Signs

The multiple patterns or subsets of joint involvement in psoriatic arthritis include the following:

1. A symmetric polyarthritis that resembles RA but, usually, fewer joints are involved.
2. An oligoarthritis that may lead to considerable destruction of the affected joints.
3. The DIP joints are primarily affected. Early, this may be monoarticular, and often the joint involvement is asymmetric. Nail pitting and onycholysis frequently accompany DIP involvement.
4. A severe deforming arthritis (arthritis mutilans) with osteolysis.
5. A spondylitic form in which sacroiliitis and spinal involvement predominate; 50% of these patients are HLA-B27 positive.

Arthritis is at least five times more common in patients with severe psoriatic skin disease than in those with only mild skin findings. Occasionally, however, patients may have a single patch of psoriasis (typically hidden in the scalp, gluteal cleft, or umbilicus) and are unaware of its presence. Thus, a detailed search for cutaneous lesions is essential in patients with arthritis of new onset. Also, the psoriatic lesions may have cleared when arthritis appears—in such cases, the history is most useful in diagnosing previously unexplained cases of monoarthritis or oligoarthritis. Nail pitting is sometimes a clue. "Sausage" swelling, or dactylitis, of one or more digits is a common manifestation of enthesopathy in psoriatic arthritis. Uveitis or IBD (or both) may occur in psoriatic arthritis and will influence treatment options.

B. Laboratory Findings

The ESR is elevated in approximately 50% of patients with psoriatic arthritis; normal values do not rule out the diagnosis. Rheumatoid factor and anti-CCP antibodies are not present. Uric acid levels may be high, reflecting the active turnover of skin affected by psoriasis.

C. Imaging

Radiographic findings are most helpful in distinguishing the disease from other forms of arthritis. There are marginal erosions of bone and irregular destruction of joint and bone, which, in the phalanx, gives the appearance of a sharpened pencil. Fluffy periosteal new bone may be marked, especially at the insertion of muscles and ligaments into bone. Such changes will also be seen along the shafts of metacarpals, metatarsals, and phalanges. Psoriatic spondylitis causes asymmetric sacroiliitis.

Treatment

Guidelines for the treatment of psoriatic arthritis recommend a "domain-based" approach (peripheral arthritis, axial disease, enthesitis, dactylitis, skin psoriasis, nail disease, IBD, uveitis) and outline therapeutic options specific to each "domain." A patient may have activity in some, but not all, domains and treatment should be tailored as such. For musculoskeletal and cutaneous features of psoriatic arthritis, TNF inhibitors, IL-12/23 inhibitors (ustekinumab), IL-17 inhibitors (secukinumab, ixekizumab, brodalumab, bimekizumab), IL-23 inhibitors (guselkumab, risankizumab), phosphodiesterase 4 inhibitors (apremilast), and JAK inhibitors (tofacitinib, upadacitinib) are recommended (Table 23–4). For axial disease, TNF inhibitors, anti-IL-17, and JAK inhibitors are specifically recommended. For non-axial domains of psoriatic arthritis and skin, conventional DMARDs, specifically methotrexate, may be considered.

Corticosteroids are less effective in psoriatic arthritis than in other forms of inflammatory arthritis and may precipitate pustular psoriasis during tapers.

REACTIVE ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Oligoarthritis, conjunctivitis, urethritis, keratoderma blennorrhagicum, and mouth ulcers.
- Usually follows dysentery or a sexually transmitted infection.
- HLA-B27–positive in 50–80% of patients.

General Considerations

Reactive arthritis is precipitated by antecedent GI or genitourinary infections and manifests as an asymmetric sterile oligoarthritis, typically of the lower extremities. It is frequently associated with enthesitis. Extra-articular manifestations are common and include urethritis, conjunctivitis, uveitis, keratoderma blennorrhagicum, and mucocutaneous lesions. Reactive arthritis occurs most commonly in young men and is associated with HLA-B27 in 80% of White patients and 50–60% of Black patients.

Clinical Findings

Most cases of reactive arthritis develop within 1–4 weeks after either a GI infection (usually with *Shigella, Salmonella, Yersinia,* or *Campylobacter*) or a sexually transmitted infection (with *Chlamydia trachomatis* or perhaps *Ureaplasma urealyticum*). Whether the inciting infection is sexually transmitted or dysenteric does not affect the subsequent manifestations. Other pathogens known to cause reactive arthritis include *Mycobacterium*, *Streptococcus*, *Staphylococcus*, and SARS-CoV-2. Synovial fluid from affected joints is culture negative. A clinically indistinguishable syndrome can occur without an apparent antecedent infection, suggesting that subclinical infection can precipitate reactive arthritis or that there are other, as yet unrecognized, triggers.

The arthritis is most commonly asymmetric and frequently involves the large weight-bearing joints (knee and ankle); sacroiliitis or ankylosing spondylitis is observed in at least 20% of patients, especially after frequent recurrences. Systemic symptoms including fever and weight loss are common at the onset of disease. The mucocutaneous lesions may include balanitis (Figure 23–11), stomatitis, and keratoderma blennorrhagicum, indistinguishable from pustular psoriasis. Involvement of the fingernails in reactive arthritis mimics psoriatic changes. When present, conjunctivitis is mild and occurs early in the disease course. Anterior uveitis, which can develop at any time in HLA-B27–positive patients, is a more clinically significant ocular complication. Carditis and aortic regurgitation may occur. While most signs of the disease disappear within

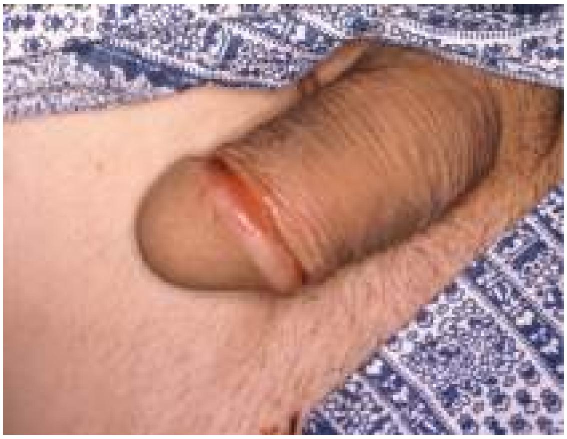

Figure 23–11. Circinate balanitis due to reactive arthritis. (From Susan Lindsley, Dr. M. F. Rein, Public Health Image Library, CDC.)

days or weeks, the arthritis may persist for several months or become chronic. Recurrences involving any combination of the clinical manifestations are common and are sometimes followed by permanent sequelae, especially in the joints (eg, articular destruction).

Differential Diagnosis

Gonococcal arthritis can initially mimic reactive arthritis, but the marked improvement after 24–48 hours of antibiotic administration in gonococcal arthritis and the culture results distinguish the two disorders. New-onset RA, ankylosing spondylitis, and psoriatic arthritis must be considered. By causing similar oral, ocular, and joint lesions, Behçet disease may mimic reactive arthritis. The oral lesions of reactive arthritis, however, are typically painless, in contrast to those of Behçet disease.

Treatment

NSAIDs have been the mainstay of therapy (Table 5–4). Antibiotics given at the time of a nongonococcal sexually transmitted infection reduce the chance that reactive arthritis will develop. For chronic reactive arthritis associated with chlamydial infection, a randomized trial demonstrated that 6 months of rifampin (300 mg orally twice daily) in combination with either doxycycline (100 mg orally twice daily) or azithromycin (500 mg orally daily for 5 days then twice weekly) was more effective than placebo. Patients who do not respond to NSAIDs may respond to the DMARDs sulfasalazine (1 g twice daily) or methotrexate (up to 25 mg once weekly). Duration of treatment is highly variable and dependent on severity of manifestations and clinical course. For patients with recent-onset disease that is refractory to NSAIDs and traditional DMARDs, anti-TNF agents or other biologics (such as anti-IL 17), which are effective in the other spondyloarthropathies, may be effective.

Agarwal A et al. Treatment of reactive arthritis with biological agents. Curr Rheumatol Rep. 2024;26:450. [PMID: 39312088]

INFLAMMATORY BOWEL DISEASE–ASSOCIATED SPONDYLOARTHRITIS

One-fifth of patients with IBD have arthritis. IBD-associated arthritis can have a peripheral arthritis pattern with or without axial involvement. The peripheral arthritis is usually a nondeforming, asymmetric, oligoarthritis of large joints. Peripheral arthritis may pre-date the onset of the IBD and the activity may be independent of intestinal symptoms. Axial involvement with IBD-associated spondyloarthritis is indistinguishable by symptoms or radiographs from axSpA and follows a course independent of the bowel disease. About 50% of these patients are HLA-B27 positive.

Controlling the intestinal inflammation usually eliminates the arthritis. NSAIDs can be effective for mild arthritis but may exacerbate IBD. TNF inhibitors, JAK inhibitors (tofacitinib, upadacitinib), and anti-IL-12/23 (ustekinumab) can treat both the bowel and joint/axial inflammation.

INFECTIOUS ARTHRITIS

NONGONOCOCCAL ACUTE BACTERIAL (Septic) ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Acute onset of inflammatory monoarticular arthritis, most often in large weight-bearing joints and wrists.
- Common risk factors include previous joint damage and injection drug use.
- Infection with causative organism commonly found elsewhere in body.
- Joint effusions are usually large; synovial fluid WBC counts > 50,000/mcL (50×10^9/L) are common.

General Considerations

Nongonococcal acute bacterial arthritis is most often due to hematogenous seeding of the joint; direct inoculation from penetrating trauma is rare. The key risk factors are bacteremia (eg, injection drug use, endocarditis, infection at other sites), damaged joints (eg, RA), prosthetic joints, compromised immunity (eg, advanced age, diabetes mellitus, advanced CKD, alcohol use disorder, cirrhosis, or immunosuppressive therapy), and loss of skin integrity (eg, cutaneous ulcer or psoriasis). *Staphylococcus aureus* is the most common cause of nongonococcal septic arthritis, accounting for about 50% of all cases. Methicillin-resistant *S aureus* (MRSA) and group B *Streptococcus* are frequent and important causes of septic arthritis. Gram-negative septic arthritis causes about 10% of cases and is especially common with injection drug use and in immunocompromised persons; *Escherichia coli* and *Pseudomonas aeruginosa* are the most common pathogens. Pathologic changes include varying degrees of acute inflammation, with synovitis, effusion, abscess formation in synovial or subchondral tissues, and, if treatment is not adequate, articular destruction.

The arthritis of Lyme disease is discussed in Chapter 39.

Clinical Findings

A. Symptoms and Signs

The onset is acute, with pain, swelling, and heat of the affected joint worsening over hours. The knee is most frequently involved; other commonly affected joints are the hip, wrist, shoulder, and ankle. Unusual sites, such as the sternoclavicular or sacroiliac joint, can be involved in those who use injection drugs. Chills and fever are common but are absent in up to 20% of patients. Infection of the hip usually does not produce apparent swelling but results in groin pain aggravated by walking. More than one joint is involved in 15% of cases of septic arthritis; risk factors for multiple joint involvement include RA, associated endocarditis, and infection with group B streptococci.

B. Laboratory Findings

Synovial fluid analysis is critical for diagnosis. The leukocyte count of the synovial fluid is always inflammatory (> 2000/mcL [2×10^9/L]), usually exceeds 50,000/mcL (50×10^9/L), and often is > 100,000/mcL (100×10^9/L), with ≥ 90% polymorphonuclear cells (Table 23–2). Synovial fluid cell count in septic arthritis may be lower in patients who are immunocompromised, especially those on biologic therapies. Gram stain of the synovial fluid is positive in 75% of staphylococcal infections and 50% of gram-negative infections. Synovial fluid cultures are positive in 70–90% of cases; administration of antibiotics prior to arthrocentesis reduces the likelihood of a positive culture result. Blood cultures are positive in approximately 50% of patients.

C. Imaging

Imaging tests generally add little to the diagnosis of septic arthritis. Other than demonstrating joint effusion, radiographs are usually normal early in the disease; however, evidence of demineralization may develop within days of onset. MRI and CT are more sensitive in detecting fluid in joints that are not accessible to physical examination (eg, the hip). Bony erosions and narrowing of the joint space followed by osteomyelitis and periostitis may be seen within 2 weeks.

D. Prosthetic Joint Infection

The clinical and laboratory manifestations of prosthetic joint infection are influenced by whether the infection is early (< 3 months after surgery), delayed (3–12 months after surgery), or late (> 12 months after surgery). Early infections present with acute redness and swelling and are usually caused by *S aureus* and gram-negative organisms. Delayed infections often present with subtle manifestations: pain is common but only 50% of patients will have fever. Less virulent organisms, such as coagulase-negative *Staphylococcus*, *Propionibacterium acnes*, and enterococci, are common causes of delayed infections. Late infections present with acute pain, swelling, and fever and are often caused by hematogenous seeding of *S aureus*, gram-negative bacilli, and hemolytic streptococci. Elevated synovial biomarkers—namely calprotectin, CRP (synovial), α-defensin, and leukocyte esterase—may be useful in identifying infection.

Differential Diagnosis

Gout and pseudogout can cause acute, very inflammatory monoarticular arthritis and fever; failure to find crystals on synovial fluid analysis excludes these diagnoses. The most common articular manifestation of chronic Lyme disease is inflammatory monoarthritis of the knee, which yields synovial fluid that is Gram stain and culture negative. Acute rheumatic fever commonly involves an inflammatory migratory oligoarthritis. Pyogenic arthritis may be superimposed on other types of joint disease, notably RA. Septic arthritis must be excluded by joint fluid examination in any patient with RA who has a joint strikingly more inflamed than the other joints, especially if the patient is receiving biologic DMARD therapy.

Prevention

The American Academy of Orthopedic Surgeons advocates prescribing antibiotic prophylaxis for any patient with a prosthetic joint replacement who undergoes a procedure that can cause bacteremia. However, the topic remains controversial.

Treatment

Treatment of septic arthritis requires appropriate antibiotic therapy together with drainage of the infected joint. If the likely causative organism cannot be determined clinically or from the synovial fluid Gram stain, treatment should be started with broad-spectrum antibiotic coverage against staphylococci, streptococci, and gram-negative organisms. The recommended initial treatment is vancomycin (1 g intravenously every 12 hours, adjusted for age, weight, and renal function) plus a third-generation cephalosporin: ceftriaxone, 1–2 g intravenously daily (or every 12 hours if concomitant meningitis or endocarditis is suspected); or cefotaxime, 1–2 g intravenously every 8 hours. Antibiotic therapy should be adjusted when culture results become available; the duration of antibiotic therapy is usually 4–6 weeks.

Effective drainage is usually achieved through early arthroscopic lavage and debridement. Options for treating prosthetic joint infections depend, in part, on the timing of the infection and include chronic suppression, debridement without removal of the prosthesis, or one- or two-stage exchange of the prosthesis.

Prognosis

The outcome of septic arthritis depends largely on the antecedent health of the patient, the causative organism (eg, *S aureus* bacterial arthritis is associated with a poor functional outcome in about 40% of cases), and the promptness of treatment. The mortality rate is 30% for patients with polyarticular sepsis. Bony ankylosis and articular destruction commonly occur if treatment is delayed or inadequate.

When to Refer

Early orthopedic consultation is essential.

When to Admit

Hospitalization is necessary for intravenous antibiotic therapy and drainage of the joint.

GONOCOCCAL ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Prodromal migratory polyarthralgias.
- Tenosynovitis is the most common sign.
- Purulent monoarthritis in 50%.
- Characteristic skin lesions, especially of the palms and soles.
- Most common in young women during menses or pregnancy.
- Symptoms of urethritis frequently absent.
- Dramatic response to antibiotics.

General Considerations

In contrast to nongonococcal bacterial arthritis, gonococcal arthritis usually occurs in otherwise healthy individuals. Host factors, however, influence the expression of the disease: gonococcal arthritis is two to three times more common in women than in men, is especially common during menses and pregnancy, and is rare after age 40. Gonococcal arthritis is also common in men who have sex with men, whose high incidence of asymptomatic gonococcal pharyngitis and proctitis predisposes them to disseminated gonococcal infection. Recurrent disseminated gonococcal infection should prompt testing of the patient's CH50 level to evaluate for a congenital deficiency of a terminal complement component (C5, C6, C7, or C8).

Clinical Findings

A. Symptoms and Signs

One to 4 days of migratory polyarthralgias involving the wrist, knee, ankle, or elbow are common at the outset. Thereafter, two patterns emerge. The first pattern is characterized by tenosynovitis that most often affects the wrists, fingers, ankles, or toes and is seen in 60% of patients. The second pattern is purulent monoarthritis that most frequently involves the knee, wrist, ankle, or elbow and is seen in 40% of patients. Less than half of patients have fever, and less than one-fourth have any genitourinary symptoms. Most patients will have asymptomatic, but highly characteristic, skin lesions that usually consist of 2 to 10 small necrotic pustules distributed over the extremities, especially the palms and soles.

B. Laboratory Findings

The peripheral WBC averages about 10,000 cells/mcL (10×10^9/L) and is elevated in less than one-third of patients. The synovial fluid WBC count usually ranges from 30,000 to 60,000 cells/mcL ($30–60 \times 10^9$/L). Positive synovial fluid Gram stain occurs in one-fourth of cases and culture in less than half. Positive blood cultures are uncommon. Urethral, throat, cervical, and rectal cultures should be done in all patients, and are often positive in the absence of local symptoms. Urinary nucleic acid amplification tests have excellent sensitivity and specificity for the detection of *Neisseria gonorrhoeae* in genitourinary sites.

C. Imaging

Radiographs are usually normal or show only soft tissue swelling.

Differential Diagnosis

Reactive arthritis can produce acute monoarthritis, urethritis, and fever in a young person but is distinguished by negative cultures and failure to respond to antibiotics. Lyme disease involving the knee is less acute, does not show positive cultures, and may be preceded by known tick exposure and characteristic rash. The synovial fluid analysis will exclude gout, pseudogout, and nongonococcal bacterial arthritis. Rheumatic fever and sarcoidosis can produce migratory tenosynovitis. Infective endocarditis with septic arthritis can mimic disseminated gonococcal infection. Meningococcemia occasionally presents with a clinical picture that resembles disseminated gonococcal infection; blood cultures establish the correct diagnosis. Rocky mountain spotted fever and dengue can produce arthritis and skin findings. Early hepatitis B infection is associated with circulating immune complexes that can cause an urticarial rash and polyarthralgias.

Treatment

The treatment of disseminated gonorrhea (arthritis-dermatitis syndrome) per CDC guidelines is ceftriaxone (1 g daily intravenously or intramuscularly). Once susceptibility testing has been obtained, 24–48 hours after clinical improvement, the antibiotic regimen can be changed to an oral agent to complete a 7-day course.

Prognosis

Generally, gonococcal arthritis responds dramatically after 24–48 hours of antibiotics, and drainage of the infected joint(s) is rarely needed. Complete recovery is the rule.

When to Refer

Consult an infectious disease specialist for questions about antibiotic resistant gonococcal strains. Report to the public health department for tracing contacts.

When to Admit

Hospitalization is indicated to establish the diagnosis and administer intravenous antibiotics until there is clinical improvement.

Vitiello A et al. Antimicrobial resistance in gonorrhea. Microb Drug Resist. 2024;30:297. [PMID: 38579162]

RHEUMATIC MANIFESTATIONS OF HIV INFECTION

Infection with HIV has been associated with various rheumatic symptoms and may coexist with autoimmune rheumatic diseases, such as RA, psoriatic arthritis, or spondyloarthritis. Acute new HIV infection (viremia) causes severe arthralgias in an oligoarticular, asymmetric pattern that resolve within 24 hours; the joint examination is normal. HIV-associated arthritis is an asymmetric oligoarticular process with objective findings of arthritis and a self-limited course that ranges from weeks to months. Along with antiretroviral therapies, immunosuppressive medications, including biologic agents, can be used if necessary in patients with HIV (see Chapter 36, HIV Infection & AIDS). Muscle weakness associated with an elevated creatine kinase can be due to nucleoside reverse transcriptase inhibitor–associated myopathy or HIV-associated myopathy; the clinical presentations of each resemble idiopathic inflammatory myopathies but muscle biopsies show minimal inflammation. Other rheumatic manifestations of HIV include diffuse infiltrative lymphocytosis syndrome (with parotid gland enlargement) and various forms of vasculitis.

VIRAL ARTHRITIS

Arthralgias occur frequently in the course of acute infections with many viruses, but frank arthritis is uncommon with the notable exceptions of acute parvovirus B19 infection and Chikungunya fever. Parvovirus B19 causes an acute polyarthritis in 50–60% of adult cases (infected children develop the febrile exanthem known as "slapped cheek fever"). The arthritis can mimic RA but is almost always self-limited and resolves within several weeks. The diagnosis is established by the presence of IgM antibodies specific for parvovirus B19. Chikungunya fever is an arthropod-borne viral infection that is endemic to West Africa but has spread to multiple locations including the Indian Ocean islands, the Caribbean and Central and Latin America. Clinical manifestations include high fever, rash, and incapacitating bone pain. Acute polyarthralgia and polyarthritis are common and can persist for months or years. For Chikungunya-associated chronic arthritis, treatment with methotrexate or other DMARD agents may be an option. There is an FDA-approved vaccine for individuals 18 and older at risk for Chikungunya infection.

Self-limited polyarthritis is common in acute hepatitis B infection and typically occurs before the onset of jaundice. Urticaria or other types of skin rash may be present. The clinical picture resembles that of serum sickness. Serum transaminase levels are elevated, and tests for hepatitis B surface antigen are positive. Serum complement levels are often low during active arthritis and become normal after remission of arthritis. The incidence of hepatitis B–associated polyarthritis has fallen substantially with the introduction of hepatitis B vaccination.

Chronic infection with hepatitis C is associated with chronic polyarthralgia (up to 20% of cases) and with chronic polyarthritis (3–5%). This can mimic RA; the presence of rheumatoid factor in most hepatitis C infections leads to further diagnostic confusion. RA always causes objective arthritis (not just arthralgias) and can be erosive (hepatitis C–associated arthritis is nonerosive). The presence of anti-CCP antibodies helps to diagnose RA.

Schneider M et al. Safety and immunogenicity of a single-shot live-attenuated chikungunya vaccine: a double-blind, multicentre, randomised, placebo-controlled, phase 3 trial. Lancet. 2023;401:2138. [PMID: 37321235]

SPINAL TUBERCULOSIS (Pott Disease)

ESSENTIALS OF DIAGNOSIS

- Seen primarily in individuals from developing countries or immunocompromised patients.
- Back pain and gibbus deformity with radiographic evidence of vertebral involvement.
- < 20% have active pulmonary tuberculosis.
- Evidence of *Mycobacterium tuberculosis* in aspirate or biopsies of spinal lesions.

General Considerations

In the developing world, children primarily bear the burden of musculoskeletal tuberculosis. In the United States, however, musculoskeletal infection is more often seen in adults who have immigrated from countries where tuberculosis is prevalent, or it develops in the setting of immunosuppression (eg, HIV infection, therapy with biologic agent). Spinal tuberculosis (Pott disease) accounts for about 50% of musculoskeletal infection due to *M tuberculosis* (see Chapter 9). Seeding of the vertebrae may occur through hematogenous spread from the respiratory tract at the time of primary infection, with clinical disease developing years later due to reactivation, or through lymphatics from infected foci in the pleura or kidneys. The thoracic and lumbar vertebrae are the most common sites of spinal involvement; vertebral infection is associated with paravertebral cold abscesses in 75% of cases.

Clinical Findings

A. Symptoms and Signs

Patients have back pain, often present for months and sometimes associated with radicular pain and lower extremity weakness. Constitutional symptoms are usually absent, and < 20% have active pulmonary disease. Destruction of the vertebral body anteriorly can produce the characteristic wedge-shaped gibbus deformity.

B. Laboratory Findings

Most patients have a positive reaction to purified protein derivative or a positive blood interferon-γ release assay. Cultures of paravertebral abscesses and biopsies of vertebral lesions are positive in up to 70–90%. Biopsies reveal characteristic caseating granulomas in most cases. Isolation of *M tuberculosis* from an extraspinal site is sufficient to establish the diagnosis in the proper clinical setting.

C. Imaging

Radiographs can reveal lytic and sclerotic lesions and bony destruction of vertebrae but are normal early in the disease. CT scanning can demonstrate paraspinal soft tissue extensions of the infection; MRI is the image of choice to detect compression of the spinal cord or cauda equina.

Differential Diagnosis

Spinal tuberculosis must be differentiated from subacute and chronic spinal infections due to pyogenic organisms, *Brucella*, fungi, and malignancy.

Complications

Paraplegia due to compression of the spinal cord or cauda equina is the most serious complication of spinal tuberculosis.

Treatment

Antimicrobial therapy should be administered for 6–9 months, usually in the form of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampin for an additional 4–7 months (see also Chapter 9). Medical management alone is often sufficient. Surgical intervention, however, may be indicated when there is neurologic compromise or severe spinal instability.

MISCELLANEOUS RHEUMATOLOGIC DISORDERS

FIBROMYALGIA

ESSENTIALS OF DIAGNOSIS

- Most frequent in women aged 20–50.
- Chronic widespread musculoskeletal pain syndrome with multiple tender points.
- Fatigue, headaches, memory problems, dysregulated sleep, mood disorders, and increased sensitivity to sensory input frequently co-occur.
- Objective signs of inflammation absent; laboratory studies normal.

General Considerations

Fibromyalgia is a common nociplastic pain syndrome, affecting 3–10% of the general population. It shares many features with myalgic encephalomyelitis/chronic fatigue syndrome, namely, an increased frequency among women aged 20–50, absence of objective findings, and absence of diagnostic laboratory test results. While many of the clinical features of the two conditions overlap, musculoskeletal pain predominates in fibromyalgia, whereas lassitude dominates myalgic encephalomyelitis/chronic fatigue syndrome.

Although the cause of fibromyalgia is unknown, the pathophysiology is aberrant CNS processing of pain and sensory stimuli. Fibromyalgia may coexist with rheumatic and medical conditions, such as SLE, hypothyroidism, RA, or sleep apnea.

Clinical Findings

Chronic aching pain and stiffness are the hallmarks of fibromyalgia. The pain frequently involves the entire body but with prominence around the neck, shoulders, low back, and hips. Fatigue, sleep disorders, numbness with paresthesias, chronic headaches, and irritable bowel symptoms are common. Even minor exertion aggravates pain and increases fatigue. Physical examination is normal except for "trigger points" of pain produced by palpation of various areas such as the trapezius, the medial fat pad of the knee, and the lateral epicondyle of the elbow. There are no specific biomarkers for fibromyalgia, and laboratory studies are generally normal.

Differential Diagnosis

Fibromyalgia is a diagnosis of exclusion. A detailed history and repeated physical examination can obviate the need for extensive laboratory testing. RA and SLE present with objective physical findings and laboratory abnormalities. Thyroid function tests are useful since hypothyroidism can produce a fibromyalgia-like syndrome. The idiopathic inflammatory myopathies produce demonstrable weakness. Polymyalgia rheumatica produces shoulder and pelvic girdle pain, is associated with anemia and elevated ESR, and occurs after age 50. The diagnosis of fibromyalgia should be made hesitantly in a patient over age 50 and should never be invoked to explain fever, weight loss, or any other objective signs or lab abnormalities.

Treatment

A multidisciplinary approach is most effective. Patient education is essential. Patients can be comforted that they have a diagnosable syndrome treatable by specific although imperfect therapies, and that the course is not progressive. Cognitive behavioral therapy, including programs that emphasize mindfulness meditation, is often helpful. Exercise programs are beneficial and should be universally recommended, particularly tai chi, yoga, and resistance exercise. The FDA-approved pharmacotherapies for fibromyalgia are pregabalin (begin with 75 mg orally twice daily and increase to 150 mg twice daily as tolerated), duloxetine (begin with 30 mg orally daily and increase to 60 mg daily as tolerated), and milnacipran (begin with 12.5 mg orally daily and increase to 50 mg twice daily as tolerated). Other pharmacotherapies that have shown modest efficacy are amitriptyline (begin with 10 mg orally nightly and increase as tolerated or needed to 75 mg nightly), tramadol, fluoxetine, cyclobenzaprine, gabapentin, and low-dose naltrexone. NSAIDs are generally ineffective. Cannabinoids may have a role in the treatment of fibromyalgia; however, dose, formulation, and frequency are unknown. Opioids and corticosteroids are ineffective and should not be used. Depression and anxiety are extremely common among patients with fibromyalgia; concurrent treatment of these comorbid conditions is highly recommended.

Prognosis

All patients have chronic symptoms. With treatment, however, many do eventually resume increased activities. Progressive or objective findings do not develop.

THORACIC OUTLET SYNDROMES

Thoracic outlet syndromes result from compression of the neurovascular structures supplying the upper extremity. Symptoms and signs arise from intermittent or continuous pressure on elements of the brachial plexus (more than 90% of cases) or the subclavian or axillary vessels (veins or arteries) by a variety of anatomic structures of the shoulder girdle region. Most commonly thoracic outlet syndromes are caused by scarred scalene neck muscles secondary to neck trauma or sagging of the shoulder girdle resulting from aging, obesity, or pendulous breasts. Faulty posture, occupation, or thoracic muscle hypertrophy from physical activity (eg, weight-lifting, baseball pitching) are other predisposing factors.

CXR will identify patients with cervical ribs (although most patients with cervical ribs are asymptomatic). MRI with the arms held in different positions is useful in identifying sites of impaired blood flow. Intra-arterial or venous obstruction is confirmed by angiography. Determination of conduction velocities of the ulnar and other peripheral nerves of the upper extremity may help localize the site of their compression.

Thoracic outlet syndrome must be differentiated from osteoarthritis of the cervical spine, tumors of the superior pulmonary sulcus, cervical spinal cord, or nerve roots, and periarthritis of the shoulder.

Treatment is directed toward relief of compression of the neurovascular bundle. More than 95% of patients can be treated successfully with conservative therapy consisting of physical therapy and avoiding postures or activities that compress the neurovascular bundle. Operative treatment, required by < 5% of patients, is more likely to relieve the neurologic rather than the vascular component that causes symptoms. The use of botulinum toxin as a diagnostic and therapeutic tool in this condition is controversial.

COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (formerly called reflex sympathetic dystrophy) is a rare disorder of the extremities characterized by autonomic and vasomotor instability. The cardinal symptoms and signs are pain localized to an arm or leg, swelling of the involved extremity, disturbances of color and temperature in the affected limb, dystrophic changes in the overlying skin and nails, and limited range of motion. Strikingly, the findings are not limited to the distribution of a single peripheral nerve. Most cases are preceded by surgery or direct physical trauma, often of a relatively minor nature, to the soft tissues, bone, or nerve. Early mobilization after injury or surgery reduces the likelihood of developing the syndrome. Any extremity can be involved, but the syndrome most commonly occurs in the hand and is associated with ipsilateral restriction of shoulder motion ("shoulder-hand" syndrome). This syndrome proceeds through phases: pain, swelling, and skin color and temperature changes develop early and, if untreated, lead to atrophy and dystrophy. The swelling in complex regional pain syndrome is diffuse ("catcher's mitt hand") and not restricted to joints. Pain is often burning in quality, intense, and greatly worsened by minimal stimuli such as light touch. The shoulder-hand variant of this disorder sometimes complicates MI or injuries to the neck or shoulder. Complex regional pain syndrome may occur after a knee injury or after knee surgery. In the early phases of the syndrome, bone scans are sensitive, showing diffuse increased uptake in the affected extremity; radiographs eventually reveal severe generalized osteopenia. In the posttraumatic variant, this is known as Sudeck atrophy. This syndrome should be differentiated from RA, thoracic outlet obstruction, and mononeuritis multiplex, among others.

Early treatment offers the best prognosis for recovery. For mild cases, NSAIDs (eg, naproxen 250–500 mg twice daily orally) can be effective. For more severe cases associated with edema, prednisone, 30–60 mg/day orally for 2 weeks and then tapered over 2 weeks, can be effective. Pain management is important and allows for effective physical therapy, which is critical to restore function. Some patients may benefit from antidepressant agents (eg, nortriptyline initiated at a dosage of 10 mg orally at bedtime and gradually increased to 40–75 mg at bedtime) or anticonvulsants (eg, gabapentin 300 mg three times daily orally). Bisphosphonates, calcitonin, regional nerve blocks, and dorsal-column stimulation have also been reported to be helpful. Vitamin C supplementation (1 g orally daily) may have a role in preventing the development of complex regional pain syndrome following surgical procedures known to be a risk factor (eg, total knee replacement, foot or ankle surgery). The prognosis partly depends on the stage in which the lesions are encountered and the extent and severity of associated organic disease.

RHEUMATOLOGIC MANIFESTATIONS OF CANCER

Rheumatologic syndromes may be the presenting manifestations for a variety of cancers. Dermatomyositis is often associated with cancer. Hypertrophic pulmonary osteoarthropathy, which is characterized by the triad of polyarthritis, clubbing, and periosteal new bone formation, is associated with both malignant diseases (most commonly lung cancer) and nonmalignant ones (eg, cyanotic heart disease, cirrhosis, and lung abscess). Cancer-associated polyarthritis is rare, has both oligoarticular and polyarticular forms, and should be considered when "seronegative RA" develops abruptly in an older patient. Palmar fasciitis manifests as bilateral palmar swelling with finger contractures and may be the first indication of cancer, particularly ovarian. Remitting seronegative synovitis with non-pitting edema ("RS3PE") presents with a symmetric small-joint polyarthritis associated with non-pitting edema of the hands; it can be idiopathic or associated with malignancy. Palpable purpura due to leukocytoclastic vasculitis may be the presenting complaint in myeloproliferative disorders. Hairy cell leukemia can be associated with medium-sized vessel vasculitis such as polyarteritis nodosa. Acute leukemia can produce severe joint and bone pain without florid synovitis. Rheumatic manifestations of myelodysplastic syndromes include cutaneous vasculitis, lupus-like syndromes, neuropathy, and episodic intense arthritis. Erythromelalgia, a painful warmth and redness of the extremities that (unlike Raynaud) improves with cold exposure or with elevation of the extremity, is often associated with myeloproliferative diseases, particularly essential thrombocythemia.

Immune-related adverse events from immune checkpoint inhibitors used to treat a variety of malignancies include pneumonitis, colitis, myositis, vasculitis, myocarditis, and inflammatory arthritis. These events are common and often can be managed with corticosteroids alone and adjustment of immunotherapy. However, the persistence of some autoimmune conditions despite cessation of cancer treatment, namely inflammatory arthritis, may require long-term immunosuppression.

NEUROGENIC ARTHROPATHY (Charcot Joint)

Neurogenic arthropathy is joint destruction resulting from loss or diminution of proprioception, pain, and temperature perception. Although initially described in the knees of patients with tabes dorsalis, it is more frequently seen in association with diabetic neuropathy (foot and ankle) or syringomyelia (shoulder). As normal muscle tone and protective reflexes are lost, secondary osteoarthritis ensues, resulting in an enlarged, boggy, relatively painless joint with extensive cartilage erosion, osteophyte formation, and multiple loose joint bodies. Radiographs can reveal striking osteolysis that mimics osteomyelitis or dramatic destruction of the joint with subluxation, fragmentation of bone, and bony sclerosis.

Treatment is directed toward the primary disease; mechanical devices are used to assist in weight bearing and prevention of further trauma. Surgical strategies, including arthrodesis, with or without orthobiologics, can be considered if nonsurgical management fails. Pharmacotherapy has not demonstrated efficacy for this condition.

OSTEONECROSIS (Avascular Necrosis of Bone)

Osteonecrosis is a complication of corticosteroid use, alcohol use, trauma, SLE, pancreatitis, gout, sickle cell disease, dysbaric syndromes (eg, “the bends”), factor deficiencies (eg, protein S and antithrombin III) and infiltrative diseases (eg, Gaucher disease). The most commonly affected sites are the proximal and distal femoral heads, leading to hip or knee pain. Other commonly affected sites include the ankle, shoulder, and elbow. Osteonecrosis of the knee can be associated with arthroscopic meniscectomy.

Osteonecrosis of the jaw can be a complication of bisphosphonates, usually when high-dose intravenous bisphosphonate therapy is used for treating metastatic cancer or plasma cell myeloma rather than osteoporosis. Initially, radiographs are normal; MRI, CT scan, and bone scan are more sensitive techniques. Treatment involves avoidance of weight bearing on the affected joint for at least several weeks. The value of surgical core decompression is controversial. For osteonecrosis of the hip, a variety of procedures designed to preserve the femoral head have been developed for early disease, including vascularized and nonvascularized bone grafting procedures. These procedures are most effective in avoiding or forestalling the need for total hip arthroplasty in young patients who do not have advanced disease. Without intervention, the natural history of avascular necrosis is progression of the bony infarction to cortical collapse, resulting in significant joint dysfunction. Total hip replacement is the usual outcome for all patients who are candidates.

ALLERGIC & IMMUNOLOGIC DISORDERS

IMMEDIATE HYPERSENSITIVITY

1. Food Allergy

Immediate hypersensitivity IgE-mediated allergic reactions to foods commonly occur within 2 hours of ingestion and are much less common in adults as a de novo food allergy than in children. Typical systemic reactions include a combination of emesis, diarrhea, urticaria with or without angioedema, bronchial hypersensitivity, and hypotension. A serum tryptase may be elevated during anaphylactic reactions within a few hours after the exposure. The most common systemic food allergies are caused by milk, egg, wheat, soy, fish, shellfish, peanuts, and tree nut allergens. Shellfish, peanuts, and tree nuts are the most common causes of food anaphylaxis in adults; milk and egg allergies are more common in children but often resolve by adulthood. Diagnosis of food allergy is based on a correlative history, skin tests, and serum specific IgE tests. Because of frequent false-positive IgE tests, the use of indiscriminate screening of IgE panels to foods is not recommended; oral food challenge with a reproducible immediate hypersensitivity reaction remains the gold standard for diagnosis. Food challenge, however, should only be conducted by an experienced provider in a setting equipped to treat anaphylaxis. There is no role for specific IgG or IgA testing for evaluating food immediate hypersensitivity. Management of food allergy involves strict avoidance of the food and guaranteed access to epinephrine autoinjectors. The use of oral immunotherapy to treat food allergy in children and adolescents should only be performed by an experienced allergist immunologist.

Other IgE-mediated food reactions include oral allergy syndrome and hypersensitivity to α-gal (galactose-α-1,3-galactose). Oral allergy syndrome and pollen-associated food allergy syndrome result from cross-reactivity between certain food and pollen proteins. Affected individuals have known seasonal pollen allergies (most commonly tree pollens) and experience itching of the oral mucosa upon ingestion of cross-reactive raw fruits and vegetables. In contrast to systemic food allergy, symptoms are mostly limited to the oropharynx.

Cafarotti A et al. Management of IgE-mediated food allergy in the 21st century. Clin Exp Allergy. 2022;00:1. [PMID: 36200952]

2. Venom Allergy

Most systemic allergic reactions to insect stings are caused by honeybees, vespids (yellow jackets, hornets, wasps, honeybee), and fire ants. Systemic anaphylactic reactions can occur after stinging events at any age. Patients at highest risk for anaphylaxis from subsequent stings are those who have had a history of recent or severe reactions, or both; thus, the risk of a systemic reaction declines over elapsed time since the last sting. If a systemic allergy is suspected because symptoms include generalized urticaria, anaphylaxis, angioedema, wheezing, or diarrhea, refer the patient to an allergist for confirmative venom allergy testing; initiation of venom immunotherapy is commonly recommended. In the interim, patients should be given self-administrated epinephrine for those with continuing exposure.

Adams KE et al. Anaphylaxis to stinging insect venom. Immunol Allergy Clin North Am. 2022;42:161. [PMID: 34823745]

3. Anaphylaxis

General Considerations

Anaphylaxis is the most serious and potentially life-threatening manifestation of mast cell and basophil mediator release. The National Institute of Allergy and Infectious

Table 23–13. NIAID/FAAN consensus criteria for anaphylaxis. Anaphylaxis is likely when any one of the three criteria is fulfilled.

Presentation	Time to Onset of Symptoms	Clinical Manifestations
Criterion 1: Acute onset of illness	Minutes to 2–3 hours	One of the following combinations of symptoms: Skin or mucosal symptoms, or both[1] *with* Respiratory compromise[2] *or* ↓ blood pressure or end-organ dysfunction[3]
Criterion 2: After exposure to *likely* allergens	Minutes to 2–3 hours	Involvement of ≥ 2 of the following systems: Skin or mucosa, or both[1] Respiratory compromise[2] ↓ blood pressure or end-organ dysfunction[3] Persistent GI symptoms[4]
Criterion 3: After exposure to *known* allergens	Minutes to 2–3 hours	Involvement of the cardiovascular system: ↓ blood pressure

[1] Indicates presence of pruritus, flushing, hives, or angioedema.

[2] Indicates presence of dyspnea, wheeze-bronchospasm, decreased peak expiratory flow, stridor, or hypoxemia.

[3] Indicates decreased blood pressure; end-organ dysfunction includes collapse, syncope, or incontinence.

[4] Indicates presence of vomiting, crampy abdominal pain, or diarrhea.

FAAN, Food Allergy and Anaphylaxis Network; NIAID, National Institute of Allergy and Infectious Disease.

Reproduced with permission from Renae Boerneke and Mildred Kwan, University of North Carolina and Sampson HA, Muñoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report–Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol*. 2006;117(2):391–397.

Diseases/Food Allergy and Anaphylaxis Network definition of anaphylaxis and criteria for diagnosis are shown in Table 23–13. Anaphylaxis is likely under these circumstances: (1) an allergen exposure followed by the acute onset of illness involving skin or mucosal tissue and either respiratory compromise or hypotension (systolic blood pressure < 90 mm Hg or 30% less than known baseline); (2) a likely allergen exposure followed by the acute onset of two or more of these conditions: skin or mucosal tissue involvement, respiratory compromise, hypotension, and persistent GI symptoms; or (3) a known allergen exposure followed by hypotension.

IgE-dependent anaphylaxis is an acute syndrome initiated by a repeat allergen exposure after a prior exposure has sensitized the patient with anti-allergen IgE antibodies; IgE-mediated anaphylaxis cannot occur on first-time exposure to allergens like medications, insect venoms, latex, and foods. Conversely, other anaphylactic reactions (sometimes called “anaphylactoid”), such as radiocontrast media, certain medications (most NSAIDs, opioids, and vancomycin), and COVID mRNA vaccine reactions, are due to different immunologic mechanisms and can occur with first-time exposure.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs typically start within 30 minutes of initial exposure but may rarely appear up to several hours later. These include: (1) skin manifestations (typically urticaria, flushing, blotchy rashes, and pruritus); (2) respiratory distress (wheezing, stridor, bronchospasm, and airway angioedema); (3) GI symptoms (cramping, emesis, and diarrhea [especially in food allergy]); and (4) hypotension. Anaphylaxis is potentially fatal, especially if untreated.

B. Laboratory Findings

Laboratory evaluation obtained shortly after onset of symptoms can support a diagnosis of anaphylaxis but should not take the place of expedient treatment. Elevated serum tryptase within 4–6 hours following onset of anaphylaxis is most useful because it is a specific biomarker of mast cell degranulation. Plasma histamine generally peaks 30 minutes after onset of symptoms, making it difficult to obtain during peak levels. Referral to an allergist is necessary because of concern for future reactions and need for appropriate education and intervention. Specific serum IgE or skin testing to suspected allergens may be performed optimally 4–6 weeks after a severe reaction; this delayed testing is to avoid falsely negative testing during a post-reaction “refractory” period where IgE consumed during anaphylaxis has not yet been regenerated. The positive predictive value of these tests depends highly on a suggestive temporal relationship to a suspected allergen exposure.

Treatment

Administration of intramuscular epinephrine (0.01 mg/kg of a 1:1000 [1 mg/mL] solution, maximum 0.5 mg in adults) at the onset of suspected anaphylaxis is the cornerstone of therapy and should not be delayed. There is no absolute contraindication to administering intramuscular epinephrine in the setting of anaphylaxis. Supportive measures, such as oxygen, intravenous fluids and, if required, airway management are also appropriate. Adjunctive therapies may include antihistamines, bronchodilators, and corticosteroids. Self-administered epinephrine at the earliest signs of recurrence can be life-sparing, whereas antihistamines and corticosteroids have limited value in reversing anaphylaxis.

When to Refer

Patients with new or unexplained onset of anaphylaxis should be evaluated by an allergist.

Alvarez-Arango S et al. Non-IgE-mediated immediate drug-induced hypersensitivity reactions. J Allergy Clin Immunol Pract. 2024;12:1109. [PMID: 38423288]

ALLERGY TESTING

Cutaneous or skin prick allergen testing produces a localized pruritic wheal (induration) and flare (erythema) that is maximal at 15–20 minutes. Such testing is used most commonly to diagnose allergic respiratory disease (rhinitis and asthma) and IgE-mediated allergy to food, drugs (penicillins), and *Hymenoptera* venom. Allergen extracts are available for pollens, fungi, animal danders, and dust mites and are appropriately selected for the patient's geographic area.

ADVERSE DRUG REACTIONS

1. Drug Allergy (IgE-mediated Immediate Hypersensitivity Reactions)

Prick skin testing for most low-molecular-weight drugs is not validated and is interpretable only if the test is positive at a nonirritating concentration. Testing for IgE-mediated allergy to penicillin (PCN) is validated; skin testing with the metabolic determinants of PCN has a high (> 98%) negative predictive value. Referral of individuals with a listed PCN allergy to an allergist for evaluation is worthwhile because more than 90% have either lost sensitization or do not have a true PCN allergy. Such patients may then safely receive β-lactam antibiotics, including penicillins and cephalosporins. Allergy testing to non-PCN drugs is more limited; an allergist may provide guidance about whether re-challenging with the drug would be advisable.

Banerji A et al. Drug allergy practice parameter updates to incorporate into your clinical practice. J Allergy Clin Immunol Pract. 2023;11:356. [PMID: 36563781]

2. Non-IgE–Mediated Anaphylactic Drug Reactions

Non-IgE–mediated anaphylaxis induced by drugs resembles immediate hypersensitivity reactions but is not mediated by allergen-IgE cross-linking on mast cells or basophils. Contrary to IgE-mediated reactions, these reactions can often be prevented by prophylactic medical regimens.

A. Radiocontrast Media Reactions

Reactions to radiocontrast media are not usually IgE antibody–mediated, yet they are clinically similar to anaphylaxis and can be life-threatening. If a patient has had an anaphylactoid reaction to conventional radiocontrast media, the risk for a second reaction upon re-exposure may be as high as 30%. Patients with a history of atopy are at increased risk.

Management includes use of low-osmolality contrast preparations and prophylactic administration of prednisone (50 mg orally every 6 hours beginning 13 hours before the procedure) and diphenhydramine (25–50 mg orally, intramuscularly, or intravenously 60 minutes before the procedure). Using lower-osmolality radiocontrast media in combination with the pretreatment regimen decreases the incidence of recurrent reactions to < 1%.

B. Vancomycin Infusion Reaction

Vancomycin infusion reaction causes non-IgE–mediated anaphylaxis with flushing, pruritus, and erythema of the upper body. Initially described as a vancomycin infusion reaction, it can also occur after intravenous infusion of opioids. The reaction is related to the rate of drug administration resulting in direct activation of mast cells. Management includes administration of an antihistamine such as diphenhydramine, 25–50 mg intravenously or intramuscularly, and re-initiation of the vancomycin infusion at no more than half the former rate. In patients who have previously experienced a vancomycin infusion reaction, premedication with an H_1-antagonist (eg, diphenhydramine 50 mg orally or intravenously) and H_2-antagonist (eg, cimetidine 200 mg orally) is recommended 1 hour before the infusion. Although rare, anaphylaxis with vancomycin use can occur. Vancomycin skin testing has not been validated as a diagnostic tool. Induction of tolerance to vancomycin is possible for patients with anaphylaxis without an acceptable alternative antibiotic.

DELAYED DRUG HYPERSENSITIVITY

Type IV delayed hypersensitivity typically occurs 48–72 hours after contact with the antigen.

1. Drug Exanthems

The clinical manifestation of drug exanthems is vast (see Chapter 6), ranging from common morbilliform rashes to severe cutaneous adverse reactions (SCARs) (eg, Stevens-Johnson syndrome [SJS]/toxic epidermal necrolysis [TEN], drug reaction with eosinophilia and systemic symptoms [DRESS], acute generalized exanthematous pustulosis [AGEP]). Given the broad range of cutaneous findings, the differential diagnosis includes miliaria, lichen planus, folliculitis, pityriasis rosea, tinea corporis, and mycosis fungoides. While many drugs can cause exanthems, there are no commercially available laboratory or other diagnostic tests to reliably confirm these adverse reactions.

Management consists of immediate cessation of suspected medications and monitoring for symptom resolution. Systemic corticosteroids may be indicated for extensive dermatitis or other organ involvement.

2. Severe Cutaneous Adverse Reactions (SCARs)

A. Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis (SJS/TEN)

SJS and TEN comprise a spectrum of disease that are differentiated by the severity of skin detachment, ranging from < 10% in SJS to > 30% in TEN. Drugs and infections are the main etiologies and include anticonvulsants, sulfonamide antibiotics, NSAIDs, allopurinol, *Mycoplasma pneumoniae,* and herpes simplex virus. Allopurinol hypersensitivity is increased with the HLA-B*58:01 allele, the prevalence of which is highest in Han Chinese, Korean, and Thai persons, as well as in Black individuals. Testing for the HLA-B*58:01 allele before starting allopurinol is conditionally recommended for these patients. Universal testing for HLA-B*58:01 is not recommended. See Chapter 6.

B. Drug Reaction with Eosinophilia & Systemic Symptoms (DRESS)/Drug-Induced Hypersensitivity Syndrome (DIHS)

DRESS typically includes eosinophilia, lymphocytosis, and systemic symptoms such as fever and lymph node enlargement, along with rash. DRESS and DIHS likely are part of a continuum of disease with DIHS representing a more severe form of DRESS with HHV-6 (see Chapter 6). A limited number of drugs are implicated in induction of DRESS including anticonvulsants, sulfonamide antibiotics (eg, sulfasalazine), allopurinol, minocycline, dapsone, and vancomycin. The diagnosis may be aided with the use of the RegiSCAR score for DRESS (https://www.researchgate.net/figure/The-RegiSCAR-scoring-system-for-diagnosing-DRESS-syndrome_tbl1_317485615).

C. Acute Generalized Exanthematous Pustulosis (AGEP)

AGEP is characterized by hundreds of small, pruritic, sterile pustules on an erythematous base distributed mainly on the trunk and intertriginous areas. Onset of AGEP occurs within hours to days following the initiation of the culprit drug. In addition to pustules, mucosal involvement is minimal to none and, if present, is only found in a single site such as the lips or buccal mucosa. Many patients will have fever and neutrophilia (> 7.5×10^6/mL).

Treatment of AGEP includes cessation of the suspected drug with resolution of symptoms within a few days. The area of skin involved desquamates as the patient recovers. Mortality occurs in < 5% of patients. Wet dressings and antiseptic solutions applied while the patient has active pustules is recommended; antibiotics should be used only if there is pustular superinfection. The utility of other treatments such as systemic corticosteroids is unclear.

3. Aspirin- & NSAID-Exacerbated Respiratory Disease

Aspirin- and NSAID-exacerbated respiratory disease is caused by aberrant arachidonic acid metabolism.

Patients typically have increased airway responsiveness, bronchospasm, rhinorrhea, and nasal congestion. Chronic rhinosinusitis with nasal polyps and asthma is called aspirin-exacerbated respiratory disease (formally known as Samter's triad). Ocular, cutaneous, and gastric symptoms may also occur. Diagnosis is largely based on history and clinical findings. A positive aspirin challenge can demonstrate NSAID hypersensitivity and may suggest benefit from nasal polypectomy and aspirin desensitization. Long-term aspirin therapy following desensitization has been shown to reduce the need for nasal polypectomy and asthma therapy. Referral to an allergist is appropriate for aspirin desensitization. Treatment may also include montelukast or inhibition of 5-LOX with zileuton.

Haque R et al. Clinical evaluation and diagnosis of aspirin exacerbated respiratory disease. J Allergy Clin Immunol. 2021;148:283. [PMID: 34364538]

PRIMARY IMMUNODEFICIENCY DISORDERS IN ADULTS

Primary immunologic deficiency diseases are estimated to affect 1 in 4000 individuals; most are genetically determined and present in early childhood. Nonetheless, several important immunodeficiency disorders present in adulthood, most notably the antibody deficiency syndromes: selective IgA deficiency, common variable immunodeficiency (CVID), and specific (functional) antibody deficiency. Antibody deficiency predisposes patients to recurrent serious bacterial infections, particularly of the respiratory tract, including refractory chronic rhinosinusitis, bronchitis, pneumonia, and bronchiectasis. Patients are most susceptible to infections with encapsulated bacteria (eg, *Haemophilus influenzae* type b, *Streptococcus pneumoniae, Neisseria meningitides*). However, the innate or cellular immune system can be defective to varying degrees, which results in infections with different spectra of organisms depending on the severity of the immune defect.

1. Selective IgA Deficiency

Selective IgA deficiency is the most common primary immunodeficiency and is characterized by undetectable serum IgA levels (< 7 mg/dL) with normal levels of IgG and IgM (Table 23–14); its prevalence is about 1 in 500 individuals, with a higher prevalence in White persons. Most individuals are healthy, and the IgA deficiency is found incidentally. A minority of patients have recurrent bacterial infections such as sinusitis, otitis, bronchitis, and GI infections. Selective IgA deficiency is associated with an increased incidence of atopic and autoimmune disorders, including Graves disease, SLE, juvenile rheumatoid arthritis, type 1 diabetes mellitus, and celiac disease.

Some individuals with undetectable levels of serum IgA have high titers of anti-IgA, IgG, or IgE antibodies and are at risk for anaphylactic reactions to IgA after infusions of plasma (or other blood transfusions). Immune globulin replacement therapy (IgG-RT) is not indicated for selective IgA deficiency and may result in anaphylaxis from

Table 23–14. Selected primary immunodeficiency syndromes.

Disease	Clinical Presentation	Diagnosis[1]	Treatment
Complement disorders	"Early" complement component (C1–C4) deficiencies: autoimmune diseases "Late" complement component (C5–C8) deficiencies: recurrent meningococcal or gonococcal infections	Screen with CH50 and AH50. Obtain individual serum complement levels if abnormal. **Genetic testing if complement level absent.**	Prompt administration of antibiotics and *Neisseria* vaccination if C5–C8 deficient. Immune suppression if C1–4 deficient to treat organ specific autoimmunity.
Good syndrome	Current or past thymoma, recurrent severe sinopulmonary infections, may also have opportunistic infections.	**Hypogammaglobulinemia (IgG, IgM, IgA), absent B cells on flow cytometry**, may present with pure red cell aplasia or cytopenias. **Chest film consistent with thymoma.**	IgG-RT (subcutaneously or intravenously) 300 mg–600 mg/kg/month
Hereditary angioedema	Unpredictable swelling of face, lips, tongue, hands, feet; no urticaria; GI tract swelling causing severe abdominal pain	**Decreased C1 esterase inhibitor serum level and/or function**, decreased serum C4 level.	Prophylactic treatment: Danazol, tranexamic acid Acute treatment: C1 esterase inhibitor product, kallikrein inhibitor, bradykinin receptor antagonist
Granulocyte disorders	Recurrent invasive skin and soft tissue infections, abscesses requiring incision and drainage Common organisms are *Staphylococcus aureus*, gram-negative bacilli, *Nocardia, Aspergillus*	CBC with differential to evaluate neutrophil count. **Dihydrorhodamine assay confirming defective oxidative burst. Genetic testing confirming diagnosis.**	Antimicrobial prophylaxis; interferon for chronic granulomatous disease

[1] **Key diagnostic findings in bold.**

preparations that contain detectable amounts of IgA. Notably, IgG-RT does not treat IgA deficiency since there is little IgA present in IgG-RT products.

When to Refer

- Refer patients with undetectable serum IgA and recurrent sinopulmonary infections, celiac disease, giardiasis, or a family history of immunodeficiency to an immunologist.
- Healthy, asymptomatic individuals with IgA deficiency do not need a referral.

2. Common Variable Immunodeficiency (CVID)

ESSENTIALS OF DIAGNOSIS

- Recurrent, severe sinopulmonary infections secondary to humoral immune deficiency.
- Two or more low (< 2 standard deviations) serum immunoglobulin levels (IgG, IgA, IgM) and deficient functional antibody responses to vaccination.
- Importantly, other causes for hypogammaglobulinemia and recurrent sinopulmonary infections have been ruled out.

General Considerations

CVID is a heterogeneous immunodeficiency characterized by recurrent, severe sinopulmonary infections with hypogammaglobulinemia and inadequate vaccination responses. Approximately half of patients with CVID will also have autoimmune disease with or without neoplastic disease. CVID onset is generally in adolescence or early adulthood, but it can occur at any age, mostly due to delay in diagnosis. Most cases are sporadic; about 10–20% are familial. Thus, routine immunoglobulin screening of family members without severe symptoms is not advised, albeit patients with CVID may have family members with a higher incidence of autoimmune disease or IgA deficiency. Since the genetic defect is not known, patients with CVID and their offspring are not recommended to undergo genetic testing unless advised by an immunologist or geneticist.

Clinical Findings

A. Symptoms and Signs

Increased susceptibility to serious infections, especially with encapsulated organisms leading to pneumonia and pyogenic infections, is the hallmark of CVID. Virtually all patients have recurrent bacterial sinusitis, bronchitis, and otitis, but it is the recurrent pneumonia that sets these individuals apart from patients with severe atopy. Infections may be prolonged or associated with unusual complications such as meningitis, empyema, or sepsis. Bronchiectasis occurs in more than 25% of patients who are not treated with IgG-RT and is a leading cause of morbidity. Recurrent viral infections are not prototypic of the disease, albeit varicella-zoster reactivation, CMV reactivation, and increased symptomatic disease from other herpes viruses and *Candida* can occur in some patients.

GI infections and autoimmunity are commonly associated with CVID. Many patients will develop an inflammatory sprue-like syndrome, with diarrhea, steatorrhea, malabsorption, protein-losing enteropathy, and hepatosplenomegaly. Norovirus and *Giardia* infections can be chronic and refractory to treatment. Paradoxically, there is an increased incidence of autoimmune disease (20%) in patients with CVID, although they rarely display prototypic serologic markers as they are hypogammaglobulinemic. Autoimmune cytopenias are most common, but autoimmune endocrinopathies, seronegative rheumatic disease, and the aforementioned GI disorders are also commonly seen. Lymph nodes may be enlarged in patients with CVID, yet biopsies show marked reduction in plasma cells. Noncaseating granulomas mimicking sarcoidosis can be found in the spleen, liver, lungs, or skin. There is an increased propensity for the development of B-cell neoplasms (50- to 400-fold increased risk of lymphoma) and gastric carcinomas.

B. Laboratory Findings

The serum IgG level is reduced at least two standard deviations below normal in most patients. IgA, IgM, or both, also are reduced two standard deviations below normal; it is common that IgA is undetectable. Demonstration of impaired antibody production in response to vaccination is essential and is performed by checking antibody response to polysaccharide (pneumococcal 23 serotypes, *H influenzae* type b) and protein (tetanus, diphtheria) antigens at baseline and 4–6 weeks after vaccination. The diagnosis is made in patients who have ≥ 2 reduced serum immunoglobulin classes and poor antibody response to vaccines after exclusion of secondary causes (eg, proteinuria, protein-losing enteropathy, drug effects from immunosuppressants, antiepileptics, hematologic malignancies) (Table 23–14).

The absolute B-cell count in the peripheral blood, however, can be normal. A subset of patients with CVID have concomitant T-cell immunodeficiency with increased numbers of activated CD8 cells, splenomegaly, and decreased delayed-type hypersensitivity.

Differential Diagnosis

Secondary causes of hypogammaglobulinemia must be excluded (Table 23–15). Secondary causes of recurrent sinopulmonary infections to also exclude are severe atopic disease, COPD, current or past prolonged cigarette smoking, chronic sinusitis, cystic fibrosis, Kartagener syndrome, and colonization with multi-drug–resistant bacteria.

Treatment

In addition to IgG-RT, patients should be treated aggressively with antibiotics at the first sign of infection. Since antibody deficiency predisposes patients to high-risk pyogenic infections, antibiotic coverage should cover encapsulated bacteria. Infections with other microorganisms can develop including viruses, parasites, and extracellular gram-positive or gram-negative bacteria (such as *S aureus* or *P aeruginosa*). The standard of care for preventive

Table 23–15. Secondary causes of hypogammaglobulinemia.

Medications	Infections	Malignancy and Transplantation	Protein-Losing Enteropathy
Anti-CD20 therapy (rituximab, ocrelizumab, ofatumumab, ublituximab, or biosimilars)	*Clostridioides difficile* with colitis	Chronic lymphocytic leukemia	Amyloidosis
Antiepileptics (carbamazepine, phenytoin, valproate)	Cytomegalovirus	GI malignancy	Celiac disease with diarrhea
Bortezomib	HIV	Good syndrome	Congenital disorders of glycosylation
BTK inhibitors	Small intestinal bacterial overgrowth	Graft-versus-host disease	Congenital heart disease
CD19 CAR-T-cell therapy	Whipple disease	Multiple myeloma	Eosinophilic gastroenteritis
Clozapine		Non-Hodgkin lymphoma	Erosive gastritis
Corticosteroids		Solid organ transplantation	IBD
Cyclophosphamide			Lymphocytic gastritis
Mycophenolate mofetil			NSAID enteropathy
Methotrexate			Peritonitis
Purine analogs (azathioprine, cladribine, fludarabine)			Primary and secondary lymphangiectasia

therapy is IgG-RT. The preferred method of administration of IgG-RT is by subcutaneous injections, 300–600 mg/kg monthly in divided weekly doses, which offers the convenience of self-administration and lower incidence of adverse effects. Adjustment of the dosage or injection interval is made primarily based on clinical responses in addition to serum IgG levels. Such therapy is essential for decreasing the incidence of potentially life-threatening infections, increasing quality of life, and reducing the progression of lung disease. IgG-RT can be administered intravenously, but this is less common due to the improved cost, ease of administration, fewer systemic side effects, and more stable IgG levels achieved with subcutaneous administration.

When to Refer

- Refer patients with ≥ 2 low serum immunoglobulins and recurrent serious or unusual infections to a clinical immunologist with expertise in immunodeficiency.
- The presence of bronchiectasis without a known underlying cause such as cystic fibrosis or Kartagener syndrome should raise the suspicion of a primary immunodeficiency and would warrant further evaluation by a clinical immunologist.
- Patients with granulomatous disease (resembling sarcoidosis) who have had recurrent, severe infections should be evaluated by a clinical immunologist.

3. Specific (Functional) Antibody Deficiency

Specific antibody deficiency is characterized by decreased or absent IgG antibody response to vaccines in the setting of normal or mildly decreased serum immunoglobulin levels. The clinical spectrum can range from mild symptoms that can be managed with antibiotics and vaccination to, more rarely, recurrent infections with features very similar to CVID. Since this can be a nuanced diagnosis, recommendations are to refer to a clinical immunologist for diagnosis and treatment recommendations.

4. Immunoglobulin Subclass Deficiency

There are four subclasses of IgG: IgG_1, IgG_2, IgG_3, and IgG_4. A low level of at least one IgG subclass has been found incidentally in 2% of the population. Thus, low or absent IgG subclass levels alone are not sufficient for a diagnosis of immunodeficiency, and IgG-RT is not clinically indicated unless other functional impairments (as discussed in the diagnosis of CVID) in the immune system are identified.

5. Secondary Hypogammaglobulinemia

Secondary causes of hypogammaglobulinemia, rather than from a primary genetic defect, are more likely to occur in the older population due to an increase in comorbid conditions and medications. Some malignancies, immunosuppressants, anti-psychotic medications, chronic diarrhea, sepsis, nephrosis, and HIV have known associations with hypogammaglobulinemia (Table 23–15). The principal therapy of secondary hypogammaglobulinemia is treatment of the underlying condition or removal of the offending medication. If hypogammaglobulinemia is persistent or severe with recurrent infections, consultation with an allergist immunologist is recommended to determine whether treatment should include IgG-RT, vaccination boosters, or antibiotic prophylaxis.

Otani IM et al. Practical guidance for the diagnosis and management of secondary hypogammaglobulinemia: a work group report of the AAAAI Primary Immunodeficiency and Altered Immune Response Committees. J Allergy Clin Immunol. 2022;149:1525. [PMID: 35176351]

Electrolyte & Acid-Base Disorders

24

Nayan Arora, MD, FASN
J. Ashley Jefferson, MD, FRCP

ASSESSMENT OF THE PATIENT

The pathophysiology of all electrolyte disorders is rooted in basic principles of total body water and its distribution across fluid compartments. The optimal evaluation and treatment of fluid and electrolyte disorders requires a careful interpretation of serum and urine chemistries in conjunction with a thorough history and physical examination. While classic teaching has focused on physical examination to determine a patient's volume status, such an approach can be challenging because of limitations in accurate bedside analysis of volume status.

A. Body Water and Fluid Distribution

Total body water depends on the relative proportions of muscle and fat in the body. Total body water is typically estimated as 50% of body weight in women and 60% in men, as women, on average, have a higher proportion of fat to body weight (Table 24–1). Total body water tends to decrease with age due to declining muscle mass. Approximately two-thirds of total body water is located in the intracellular compartment and one-third in the extracellular compartment. The volume in the extracellular compartment is further divided into two components: the interstitial fluid (15% of body weight) and the plasma fluid (5% of body weight).

Changes in total body water content are best evaluated by documenting changes in body weight. Extracellular volume (ECV) may be assessed by physical examination (eg, blood pressure, pulse, jugular venous distention, peripheral or central edema). Quantitative assessments of ECV and intravascular volume may be invasive (ie, CVP assessed via a catheter or pulmonary wedge pressure from right heart catheterization) or noninvasive (ie, inferior vena cava diameter and right atrial pressure assessed by surface echocardiography). Intracellular volume (ICV) is assessed using the serum sodium concentration.

Table 24–1. Total body water (as percentage of body weight) in relation to age and sex.

Age	Male	Female
18–40	60%	50%
41–60	60–50%	50–40%
Over 60	50%	40%

B. Serum Electrolytes

Under healthy conditions, serum electrolytes are maintained within a narrow range by the kidneys (homeostasis). The serum level of an electrolyte may be normal, elevated, or decreased but may not correlate with the total body levels of that electrolyte due to shift of water or electrolytes into and out of cells.

C. Evaluation of Urine

The urine concentration of an electrolyte is helpful to determine whether the kidney is excreting or retaining the electrolyte in response to high or low serum levels. A 24-hour urine collection for daily electrolyte excretion remains the gold standard for assessment of renal electrolyte handling; however, the collection process can be cumbersome, as well as technically challenging in certain patients. A more convenient method to determine renal electrolyte handling is the use of fractional excretion (FE) of an electrolyte X (FE_x), which is calculated from a spot urine sample and concomitant serum sample, using creatinine (Cr):

$$\mathrm{FE}_x(\%) = \frac{\mathrm{urine}_x \times \mathrm{serum}_{Cr}}{\mathrm{serum}_x \times \mathrm{urine}_{Cr}} \times 100$$

A low fractional excretion indicates renal reabsorption (electrolyte retention), while a high fractional excretion indicates renal wasting (electrolyte excretion). Thus, fractional excretion helps determine whether the kidney's response is appropriate for a specific electrolyte disorder.

D. Serum Osmolality

Total solute concentration is measured by osmolality in millimoles per kilogram. Osmolarity is measured in millimoles of solute per liter of solution. These terms are often used interchangeably in clinical medicine. Plasma osmolality is the total concentration of all the solutes contained in plasma, both electrolytes and non-electrolytes, and normally ranges between 285 and 295 mOsm/kg. Differences in osmole concentration across cell membranes lead to movement of water to the region of higher osmolality. Substances that easily permeate cell membranes (eg, urea, ethanol) are ineffective osmoles and do not cause fluid shifts across fluid compartments. High serum osmolality stimulates thirst and increases secretion of antidiuretic hormone (ADH).

Serum osmolality (Osm) can be estimated using the following formula:

$$\text{Osm} = 2(\text{Na}^{+}\ \text{mEq/L}) + \frac{\text{Glucose mg/dL}}{18} + \frac{\text{BUN mg/dL}}{2.8}$$

(*Note:* dividing urea by 2.8 converts mg/dL to mmol/L; dividing glucose by 18 converts mg/dL to mmol/L)

Sodium is the major extracellular cation; in the body doubling the serum sodium in the formula for estimated osmolality accounts for corresponding anions. A discrepancy between measured and estimated osmolality of > 10 mmol/kg suggests an osmolar gap, which is due to the presence of unmeasured osmoles such as ethanol, methanol, isopropanol, and ethylene glycol (see Table 43–5).

DISORDERS OF SODIUM CONCENTRATION

HYPONATREMIA

ESSENTIALS OF DIAGNOSIS

- Must know volume status as well as serum and urine osmolality to determine etiology.
- Hyponatremia usually reflects excess water retention rather than sodium deficiency. The serum sodium concentration is not a measure of total body sodium.
- Hyponatremia in hospitalized patients is commonly caused by administration of hypotonic fluids.

General Considerations

Hyponatremia is defined as a serum sodium concentration < 135 mEq/L (135 mmol/L) and is the most common electrolyte abnormality encountered in clinical practice. Hyponatremia represents an excess of water relative to sodium in the plasma leading to a reduction in plasma osmolality and subsequent movement of water from the extracellular fluid into the intracellular fluid compartment. If this movement of water happens acutely, cerebral edema can occur, increasing the risk of seizures and even brain herniation.

Chronic hyponatremia is often asymptomatic or presents with mild confusion, nausea, or falls; cerebral adaptation occurs as the brain cells excrete intracellular osmoles to limit cellular swelling. In this chronic setting, hyponatremia is traditionally corrected slowly due to concern for instigating profound neurologic abnormalities (osmotic demyelination syndrome). However, this concern has been challenged by recent studies; in practice, osmotic demyelination is rare, suggesting factors other than correction rates are likely implicated. Regardless, caution is still recommended when correcting chronic hyponatremia in terms of the rate of hypertonic fluid administration.

A common misconception is that hyponatremia is secondary to a deficiency in total body sodium; however, it usually reflects an excess of total body water. The basic pathophysiologic principle is that more water (oral or intravenous) is ingested than the kidney can excrete (commonly due to the action of ADH). A diagnostic algorithm (Figure 24–1) separates the causes of hyponatremia using serum osmolality, urine sodium, and volume.

Etiology

A. Isotonic and Hypertonic Hyponatremia

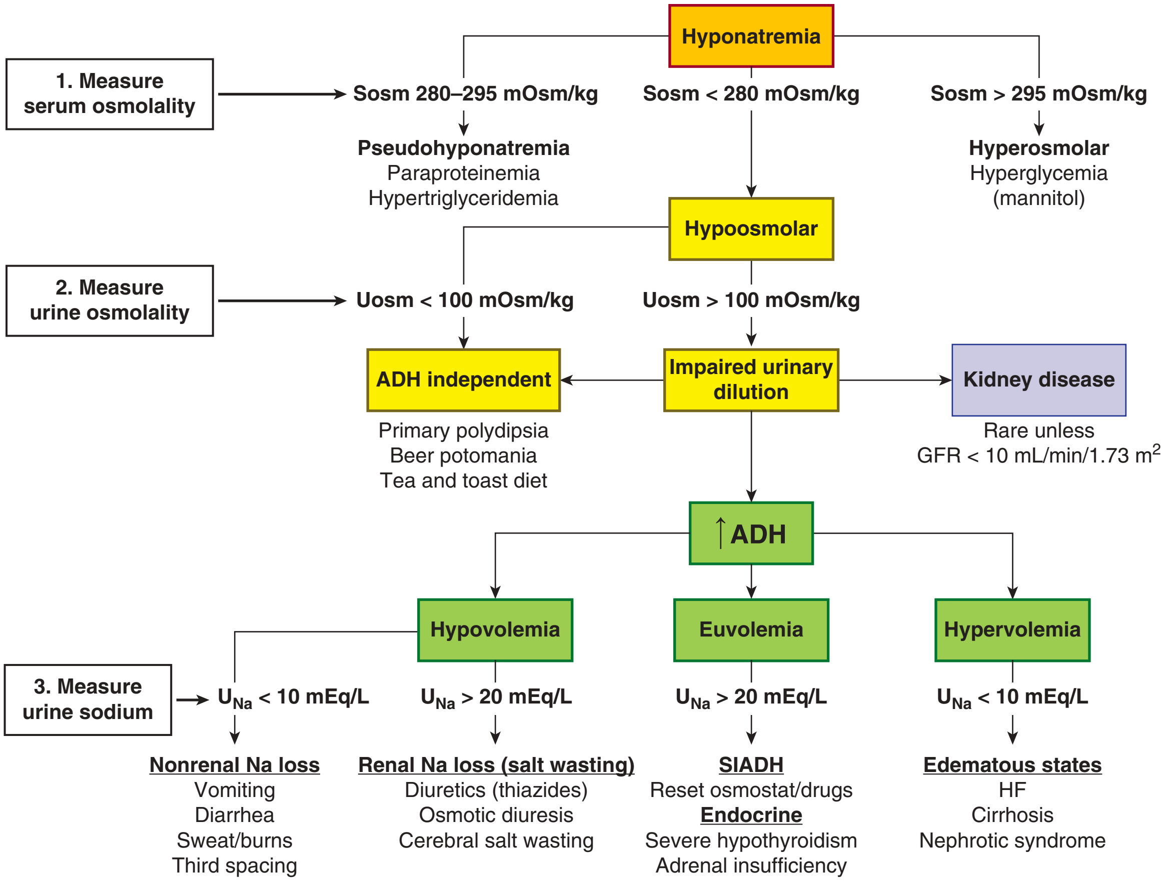
Hyponatremia is typically associated with hypoosmolality with two exceptions: pseudohyponatremia and hypertonic hyponatremia.

1. Pseudohyponatremia—This represents a rare laboratory artifact in patients with marked hypertriglyceridemia or hypergammaglobulinemia. In these settings, there is an increase in the solid components of plasma, relative to plasma water, resulting in a lower sodium level per given volume. This issue has become less prevalent since most laboratories now use direct ion selective electrodes without blood dilution. Consult the clinical laboratory if this condition is suspected.

2. Hypertonic hyponatremia—The best clinical examples of this situation occur in the setting of hyperglycemia. Glucose is an active osmole that increases the osmolality of the extracellular fluid, pulling water from inside cells into the extracellular space, diluting the sodium content. Note, this leads to a reduction in intracellular volume, and therefore hyponatremia does not cause cerebral edema in this setting. However, cerebral edema may occur in the treatment phase of this condition due to over-rapid correction of hyperglycemia and injudicious use of intravenous fluids. The increased tonicity also stimulates thirst and vasopressin release, further contributing to water retention. To determine whether the hyponatremia can be entirely attributed to hyperglycemia, a sodium correction factor is often used. Most guidelines recommend using a decrease in the serum sodium concentration of 1.6 mEq/L (1.6 mmol/L) for every 100 mg/dL (5.5 mmol/L) rise in plasma glucose above normal for this correction.

B. Hypotonic Hyponatremia

Most cases of hyponatremia are hypotonic, highlighting sodium's role as the predominant extracellular osmole. The presence of hypotonic hyponatremia indicates that water intake exceeds the kidney's excretional capacity. The next step is to classify hypotonic cases as ADH dependent or independent based on the kidney's ability to excrete dilute urine.



Hyponatremia
1. Measure serum osmolality
Sosm 280–295 mOsm/kg
Sosm < 280 mOsm/kg
Sosm > 295 mOsm/kg
Pseudohyponatremia
Paraproteinemia
Hypertriglyceridemia
Hyperosmolar
Hyperglycemia
(mannitol)
Hypoosmolar
2. Measure urine osmolality
Uosm < 100 mOsm/kg
Uosm > 100 mOsm/kg
ADH independent
Impaired urinary dilution
Kidney disease
Primary polydipsia
Beer potomania
Tea and toast diet
Rare unless GFR < 10 mL/min/1.73 m2
↑ADH
Hypovolemia
Euvolemia
Hypervolemia
3. Measure urine sodium
UNa < 10 mEq/L
UNa > 20 mEq/L
UNa > 20 mEq/L
UNa < 10 mEq/L
Nonrenal Na loss
Vomiting
Diarrhea
Sweat/burns
Third spacing
Renal Na loss (salt wasting)
Diuretics (thiazides)
Osmotic diuresis
Cerebral salt wasting
SIADH
Reset osmostat/drugs
Endocrine
Severe hypothyroidism
Adrenal insufficiency
Edematous states
HF
Cirrhosis
Nephrotic syndrome

▲ **Figure 24–1.** A diagnostic algorithm for the causes of hyponatremia using serum osmolality, urine osmolality, and urine sodium.

1. ADH-independent causes—In rare circumstances, hypotonic hyponatremia can occur when the kidney's ability to excrete free water is intact (urine osmolality < 100 mOsm/kg).

A. Primary polydipsia—This condition develops when excess water intake overwhelms the kidney's capacity to excrete adequately dilute urine. ADH is appropriately suppressed, reflected by a urine osmolality < 100 mOsm/kg. Polydipsia without physiologic thirst occurs primarily in patients with psychiatric disorders. Psychiatric medications may also interfere with water excretion or increase thirst through anticholinergic side effects, further increasing water intake.

B. Low dietary solute intake—Patients who consume large quantities of beer, which is generally very low in sodium (beer potomania), or those who consume a low protein ("tea and toast") diet may have a marked reduction in free water excretion due to insufficient dietary solute intake. The kidney's ability to excrete free water depends not only on ADH suppression, but also on solute delivery to the distal nephron. With a typical Western diet generating 1000 mOsm of solute per day, normal kidneys can dilute urine to 50 mOsm/kg, allowing a maximum urine volume of 20 L. By contrast, with a low protein and electrolyte diet generating 200 mOsm per day, urinary output would be limited to a maximum of 4 L per day.

C. Renal impairment—Patients with advanced renal impairment (GFR < 15 mL/min/1.73 m^2), whether due to severe CKD or AKI, may be unable to dilute their urine. Patients with advanced renal impairment can often only achieve a minimum urine osmolality of 200–250 mOsm/kg even with maximal ADH suppression and are prone to develop water retention and hyponatremia. This can occur in the setting of normal or high plasma osmolality due to accumulation of urea. Water retention and hyponatremia from the kidney's impaired ability to dilute urine differ from hypertonic hyponatremia because urea is an ineffective osmole and is freely permeable across cell membranes, only minimally pulling water into the plasma space.

2. ADH-dependent causes—The most common cause of hypotonic hyponatremia involves a failure to suppress ADH action. This can either be **appropriate** in the setting of hypovolemia, or a reduced effective arterial volume secondary to cirrhosis or HF (hypervolemia), or **inappropriate,** in the absence of hypovolemia or edematous states, which is known as the syndrome of inappropriate ADH secretion (SIADH).

A. Hypovolemic hyponatremia—Hypovolemic hyponatremia occurs with renal or extrarenal volume loss (sodium and water) and subsequent hypotonic fluid replacement (Figure 24–1). The reduced blood pressure results in an increase in ADH secretion by the pituitary gland, limiting free water excretion. In this setting, the body sacrifices serum osmolality to preserve intravascular volume.

Cerebral salt wasting is a rare subset of hypovolemic hyponatremia that occurs with intracranial disease (eg, infections, cerebrovascular accidents, tumors, and neurosurgery). Clinical features include refractory hypotension, often in the setting of continuous infusion of isotonic or hypertonic saline. The pathophysiology is unclear but has been attributed to renal sodium wasting, although there is uncertainty as to whether cerebral salt wasting represents a distinct entity or SIADH with desalination of the administered saline.

B. Hypervolemic hyponatremia—Hypervolemic hyponatremia commonly occurs in the edematous states of cirrhosis and HF, and rarely in nephrotic syndrome (Figure 24–1). In these settings, a decreased effective arterial blood volume occurs despite an overall increase in extracellular volume (edema) resulting in ADH secretion. In cirrhosis and HF, effective circulating volume is decreased due to systemic vasodilation and reduced cardiac output, respectively.

C. SIADH—In this condition, ADH is secreted in the absence of an appropriate physiologic stimuli such as a decreased effective circulating volume or hyperosmolality. The major causes of SIADH (Table 24–2) are disorders affecting the CNS or the lungs (eg, cancer or infections) and medications. SIADH is a diagnosis of exclusion, which involves ruling out other causes of hyponatremia (eg, low effective circulating volume, decreased solute intake, cortisol deficiency, and severe hypothyroidism).

Table 24–2. Common causes of syndrome of inappropriate ADH secretion.

CNS disorders
- Stroke
- Hemorrhage
- Infection
- Trauma
- Inflammatory and demyelinating diseases

Pulmonary lesions
- Infections (viral, bacterial, fungal)

Malignancies
- Many but particularly small cell carcinoma of the lung

Drugs (this is only a partial list as many have been implicated)
- Antidepressants: SSRIs, tricyclics, MAO inhibitors
- Antineoplastics: cyclophosphamide, ifosfamide, methotrexate
- Anticonvulsants: carbamazepine, sodium valproate, lamotrigine
- Neuroleptics: haloperidol, fluphenazine, trifluoperazine thioridazine, thiothixene
- NSAIDs
- Amiodarone
- Ciprofloxacin
- Opioids
- Methylenedioxymethamphetamine (MDMA; ecstasy)

Others
- HIV
- Pain, postoperative, stress
- Hereditary
- Idiopathic

D. Reset osmostat—This is a rare cause of hyponatremia in which patients regulate vasopressin release around a lower, or hypotonic, set point. Diagnosis involves documentation of dilute urine when serum sodium is lowered by administration of free water; however, this is rarely done in clinical practice. The mild hypo-osmolality of pregnancy is a form of reset osmostat.

E. Adrenal insufficiency and hypothyroidism—Cortisol normally provides negative feedback on ADH release, and therefore cortisol deficiency can lead to uninhibited ADH activity and hyponatremia. Concomitant mineralocorticoid deficiency may result in hyperkalemia and metabolic acidosis. Hyponatremia due to hypothyroidism has been described in the context of myxedema coma; the hyponatremia may be due to appropriate ADH release from reduced cardiac output and concurrent adrenal insufficiency, rather than from the absence of thyroid hormone. Despite the lack of evidence associating thyroid hormone deficiency with hyponatremia, ruling out hypothyroidism remains a criterion for diagnosing SIADH (Barrter and Schwartz criteria).

F. Nausea, pain, and surgery—Nausea and pain are potent stimulators of ADH release. Severe hyponatremia can develop after elective surgery in healthy patients due to excessive use of hypotonic fluids.

G. Exercise-associated hyponatremia—Hyponatremia during or after exercise, especially endurance events, may be caused by a combination of excessive hypotonic fluid intake and ADH secretion (due to hypovolemia, pain, or nausea). Guidelines that endurance athletes drink water according to thirst rather than according to specified hourly rates of fluid intake are sound and should be followed. Contrary to impressions in the general population, electrolyte-containing sport drinks do not protect against hyponatremia since they are markedly hypotonic relative to serum.

H. Thiazide diuretics and other medication—Thiazides may induce hyponatremia, typically in older patients, within a few weeks of initiating therapy, and may be exacerbated by increased thirst and low solute intake. The mechanism appears to be a combination of water intake and impaired water excretion. Loop diuretics do not cause hyponatremia as frequently as thiazides due to impairment of the medullary concentration gradient, limiting the ability of ADH to promote water retention.

NSAIDs increase ADH by inhibiting prostaglandin formation. SSRIs (eg, fluoxetine, paroxetine, and citalopram) can also cause hyponatremia, especially in older adults. Enhanced secretion or action of ADH may result from increased serotonergic tone.

Use of 3,4-methylenedioxymethamphetamine (MDMA, also known as ecstasy) can lead to hyponatremia and severe neurologic symptoms, including seizures, cerebral edema, and brainstem herniation. MDMA and its metabolites increase ADH release from the hypothalamus. Polydipsia may contribute to hyponatremia since MDMA users typically increase fluid intake to prevent hyperthermia.

Clinical Findings

A. Symptoms and Signs

Whether hyponatremia is symptomatic depends on both its severity and acuity. **Acute hyponatremia** (defined as lasting < 48 hours) can result in marked neurologic symptoms, even with relatively modest hyponatremia, due to acute brain cell swelling and subsequent rise in intracranial pressure. Early symptoms include headache and decrease in attentiveness, which can lead to lethargy, disorientation, and nausea. The most serious symptoms include marked confusion and decreased levels of consciousness, vomiting, seizures, coma, brainstem herniation, and death. **Chronic hyponatremia,** defined as lasting longer than 48 hours, is often diagnosed on routine electrolyte measurements; patients are often asymptomatic as the brain has adapted to the surrounding hypotonicity. Subtle abnormalities, such as mild concentration and cognitive deficits, as well as gait disturbances that can lead to falls, may be present.

Clinical evaluation starts with eliciting a history of medications and noting any changes to drugs and medications, fluid intake (polydipsia, anorexia, intravenous fluid rates and composition), and fluid output (nausea and vomiting, diarrhea, ostomy output, polyuria, oliguria, insensible losses). The physical examination should attempt to categorize volume status (see Body Water and Fluid Distribution, above). The next determination is why ADH is being released and conditions in which release may be halted abruptly, which can impact the approach to therapy.

B. Laboratory Findings

The initial laboratory assessment should include serum and urine electrolytes and serum and urine osmolality. The severity of hyponatremia can be classified as mild (130–134 mEq/L), moderate (125–129 mEq/L), or severe (< 125 mEq/L), with complications of untreated hyponatremia and rapid/overcorrection most commonly occurring in patients with severe hyponatremia. In clinical practice ADH levels are not measured; urine osmolality is used as a surrogate for ADH activity. Urine osmolality should be checked not only at the time of diagnosis but serially during therapy. Bedside assessment of volume status is often insensitive; therefore, a urine sodium may help differentiate between hypovolemia and euvolemia, particularly in nonedematous patients (Figure 24–1). The etiology of most cases of hyponatremia will be apparent by appropriate interpretation of the above laboratory values, in addition to patient history and assessment of volume status. Additional testing, such as thyroid and adrenal function tests, may be warranted in the appropriate context.

SIADH is a clinical diagnosis characterized by (1) hyponatremia; (2) decreased plasma osmolality (< 280 mOsm/kg); (3) absence of heart, kidney, or liver disease; (4) normal thyroid and adrenal function (see Chapter 29); and (5) urine sodium usually over 20 mEq/L. Patients with SIADH may have low BUN (< 10 mg/dL [3.6 mmol/L]) and hypouricemia (< 4 mg/dL [238 mcmol/L]), which are not only dilutional but result from increased urea and uric acid clearances in response to the volume-expanded state.

Treatment

The initial treatment of hyponatremia is contingent on two primary factors, the acuity of onset and the severity of symptoms. **In patients with documented acute hyponatremia (ie, onset within 48 hours), sodium can be corrected at the rate at which it fell. In general, most cases are chronic and therefore typically corrected more slowly to minimize risk of osmotic demyelination.**

A. Symptomatic Hyponatremia

If a patient has hyponatremia and severe symptoms (eg, seizures, confusion), regardless of etiology, then emergent treatment with hypertonic saline should commence. A relatively small increase in serum sodium of 4–5 mEq/L is generally sufficient to promptly reverse severe neurologic symptoms and decrease intracranial pressure. This can be accomplished most effectively by using boluses of 100 mL of 3% NaCl over 10 minutes, which can be repeated twice if needed. Each bolus might be predicted to raise the serum sodium by 1–2 mEq/L. In patients with less severe symptoms, 3% NaCl may be infused intravenously at a rate of 0.5–2 mL/kg/hour.

The importance of frequent laboratory monitoring—every 1–2 hours—during treatment of hyponatremia cannot be overemphasized.

B. Chronic Hyponatremia

The cornerstone of therapy in most patients with chronic hyponatremia, regardless of etiology, is restricting fluid intake below the level of urinary output. However, this strategy is only minimally effective in most patients. The electrolyte free water equation (see Chronic Hypernatremia below) is used to determine what proportion of a patient's urine volume is electrolyte free water. Because urine volume is not always available, the Furst ratio—a calculated ratio of $(U_{Na} + U_K)/P_{Na}$—is sufficient. A ratio > 1 is highly predictive of failure with fluid restriction alone, and other measures to increase free water excretion should be considered. Loop diuretics (with or without salt tablets) are frequently used since they impair the medullary concentration gradient, thereby limiting renal concentration; despite this physiologic principle, this therapy has not been shown to be superior to fluid restriction alone. Other options include vasopressin receptor antagonists (vaptans), SGLT-2 inhibitors, and oral urea.

Vaptans impair ADH action by inhibiting the vasopressin type 2 (V_2) receptors in the collecting duct, thereby inducing a water diuresis. While a logical target for therapy in refractory hyponatremia, these agents have not been shown to improve outcomes and are associated with risks of liver toxicity and sodium overcorrection. If these agents are used, they should generally be avoided in patients with cirrhosis, duration should be limited to 30 days, and fluid restriction should concurrently be lifted to reduce the risk of excessive serum sodium correction. An alternative option is the use of oral urea to induce an osmotic diuresis, which enhances free water clearance. The disadvantage of palatability of oral urea alone has been addressed by combining urea with sodium bicarbonate, citric acid, and sucrose in commercially available formulations. SGLT-2 inhibitors may be an option via their ability to induce an osmotic diuresis through glycosuria and have demonstrated greater improvements in serum sodium levels in patients with SIADH, compared with placebo, when combined with standard fluid restriction.

Osmotic demyelination and correction rate—Iatrogenic osmotic demyelination syndrome is thought to be the result of overly rapid correction of serum sodium in patients with chronic hyponatremia, though, as stated above, this paradigm has been challenged. Previously called central pontine myelinolysis, osmotic demyelination syndrome may also occur outside the brainstem. Demyelination generally occurs 2–6 days after inappropriate sodium correction and presents with profound neurologic deficits that are often irreversible. Risk factors for osmotic demyelination syndrome include the severity of hyponatremia (majority < 120 mEq/L), alcohol use disorder, liver disease, malnutrition, and concurrent hypokalemia.

Despite studies suggesting sodium correction alone is not the sole risk factor for osmotic demyelination, guidelines continue to recommend caution with correction rates. The optimal correction rate for hyponatremia is debated, though consensus guidelines suggest that correction not exceed 8 mEq/L in a 24-hour period. It should be emphasized that this represents a limit and not a goal. In fact, in patients who are deemed at high risk for osmotic demyelination syndrome based on criteria detailed above, a lower goal of 4–6 mEq/L/day is appropriate. If rapid discontinuation of the effects of vasopressin is anticipated, particularly in patients who are at high risk for osmotic demyelination syndrome, prophylactic use of intravenous desmopressin acetate (DDAVP) clamp to prevent a water diuresis should be considered.

C. Isotonic and Hypertonic Hyponatremia

Pseudohyponatremia from hypertriglyceridemia or hyperproteinemia requires no therapy except confirmation with the clinical laboratory. Hypertonic hyponatremia from translocational hyponatremia due to hyperglycemia can be managed with glucose correction.

D. Hypotonic Hyponatremia

In addition to the considerations discussed above, patients with **hypovolemic hyponatremia** require fluid resuscitation. There is no clear consensus regarding the optimal fluid for resuscitation, due to conflicting data, between normal saline and balanced solutions such as Ringer lactate or Plasma-lyte. The correction of the volume depletion removes the stimulus for ADH and permits renal excretion of a dilute urine. The fluid resuscitation should be undertaken carefully because rapid renal excretion of the excess water may correct the serum sodium level too quickly.

When to Refer

- Nephrology consultation should be considered in patients with hyponatremia of uncertain cause or in refractory or complicated cases.
- Aggressive therapies with hypertonic saline, V_2-antagonists, or dialysis mandate specialist consultation.
- Consultation may be necessary with severe liver or heart disease.

When to Admit

Hospital admission is necessary for severe or symptomatic patients or those requiring aggressive therapies (such as hypertonic saline) for close monitoring and frequent laboratory testing.

HYPERNATREMIA

ESSENTIALS OF DIAGNOSIS

- Increased thirst and water intake are the main defense against hypernatremia.
- Urine osmolality helps differentiate renal from nonrenal water loss.

General Considerations

Hypernatremia is defined as a sodium concentration > 145 mEq/L. All patients with hypernatremia have hyperosmolality (unlike hyponatremic patients, who can have a low, normal, or high serum osmolality). Hypernatremia develops when there is a relative loss of water with inadequate compensation by water ingestion. Rarely, administration of excess sodium in relation to water ingestion or administration contributes to hypernatremia. This is most often encountered in critically ill patients when large amounts of hypertonic fluid are administered.

The primary responses to hypernatremia are stimulation of thirst (to increase water intake) and increased secretion of ADH (to minimize water loss in the urine). Cells in the hypothalamus can sense minimal changes in serum osmolarity, triggering the thirst mechanism and subsequent intake of water. It is nearly impossible to develop hypernatremia in the context of an intact thirst mechanism with appropriate access to water.

Clinical Findings

A. Symptoms and Signs

Acute, severe hypernatremia (serum sodium > 160 mEq/L) can manifest as lethargy, irritability, and weakness sometimes progressing to hyperthermia, delirium, seizures, and coma. Irreversible neurologic damage may occur if the hypernatremia is left untreated. Because water shifts from the cells to the intravascular space to protect volume status, symptoms may be delayed. Symptoms in older adults may not be specific.

B. Laboratory Findings

The first steps in evaluating patients with hypernatremia are assessing the urine volume, osmolality, and the osmole excretion rate. The latter can be calculated by multiplying the urine osmolality and urine volume. The copeptin test is discussed below.

C. Etiology

The initial step for the diagnosis of hypernatremia is to determine whether the patient is oliguric (ie, urine flow < 0.5 mL/min) or nonoliguric. Patients who are nonoliguric can be categorized by measuring urine osmolality.

1. The oliguric patient (urine flow < 0.5 mL/min)—This is found in several scenarios.

A. REDUCED WATER INTAKE—Hypernatremia develops in patients with reduced water intake secondary to the inability to communicate or limited access to water, or both.

B. NONRENAL WATER LOSSES—Nonrenal sites of water loss include sweat, GI tract, and the respiratory tract. This is most commonly seen in patients with diarrhea or in febrile patients on a ventilator.

C. SHIFT OF WATER INTO CELLS—Rarely, hypernatremia may manifest from a shift of water into cells due to the intracellular gain of an effective osmole. This may be seen with seizures or rhabdomyolysis.

2. The nonoliguric patient (urine flow > 0.5 mL/min)—

A. URINE OSMOLALITY < 250 MOSM/KG—Hypernatremia in the setting of dilute urine is characteristic of diabetes insipidus (DI). Central DI results from inadequate ADH release from the pituitary as a result of stroke, tumor, or infiltration. In nephrogenic DI, ADH levels are normal or even elevated, but the kidneys are less sensitive to its effects. Common causes include lithium therapy, post-relief of urinary obstruction, chronic interstitial nephritis, hypercalcemia, and hypokalemia. Central and nephrogenic DI can be distinguished by the response to exogenous DDAVP administration while polyuric. Measuring copeptin (a C-terminal peptide synthesized with vasopressin, which mirrors its concentration over a wide range of plasma osmolalities) assists in the differential diagnosis of DI. Elevated levels of copeptin in the setting of hypernatremia suggest the presence of vasopressin and therefore exclude a diagnosis of central DI. Vasopressin is unstable in isolated plasma, and obtaining levels is therefore not helpful.

B. URINE OSMOLALITY > 300 MOSM/KG—Patients with an elevated urine osmolality and a high urine volume have an osmotic diuresis. Both glucose and urea in the urine can promote polyuria associated with increased free water excretion.

Treatment

Treatment of hypernatremia includes both correcting the cause of the fluid loss and replacing the water deficit.

A. Choice of Fluid for Replacement

In general, hypernatremia treatment requires induction of a positive water balance by administering hypotonic fluids, either intravenously or enterally or via a combination of both. Because correcting large water deficits via the GI tract alone can be difficult, the most common strategy is infusion of 5% dextrose in water (distilled water is contraindicated due to the development of hemolysis). Although there appears to be little risk in the rapid correction of hypernatremia in adults, caution is advised when infusing large amounts of 5% dextrose in water due to the risk of hyperglycemia. In patients who are concurrently volume depleted, priority should be to restore euvolemia using isotonic fluids (eg, 0.9% normal saline), followed by hypotonic fluids to correct any remaining free water deficit. In the rare situation when hypernatremia is due to excess sodium balance (sodium ingestion or intravenous hypertonic saline), diuretics may be administered to enhance sodium excretion.

B. Calculation of Water Deficit

Fluid replacement should include correcting the free water deficit and adding maintenance fluid to replace ongoing and anticipated fluid losses.

1. Acute hypernatremia—This is relatively rare and generally encountered in patients with DI who do not have access to water, or even less commonly, in patients with salt poisoning; rapid restoration of water balance is indicated. Infusion of 0.5% dextrose in water is initiated at a rate of 3–6 mL/kg/hour until the serum sodium is below 145 mEq/L, then the infusion is slowed until the serum sodium normalizes (140 mEq/L). DDAVP is needed to reduce urine water losses in patients with central DI. Rarely, renal replacement therapy may be needed in patients with acute hypernatremia and severe kidney injury.

2. Chronic hypernatremia—Restoration of water balance with either intravenous 5% dextrose in water or oral rehydration in clinically stable patients with an adequate ability to tolerate oral intake should be initiated based on water deficit. The water deficit is the amount of water calculated to restore the sodium concentration to normal (140 mEq/L). Total body water (TBW) (Table 24–1) correlates with muscle mass and therefore decreases with advancing age, cachexia, and dehydration and, on average, is lower in women than in men. Current TBW equals 40–60% of body weight. This equation provides a guide for initial therapy and does not negate the need for repeated measurements to assess response to treatment.

$$\text{Water deficit (L)} = \text{Current TBW} \times \frac{S_{Na} - 140}{140}$$

It should be emphasized that the water deficit represents a static period in time. When considering the volume of water needed to restore sodium balance, a critical mistake that is often made is failure to incorporate ongoing water loss via urinary output and insensible losses. Insensible losses can be estimated as 500–1000 mL daily; however, they can vary significantly. The proportion of urine volume that is free water can be estimated by calculating the electrolyte free water (EFW) clearance via the equation below.

$$C_{EFW}\,(\text{L}) = \text{Urine volume} \times \left(1 - \frac{U_{Na} + U_K}{S_{Na}}\right)$$

3. Rate of sodium correction—Although it would be appealing to apply similar principles for patients with hyponatremia to patients with hypernatremia, this practice is not supported by the literature. Adverse neurologic symptoms from overly rapid correction of hypernatremia have only been described in children. Furthermore, a large retrospective study found no evidence of morbidity or mortality with rapid correction of hypernatremia in critically ill patients with admission or hospital-acquired hypernatremia; however, a slow rate of correction is usually recommended on the basis of osmotic brain adaptation that occurs with chronic hypernatremia and corresponding theoretical risk of cerebral edema if hypernatremia is corrected too quickly. Common clinical practice is to limit correction of chronic hypernatremia to below 12 mEq/L in 24 hours; however, if this rate is inadvertently exceeded, the serum sodium should not be raised. In patients with acute hypernatremia, the serum sodium should be corrected to normal (ie, 140 mEq/L) within 24 hours.

4. Treatment of the underlying cause—The underlying cause of the hypernatremia should be identified and addressed. For patients who have central DI, vasopressin deficiency should be replaced by administration of DDAVP.

When to Refer

Patients with refractory or unexplained hypernatremia should always be referred for nephrology consultation.

When to Admit

- Patients with symptomatic hypernatremia require hospitalization for evaluation and treatment.
- Significant comorbidities or concomitant acute illnesses, especially if contributing to hypernatremia, may necessitate hospitalization.

DISORDERS OF POTASSIUM CONCENTRATION

HYPOKALEMIA

ESSENTIALS OF DIAGNOSIS

- Serum potassium < 3.5 mEq/L (3.5 mmol/L).
- Severe hypokalemia may induce arrhythmias and rhabdomyolysis.
- Assessment of urine potassium excretion (urine potassium to creatinine ratio) can distinguish renal from nonrenal loss of potassium.

General Considerations

Hypokalemia can result from intracellular shifting of potassium from the extracellular space, potassium loss (renal or extrarenal) (Table 24–3) or, rarely, insufficient dietary potassium intake. A low dietary potassium intake is usually not sufficient to cause hypokalemia as the kidneys can lower urine potassium excretion to very low levels (< 15 mEq/L). The shift of potassium into cells is increased by both insulin and β-adrenergic stimulation. Excess potassium excretion by the kidneys is usually due to increased aldosterone action in the setting of preserved delivery of sodium to the distal nephron. Magnesium is an important regulator of potassium handling and low levels lead to persistent renal excretion of potassium; hypokalemia is often refractory to treatment until the magnesium deficiency is corrected. Several classes of diuretics, carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics cause substantial renal potassium and magnesium losses.

Clinical Findings

A. Symptoms and Signs

Hypokalemia is usually asymptomatic but can lead to muscle weakness and cardiac arrhythmias when severe. Hypokalemia can also lead to dysfunction of the smooth muscle of the GI tract, which can result in constipation or ileus. Rhabdomyolysis with associated AKI can be seen with serum potassium levels < 2.5 mEq/L. Hypokalemia may additionally present as polyuria and polydipsia due to diminished concentrating ability of the kidney (nephrogenic DI) and eventual kidney disease (tubulointerstitial nephritis).

B. Laboratory Findings

Assessment of renal potassium excretion can help distinguish renal from nonrenal causes of hypokalemia. A 24-hour urine collection is the most accurate method for assessing

Table 24–3. Causes of hypokalemia.

- **Decreased potassium intake**
- **Potassium shift into the cell**
  - Alkalosis
  - β-Adrenergic agonists
  - Insulin release (postprandial, exogenous, insulinoma)
  - Hypokalemic periodic paralysis
- **Renal potassium loss with metabolic acidosis**
  - Proximal and distal RTAs
  - Toluene inhalation (glue sniffing)
- **Renal potassium loss with metabolic alkalosis**
- **Normal/low blood pressure**
  - Vomiting
  - Magnesium deficiency
  - Loop/thiazide diuretics
  - Bartter syndrome
  - Gitelman syndrome
- **High blood pressure**
  - Elevated renin and aldosterone
    - Malignant hypertension
    - Renin-producing tumor
    - Renal artery stenosis
  - Depressed renin and elevated aldosterone
    - Adrenal adenoma
    - Glucocorticoid-remediable aldosteronism
    - Adrenal hyperplasia
  - Depressed renin and aldosterone
    - Cushing syndrome
    - Black licorice
    - Apparent mineralocorticoid excess
    - Liddle syndrome
- **Increased GI losses**
  - Diarrhea
  - Laxative abuse

RTA, renal tubular acidosis.

renal handling of potassium. A urine potassium < 25 mEq/day indicates appropriate renal potassium retention, and higher values correspond to renal potassium wasting. A more immediate assessment can be made by measuring a urine potassium to creatinine ratio (U_K/U_{Cr}) on a spot urine sample (Figure 24–2). In the setting of hypokalemia, a U_K/U_{Cr} ratio < 13 mEq/g (or 1.5 mEq/mmol) is suggestive of a nonrenal etiology, most commonly GI losses, intracellular potassium shifts, or inadequate dietary intake, whereas higher values imply renal potassium wasting.

C. ECG

Hypokalemia leads to a characteristic progression of ECG changes, initially T wave flattening, subsequently ST depressions and T wave inversions, ultimately leading to U waves as the hypokalemia becomes more severe. Such changes can trigger arrhythmias and be life-threatening. There is significant interpatient variability in the degree of hypokalemia and corresponding ECG findings; therefore, typical ECG patterns may not be observed in all patients.

Etiology

1. Inadequate dietary intake—While the kidney can excrete urine that is virtually free of sodium, a small amount of potassium excretion occurs even in the setting of diets devoid of potassium. With extreme potassium-free diets, such as can occur with anorexia nervosa and alcohol use disorder, the hypokalemia is worsened by concurrent magnesium depletion.

2. Intracellular shift—The most important determinants of intracellular potassium shifts are postprandial insulin and catecholamine release. These physiologic conditions can be exacerbated by β-adrenergic–agonist administration and high adrenergic states, which can be seen in situations such as alcohol withdrawal and MI. Rare causes include insulinomas and hypokalemic periodic paralysis.

3. GI losses—The most common cause of nonrenal potassium wasting is GI loss, either diarrhea or vomiting. Diarrhea may have a high potassium and bicarbonate content resulting in hypokalemia with a concurrent normal anion gap (hyperchloremic) metabolic acidosis. Vomiting leads to hypokalemia with a metabolic alkalosis and potassium loss due to renal wasting (secondary to hypovolemia-induced hyperaldosteronism coupled with distal sodium delivery in the form of sodium bicarbonate).

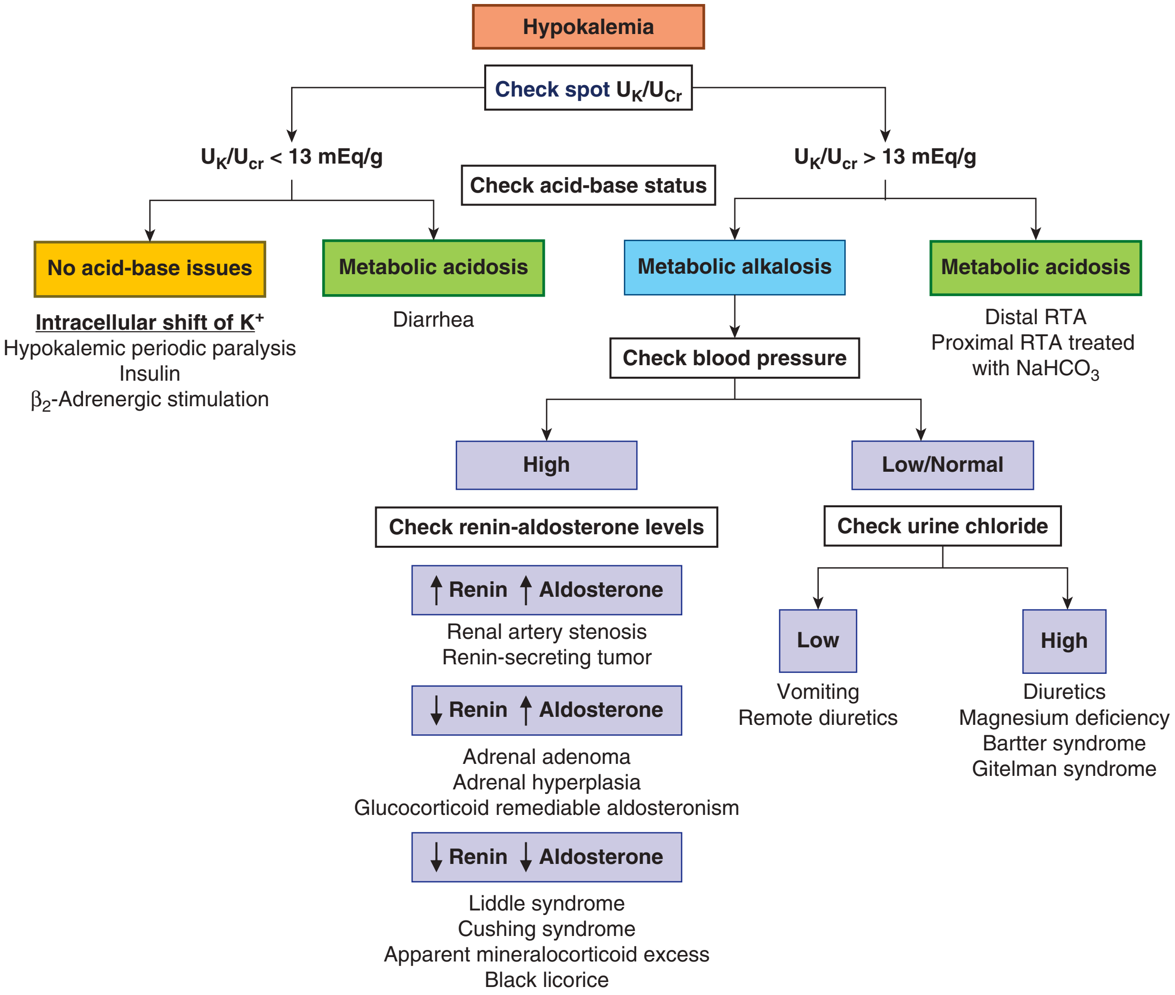
4. Renal wasting—Renal potassium wasting occurs in states where increased distal sodium delivery is coupled to increased aldosterone activity. This most commonly occurs with diuretic use. Rarely, renal tubulopathies (Bartter syndrome or Gitelman syndrome) or renal tubular acidosis (RTA) may present with hypokalemia.

Primary hyperaldosteronism is due to excess aldosterone production by the adrenal glands, which causes extracellular volume expansion resulting in hypertension associated with hypokalemia and a metabolic alkalosis. Other rare forms of increased mineralocorticoid activity may be identified by measuring plasma renin activity and serum aldosterone levels.

Treatment

Any underlying conditions should be treated and causative drugs discontinued. Magnesium deficiency should be corrected, particularly in refractory hypokalemia. Oral potassium supplementation is the safest treatment for mild to moderate deficiency, although potassium supplements may cause GI upset. With mild to moderate diuretic doses, 20 mEq/day of oral potassium is generally sufficient to prevent hypokalemia, whereas with established hypokalemia, 40–100 mEq/day over a period of days to weeks may be needed to treat hypokalemia and fully replete potassium stores.

Intravenous potassium is generally reserved for severe hypokalemia (< 3.0 mEq/L) and requires careful monitoring due to the risk of transient hyperkalemia. Potassium chloride may be given through a peripheral intravenous line at rates up to 10–15 mEq/hour diluted in 0.45% or 0.9% normal saline, but higher rates (up to 20 mEq/hour) require central access due to the risk of peripheral vein irritation. In the event of concurrent metabolic acidosis, potassium repletion should take precedence over alkali administration as correction of the acidosis results in intracellular shift of potassium, further decreasing extracellular potassium



Hypokalemia
Check spot U_K/U_{Cr}
$U_K/U_{cr} < 13$ mEq/g
$U_K/U_{cr} > 13$ mEq/g

concentration. Similarly, potassium should be given in a saline, rather than dextrose, solution since dextrose would stimulate insulin release and, hence, intracellular shift.

When to Refer

Patients with unexplained hypokalemia, refractory or persistent hypokalemia, or suggestive alternative diagnoses (eg, aldosteronism or hypokalemic periodic paralysis) should be referred for nephrology consultation.

When to Admit

Patients with symptomatic or severe hypokalemia (< 2.5 mEq/L), especially with cardiac manifestations, require admission for cardiac monitoring, potassium supplementation, and frequent laboratory testing.

Piner A et al. Disorders of potassium. Emerg Med Clin North Am. 2023;41:711. [PMID: 37758419]

HYPERKALEMIA

ESSENTIALS OF DIAGNOSIS

- Serum potassium > 5.2 mEq/L (5.2 mmol/L).
- Check medications carefully. Hyperkalemia may develop from ACE inhibitors, ARBs, and potassium-sparing diuretics, most commonly in patients with kidney dysfunction.
- The ECG may be normal despite life-threatening hyperkalemia.
- Rule out extracellular potassium shift from cells, especially hyperglycemia.

General Considerations

Hyperkalemia is a rare occurrence in normal individuals due to adaptive mechanisms designed to prevent accumulation of potassium in the extracellular fluid, mainly via rapid urinary excretion. **Persistent hyperkalemia** generally requires an impairment in renal potassium excretion due to impaired secretion of or hyporesponsiveness to aldosterone, impaired delivery of sodium and water to the distal nephron, or kidney disease (acute or chronic) (Table 24–4). **Transient hyperkalemia** suggests shift of potassium from inside cells into the extracellular fluid, which can occur in the context of tissue damage (rhabdomyolysis, tumor lysis, massive hemolysis, and trauma) or metabolic acidosis.

Clinical Findings

A. Symptoms and Signs

The symptoms of hyperkalemia are due to impaired neuromuscular transmission. The most serious manifestations are cardiac conduction abnormalities and neuromuscular manifestations, such as muscle weakness, which may be profound. This generally occurs with potassium concentrations above 7 mEq/L but can vary depending on the acuity of development of hyperkalemia. Hyperkalemia impairs urinary ammonium excretion and may lead to metabolic acidosis.

B. ECG

ECG is an unreliable method for detecting hyperkalemia; clinical studies show poor correlation between serum potassium and cardiac manifestations. The rapidity in development of hyperkalemia may correlate with the development of ECG changes. Typical sequential changes on the ECG are peaking of the T waves, ST-segment depression, and widening of the PR and QRS intervals. As the QRS continues to widen, sine waves may develop, which are concerning for imminent ventricular fibrillation and ultimately asystole.

Table 24–4. Causes of hyperkalemia.

- **Pseudohyperkalemia**
  - Repeated fist clenching during phlebotomy, tourniquet application, use of small-bore needles during lab draw
  - Marked thrombocytosis or leukocytosis with release of intracellular K^+
- **Extracellular shift of K^+**
  - Metabolic acidosis
  - Insulin deficiency
  - Hyperglycemia
  - α-Adrenergic stimulation
  - Tissue injury (rhabdomyolysis, hemolysis, tumor lysis)
  - Hyperkalemic periodic paralysis
  - Drugs (digoxin overdose, succinylcholine)
- **Kidney disease, acute and chronic**
  - Renal secretory defects (may or may not have reduced kidney function): interstitial nephritis, SLE, sickle cell disease, amyloidosis, obstructive nephropathy, kidney transplant
- **Hypoaldosteronism**
  - Type IV renal tubular acidosis
  - Addison disease
  - Heparin
  - Ketoconazole
- **Drugs that inhibit potassium excretion**
  - Spironolactone, eplerenone, drospirenone, NSAIDs, ACE inhibitors, angiotensin II receptor blockers, triamterene, amiloride, trimethoprim, pentamidine, cyclosporine, tacrolimus
- **Excessive intake of K^+**
  - Especially in patients with diminished kidney excretion

Etiology

1. Increased potassium release from cells—

A. Pseudohyperkalemia—This condition arises during specimen collection due to fist clenching, application of tourniquets, or using small-bore needles during phlebotomy. The presence of hemolysis in the processed sample suggests these etiologies. A more striking example occurs with marked thrombocytosis (> 500,000/μL [500 × 10^9/L]) or leukocytosis (> 100,000/μL [100 × 10^9/L]), particularly leukemic cells. Centrifugation or transport via a pneumatic tube system causes significant cell destruction. If this condition is suspected, a non-centrifuged whole blood sample that is walked to the laboratory is required for confirmation.

B. Tissue breakdown—Tissue damage results in release of intracellular potassium to the extracellular space. Common clinical examples include tumor lysis syndrome, crush injuries, and severe hemolysis. Hyperkalemia is more common when concurrent renal impairment is present.

C. Hyperglycemia—Patients with uncontrolled diabetes may have hyperkalemia, even in the setting of a low total body potassium, due to a combination of insulin deficiency and hyperosmolarity from hyperglycemia.

D. Metabolic acidosis—Acidosis results in potassium shifting out of the intracellular fluid due to buffering of hydrogen ions into cells. Serum potassium concentration rises approximately 0.7 mEq/L for every decrease of 0.1 pH unit. This effect is not seen with organic acidosis, such as lactic acidosis or ketoacidosis.

2. Impaired kidney excretion—

A. AKI—A rapid reduction in kidney function leads to poor renal excretion of potassium and does not allow sufficient time for nonrenal adaptive mechanisms to take effect. Hyperkalemia occurs more commonly in oliguric patients.

B. CKD—The ability to maintain normal serum potassium is generally preserved until GFR declines to < 20–30 mL/min/1.73 m^2. This is primarily due to adaptive mechanisms, particularly increases in potassium excretion by remaining functioning nephrons and by increased GI tract potassium excretion. Hyperkalemia with more modest decreases in GFR is often due to medications that disrupt the renin-angiotensin-aldosterone system, which are commonly used in these patients.

C. Low effective circulating volume—Volume depletion and the edematous states of cirrhosis and HF can cause hyperkalemia due to a decrease in delivery of sodium and water to the distal nephron, which impairs potassium excretion.

D. Reduced aldosterone action—Mineralocorticoid deficiency from Addison disease may cause hyperkalemia due to decreased renal excretion of potassium. Mineralocorticoid resistance due to genetic disorders, interstitial kidney disease, or urinary tract obstruction also leads to hyperkalemia.

3. Medications—Several medications may be implicated in the development of hyperkalemia and a careful review of a patient's medication list is imperative. Common medications implicated in hyperkalemia include ACE inhibitors, ARBs, and NSAIDs, which reduce aldosterone release. Concomitant use of aldosterone antagonists (spironolactone or eplerenone) or medications that directly block the sodium channels of the principal cells (amiloride, triamterene, or trimethoprim) further increase the risk of hyperkalemia. β-Blockers can cause mild hyperkalemia by interfering with potassium uptake by cells, a phenomenon more commonly observed with nonselective β-blockers. Heparin inhibits aldosterone production in the adrenal glands. Calcineurin inhibitors, such as cyclosporine and tacrolimus, can induce hyperkalemia, partly stimulating the sodium chloride cotransporter in the distal nephron impairing distal sodium delivery. These medications should be used cautiously in patients with renal impairment, and laboratory monitoring is indicated within 1–2 weeks of drug initiation or dosage increase.

Treatment

The diagnosis of hyperkalemia should be confirmed by repeat laboratory testing to rule out spurious elevation, especially in the absence of medications that cause hyperkalemia or in patients without kidney disease. The initial treatment is determined by the presence of signs and symptoms as well as the severity in plasma potassium elevation. In all patients, exogenous sources of potassium should be eliminated, medications that can impair potassium excretion discontinued, volume depletion corrected, and metabolic acidosis treated.

In emergency situations (cardiac toxicity, muscle weakness, or potassium > 6.5 mEq/L), initial therapy should be intravenous calcium gluconate to stabilize the myocardium to protect against arrhythmias, followed by therapies to shift potassium into cells. Insulin and β-agonists shift potassium intracellularly within 10–15 minutes of administration but have a short duration of action (1–2 hours) (Table 24–5). Sodium bicarbonate may help shift potassium into cells in patients with a concurrent metabolic acidosis. Once the patient is stabilized, therapies are focused on potassium excretion.

Renal potassium excretion may be enhanced with the use of loop diuretics. Patiromer and sodium zirconium cyclosilicate are oral potassium-binding drugs that increase gut potassium excretion. Studies have demonstrated that these drugs are well tolerated and effective in patients with hyperkalemia who have either CKD or HF and take at least one medication that inhibits the renin-angiotensin-aldosterone system. Emerging evidence has demonstrated utility in acute hyperkalemia as well, although these agents should not be used for emergent management of life-threatening hyperkalemia due to their delayed onset of action. Sodium polystyrene (Kayexalate) has been used for decades, although its efficacy and safety have been questioned. It may not increase potassium excretion greater than laxatives alone. It is associated with colonic necrosis and contraindicated in patients with bowel obstruction or postoperative ileus. Hemodialysis may be necessary to remove potassium in patients with acute or chronic kidney injury, particularly in patients who are oliguric. SGLT-2 inhibitors have emerged as an option for decreasing the risk of chronic hyperkalemia with angiotensin and mineralocorticoid antagonists.

When to Refer

- Nephrology consultation should be obtained for patients with hyperkalemia from kidney disease.
- Transplant patients may need adjustment of their immunosuppression regimen by transplant specialists.

When to Admit

Patients with severe hyperkalemia (> 6 mEq/L), any degree of hyperkalemia associated with ECG changes, or concomitant illness that may worsen hyperkalemia (eg, tumor lysis, rhabdomyolysis, metabolic acidosis) should be sent to the emergency department for immediate treatment.

DISORDERS OF CALCIUM CONCENTRATION

The normal total plasma (or serum) calcium concentration is 8.5–10.5 mg/dL (2.1–2.6 mmol/L). Ionized calcium (normal: 4.6–5.3 mg/dL [1.16–1.31 mmol/L]) is the physiologically active portion of calcium and is necessary for muscle contraction and nerve function. In most situations, measuring total calcium concentration is sufficient since changes mirror those seen in ionized calcium concentration; exceptions include patients with hypoalbuminemia and certain acid-base disorders.

HYPOCALCEMIA

ESSENTIALS OF DIAGNOSIS

- Usually asymptomatic but can cause cramps or tetany if severe.
- Check for decreased serum parathyroid hormone (PTH), vitamin D, or magnesium levels.
- Total serum calcium may be low with hypoalbuminemia, but ionized calcium level is normal in this setting.

General Considerations

The most common cause of low total serum calcium is hypoalbuminemia, which decreases the amount of bound calcium. Correction factors that adjust total serum calcium for low serum albumin have been shown to be inaccurate; therefore, an ionized calcium level should be obtained.

Table 24–5. Treatment of hyperkalemia.

Treatment of Hyperkalemia

Emergent/Stabilizing Therapy

Modality	Mechanism of Action	Onset	Duration	Prescription	K^+ Removed From Body
Calcium	Antagonizes cardiac conduction abnormalities	0–5 minutes	1 hour	Intravenous: calcium gluconate 10%, 5–30 mL, or calcium chloride 5%, 5–30 mL	None
Bicarbonate	Distributes K^+ into cells	15–30 minutes	1–2 hours	Intravenous: $NaHCO_3$, 50–100 mEq **Note:** Sodium bicarbonate may not be effective in ESKD patients; dialysis is more expedient and effective. Some patients may not tolerate the additional sodium load of bicarbonate therapy.	None
Insulin	Distributes K^+ into cells	15–60 minutes	4–6 hours	Intravenous: regular insulin, 5–10 units, plus glucose 50%, 25 g	None
Albuterol	Distributes K^+ into cells	15–30 minutes	2–4 hours	Nebulized albuterol, 10–20 mg in 4 mL normal saline, inhaled over 10 minutes **Note:** Much higher doses are necessary for hyperkalemia treatment (10–20 mg) than for airway disease (2.5 mg).	None

Nonemergent/Excretory Therapy

Modality	Mechanism of Action	Onset of Action	Prescription	K^+ Removed From Body
Loop diuretic	Renal K^+ excretion	0.5–2 hours	Intravenous: furosemide, 40–160 mg	Variable
Patiromer	Ca^{2+}-K^+ cation exchange resin	~7 hours	Oral: 4.2–16.8 g once or twice daily	Mean 0.75 mEq/L
Sodium zirconium cyclosilicate	Selective potassium cation trapping agent	1 hour	Oral: 10 g up to three times daily	0.7 mEq/L per 10 g dose
Sodium polystyrene sulfonate (eg, Kayexalate)	Ion-exchange resin binds K^+	1–3 hours	Oral: 15–60 g in 20% sorbitol (60–240 mL) Rectal: 30–60 g in 20% sorbitol **Note:** Resins with sorbitol may cause bowel necrosis and intestinal perforation, especially in patients with abnormal bowel function.	0.5–1 mEq/g resin
Hemodialysis[1]	Extracorporeal K^+ removal	1–8 hours	**Note:** A fast and effective therapy for hyperkalemia, hemodialysis can be delayed by vascular access placement and equipment or staff availability, or both. Serum K can be rapidly corrected within minutes, but post-dialysis rebound can occur.	25–50 mEq/hour
Peritoneal dialysis	Peritoneal K^+ removal	1–4 hours	Frequent exchanges	50–70 mEq/24 hour

[1] Can be both acute immediate and urgent treatment of hyperkalemia.

Reproduced, with permission, from Cogan MG. *Fluid and Electrolytes: Physiology and Pathophysiology*. New York: McGraw-Hill, 1991.

True hypocalcemia (decreased ionized calcium) implies insufficient action of PTH or active vitamin D. Important causes of hypocalcemia are listed in Table 24–6. The most common cause is advanced CKD, in which decreased production of calcitriol and hyperphosphatemia both play a role (see Chapter 25). Magnesium depletion reduces both PTH release and tissue responsiveness to PTH, causing hypocalcemia. Hypocalcemia in pancreatitis is a marker of severe disease. Hospitalized older adults with hypocalcemia and hypophosphatemia, with or without an elevated PTH level, are likely vitamin D deficient.

Clinical Findings

A. Symptoms and Signs

The hallmark of severe hypocalcemia (ionized calcium below 1 mmol/L) is tetany from increased neuromuscular irritability. Laryngospasm with stridor can obstruct the airway. Convulsions, perioral and peripheral paresthesias, and abdominal pain can develop with hypocalcemia. Less pronounced symptoms include fatigue, anxiety, and depression. Classic physical findings include Chvostek sign (contraction of the facial muscle in response to tapping the facial nerve) and Trousseau sign (carpal spasm occurring with occlusion of the brachial artery by a blood pressure cuff). QT prolongation predisposes to ventricular arrhythmias, though serious dysrhythmias are rare.

B. Laboratory Findings

A serum total calcium < 8.5 mg/dL (2.1 mmol/L) is low. In true hypocalcemia, the ionized serum calcium concentration is also low (< 4.6 mg/dL [1.15 mmol/L]). Serum phosphate is usually elevated in hypoparathyroidism or in advanced CKD, whereas it is suppressed in vitamin D deficiency. Serum magnesium concentration is often low in hypocalcemia. The ECG shows a prolonged QT interval.

Table 24–6. Causes of hypocalcemia.

- **Decreased intake or absorption**
  - Vitamin D deficit (decreased absorption, decreased production of 25-hydroxyvitamin D or 1,25-dihydroxyvitamin D)
  - Malabsorption
  - Small bowel bypass, short bowel
- **Increased loss**
  - Diuretic therapy
  - Alcohol use disorder
  - CKD
- **Endocrine disease**
  - Hypoparathyroidism, genetic or acquired (including hypo- and hypermagnesemia)
  - Post-parathyroidectomy (hungry bone syndrome)
  - Pseudohypoparathyroidism
  - Calcitonin secretion with medullary carcinoma of the thyroid
  - Familial hypocalcemia
- **Associated diseases**
  - Pancreatitis
  - Rhabdomyolysis
  - Septic shock
- **Physiologic causes**
  - Decreased serum albumin[1]
  - Decreased end-organ response to vitamin D
  - Hyperphosphatemia
  - Aminoglycoside antibiotics, plicamycin, loop diuretics, foscarnet

[1] Ionized calcium concentration is normal.

Treatment

A. Severe, Symptomatic Hypocalcemia

In the presence of tetany, arrhythmias, or seizures, intravenous calcium gluconate is indicated. Because of the short duration of action, continuous calcium infusion is usually required. Ten to 15 milligrams of calcium per kilogram body weight, or six to eight 10-mL vials of 10% calcium gluconate (558–744 mg of calcium), are added to 1 L of D_5W and infused over 4–6 hours. By monitoring the serum calcium frequently (every 4–6 hours), the infusion rate is adjusted to maintain the serum calcium at 7–8.5 mg/dL. See Chapter 30 for further discussion of hypoparathyroidism treatment.

B. Asymptomatic Hypocalcemia

Oral calcium (1–2 g of elemental calcium) and vitamin D preparations, including active vitamin D sterols, are used for hypocalcemia without accompanying symptoms. Calcium carbonate is well tolerated and less expensive than many other calcium tablets. The low serum calcium associated with hypoalbuminemia does not require replacement therapy. If serum magnesium is low, therapy must include magnesium replacement, which by itself often corrects hypocalcemia.

When to Refer

Patients with complicated hypocalcemia from hypoparathyroidism, familial hypocalcemia, or CKD require referral to an endocrinologist or nephrologist.

When to Admit

Patients with tetany, arrhythmias, seizures, or other symptoms of hypocalcemia require immediate therapy.

Melchers M et al. Management of hypocalcaemia in the critically ill. Curr Opin Crit Care. 2023;29:330. [PMID: 37395330]

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- Most common causes: primary hyperparathyroidism and malignancy-associated hypercalcemia.
- Asymptomatic, mild hypercalcemia (< 10.5 mg/dL [2.6 mmol/L]) is usually due to primary hyperparathyroidism.
- Symptomatic, severe hypercalcemia (> 14 mg/dL [3.2 mmol/L]) is usually due to malignancy-associated hypercalcemia.

General Considerations

Important causes of hypercalcemia are listed in Table 24–7. Primary hyperparathyroidism and malignancy account for 90% of cases. Primary hyperparathyroidism is the most common cause of hypercalcemia (usually mild) in ambulatory patients. Hypercalcemia above 14 mg/dL is most often associated with malignancy and is rare with primary hyperparathyroidism. Tumor production of PTH-related proteins (PTHrP) is the most common paraneoplastic endocrine syndrome. The neoplasm is clinically apparent in nearly all cases when the hypercalcemia is detected, and the prognosis is poor. Granulomatous diseases, such as sarcoidosis and tuberculosis, cause hypercalcemia via overproduction of active vitamin D (1,25-dihydroxyvitamin D_3).

Milk-alkali syndrome has had a resurgence due to calcium ingestion for prevention of osteoporosis and treatment of dyspepsia.

Clinical Findings

A. Symptoms and Signs

The history and physical examination should focus on the duration of hypercalcemia and evidence for a neoplasm. Hypercalcemia may affect GI, kidney, and neurologic function. Mild hypercalcemia (below 12 mg/dL) is often asymptomatic. Moderate hypercalcemia (12–14 mg/dL) may be tolerated if it is longstanding yet tends to be symptomatic if acute. Severe hypercalcemia (above 14 mg/dL) is frequently symptomatic. Common symptoms include anxiety, lethargy, constipation, anorexia, and cognitive changes, which can progress to lethargy and stupor in severe cases. Pancreatitis from calcium deposition in the pancreatic ducts is a rare complication. Polyuria and dehydration may occur from impaired renal concentrating ability. Other symptoms include renal colic and hematuria from nephrolithiasis. Acute hypercalcemia can shorten the QT interval, though clinically relevant arrhythmias are rare.

Table 24–7. Causes of hypercalcemia.

- **Increased intake or absorption**
  - Milk-alkali syndrome
  - Vitamin D or vitamin A excess
- **Endocrine disorders**
  - Primary hyperparathyroidism
  - Secondary or tertiary hyperparathyroidism (usually associated with hypocalcemia)
  - Acromegaly
  - Adrenal insufficiency
  - Pheochromocytoma
  - Thyrotoxicosis
- **Neoplastic diseases**
  - Tumors producing PTH-related proteins (ovary, kidney, lung)
  - Plasma cell myeloma (elaboration of osteoclast-activating factor)
  - Lymphoma (occasionally from production of calcitriol)
- **Miscellaneous causes**
  - Thiazide diuretics
  - Granulomatous diseases (production of calcitriol)
  - Paget disease of bone
  - Hypophosphatasia
  - Immobilization
  - Familial hypocalciuric hypercalcemia
  - Complications of kidney transplantation
  - Lithium intake

PTH, parathyroid hormone.

B. Laboratory Findings

The serum ionized calcium exceeds 1.32 mmol/L (correct for serum albumin if ionized calcium is unavailable [see Hypocalcemia, above]). Check serum PTH to determine if hypercalcemia is PTH-mediated or non–PTH-mediated.

PTH should be completely suppressed in the presence of hypercalcemia if kidney function is normal. Therefore, "normal" levels of PTH with hypercalcemia do not rule out hyperparathyroidism. Asymptomatic patients with mild hypercalcemia and PTH in the normal or slightly elevated range should have a 24-hour urine calcium or spot urine calcium to creatinine ratio checked for familial hypocalciuric hypercalcemia. If PTH is appropriately suppressed (typically below 20 pg/mL), PTHrP as well as vitamin D and its metabolites should be measured. Causes of a suppressed PTH and PTHrP with low or normal 25-OH and 1,25-OH vitamin D_3 levels include plasma cell myeloma, vitamin A intoxication, thyrotoxicosis, and immobilization. Hypocalciuria (below 100 mg/day) occurs in familial hypocalciuric hypercalcemia, thiazide diuretic use, and milk-alkali syndrome. Hypophosphatemia is more common with primary hyperparathyroidism and humoral hypercalcemia of malignancy (elevated PTHrP). In patients with an elevated 1,25-OH vitamin D_3, a CXR may demonstrate the presence of granulomatous disease.

Treatment

Until the primary cause can be identified and treated, therapy is initiated to promote immediate reduction in serum calcium. Asymptomatic patients with mild hypercalcemia (below 12 mg/dL) do not require immediate therapy; patients should be cautioned to avoid measures that exacerbate hypercalcemia, such as volume depletion and thiazide diuretics. Patients with symptomatic hypercalcemia, a sudden rise in serum calcium above 12 mg/dL, and severe hypercalcemia (above 14 mg/dL) should receive immediate therapy. Begin treatment with volume resuscitation, 200–300 mL/hour, or targeting a urinary output of 100–150 mL/hour, until euvolemia is achieved. Traditionally, normal saline is the recommended fluid of choice, although evidence for this is lacking. Loop diuretics to enhance renal calcium excretion should be avoided due to possible complications, such as nephrolithiasis. These agents were used more commonly prior to the availability of more effective medications, such as bisphosphonates and calcitonin. Loop diuretics may be carefully used in the context of preventing or managing volume overload, particularly in patients with HF or kidney dysfunction.

Calcitonin, 4–8 IU/kg intramuscularly or subcutaneously every 6–12 hours, enhances renal excretion of calcium and decreases bone resorption by interfering with osteoclast activity. Calcitonin efficacy is limited to 48 hours because of tachyphylaxis. Bisphosphonates are the treatment of choice for hypercalcemia secondary to excessive bone resorption. Denosumab, a monoclonal antibody against RANKL, inhibits osteoclasts, reduces bone resorption and serum calcium levels; this medication is an option when hypercalcemia is refractory to bisphosphonate therapy or when bisphosphonates are contraindicated (ie, severe renal impairment). The calcimimetic agent cinacalcet suppresses PTH secretion and decreases serum calcium concentration; it has been recommended for use in patients with symptomatic or severe primary hyperparathyroidism who are unable to undergo parathyroidectomy and patients with inoperable parathyroid carcinoma. (See Chapters 30 and 44.) Hemodialysis using a low calcium dialysate is an effective therapy for hypercalcemia refractory to the above therapies. Hypercalcemia in granulomatous disease is from overproduction of calcitriol; prednisone inhibits calcitriol synthesis and reduces serum calcium levels within 2–5 days.

Typically, if dialysis patients do not receive proper supplementation of active vitamin D, hypocalcemia and hyperphosphatemia develop. Conversely, hypercalcemia can develop in severe tertiary hyperparathyroidism with high PTH levels, or from excess vitamin D supplementation. Metastatic calcification may occur when patients undergoing dialysis have hyperphosphatemia and hypercalcemia.

When to Refer

- Patients may require referral to an oncologist or endocrinologist depending on the cause of hypercalcemia.
- Patients with granulomatous diseases (eg, tuberculosis and other chronic infections, granulomatosis with polyangiitis, sarcoidosis) may require assistance from infectious disease specialists, rheumatologists, or pulmonologists.

When to Admit

- Patients with symptomatic or severe hypercalcemia require immediate treatment.
- Unexplained hypercalcemia with associated conditions, such as AKI or suspected malignancy, may require urgent treatment and expedited evaluation.

Goltzman D. Pathophysiology of hypercalcemia. Endocrinol Metab Clin North Am. 2021;50:591. [PMID: 34774236]

Murray SL et al. Calcium and phosphate disorders: Core Curriculum 2024. Am J Kidney Dis. 2024;83:241. [PMID: 38099870]

DISORDERS OF PHOSPHORUS CONCENTRATION

Plasma phosphorus is mainly inorganic phosphate and represents a small fraction (< 0.2%) of total body phosphate. Important determinants of plasma inorganic phosphate are renal excretion, intestinal absorption, and shift between the intracellular and extracellular spaces. The kidney is the most important regulator of the serum phosphate level. PTH decreases reabsorption of phosphate in the proximal tubule while 1,25-dihydroxyvitamin D increases reabsorption. Renal proximal tubular reabsorption of phosphate is decreased by hypertension, corticosteroids, metabolic acidosis, and proximal tubular dysfunction (as in Fanconi syndrome). Fibroblast growth factor 23 (FGF23) is a potent phosphaturic hormone. Intestinal absorption of phosphate is facilitated by active vitamin D. Cellular phosphate uptake is stimulated by various factors and conditions, including alkalemia, insulin, epinephrine, refeeding syndrome, hungry bone syndrome, and accelerated cell proliferation.

Phosphorus metabolism and homeostasis are intimately related to calcium metabolism.

HYPOPHOSPHATEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Severe hypophosphatemia may cause tissue hypoxia and rhabdomyolysis.
- ▶ Renal loss of phosphate can be diagnosed by calculating the fractional excretion of phosphate ($FEPO_4$).
- ▶ PTH and FGF23 are the major factors that increase urine phosphate.

General Considerations

The etiology of hypophosphatemia is due to decreased intestinal absorption, increased urinary excretion, or transcellular shift (Table 24–8). Hypophosphatemia may occur in the presence of normal phosphate stores. Serum phosphate levels decrease transiently after food intake, which stimulates endogenous insulin release. In patients with depleted phosphate stores, such as those who are malnourished or have alcohol use disorder, carbohydrate intake can induce severe hypophosphatemia (refeeding syndrome). Acute respiratory alkalosis can lower serum phosphate concentrations by stimulating glycolysis. Several drugs can impair intestinal absorption of phosphate, particularly calcium-, magnesium-, and aluminum-containing antacids. Elevated PTH causes hypophosphatemia by inhibiting reabsorption in the kidney. Vitamin D deficiency decreases intestinal phosphate and calcium absorption with the resultant hypocalcemia stimulating PTH release, increasing urinary phosphate excretion. Generalized dysfunction in the proximal tubule (Fanconi syndrome) is characterized by hypophosphatemia, metabolic acidosis, glucosuria, and aminoaciduria. Mutations in FGF23 are associated with urinary phosphorous wasting with rickets or osteomalacia.

Clinical Findings

A. Symptoms and Signs

Phosphorous is a key ingredient component of adenosine triphosphate (ATP), and clinical manifestations are related to ATP deficiency. Symptoms are rare until blood phosphate levels fall below 1.0 mg/dL and are more prominent with acute declines. Symptoms include weakness, paresthesias, and encephalopathy (irritability, confusion,

Table 24–8. Causes of hypophosphatemia.

- **Decreased intestinal absorption**
  - Starvation
  - Absorption blocked by oral antacids or phosphate binders
  - Parenteral alimentation with inadequate phosphate content
  - Malabsorption syndrome, small bowel bypass
  - Vitamin D–deficient and vitamin D–resistant osteomalacia
- **Increased urinary excretion**
  - Hyperparathyroidism (primary or secondary)
  - Hyperthyroidism
  - Inadequately controlled diabetes mellitus
  - Renal tubular defects with excessive phosphaturia (congenital, Fanconi syndrome induced by monoclonal gammopathy, heavy metal poisoning), alcohol use disorder
  - Hypokalemic nephropathy
  - Hypophosphatemic rickets
  - Phosphaturic medications: intravenous iron, acetazolamide, tenofovir
  - Phosphatonins of oncogenic osteomalacia (eg, FGF23 production)
- **Transcellular shift of phosphorus**
  - Acute respiratory alkalosis
  - Increased insulin secretion (ie, during refeeding)
  - Anabolic steroids, estrogen, oral contraceptives, β-adrenergic agonists, xanthine derivatives
  - Hungry bone syndrome
  - Salicylate poisoning
- **Other**
  - Electrolyte abnormalities
    - Hypercalcemia
    - Hypomagnesemia
    - Metabolic alkalosis
  - Abnormal losses followed by inadequate repletion
    - Diabetes mellitus with acidosis, particularly during aggressive therapy
    - Recovery from starvation or prolonged catabolic state
    - Alcohol use disorder, particularly during restoration of nutrition; associated with hypomagnesemia
    - Recovery from severe burns

FGF23, fibroblast growth factor 23.

dysarthria, seizures, and coma). Respiratory failure or failure to wean from mechanical ventilation may occur because of diaphragmatic weakness. Decreased myocardial contractility is uncommon but a serious manifestation. Chronic severe depletion may cause anorexia, pain in muscles and bones, and fractures.

B. Laboratory Findings

While the etiology of hypophosphatemia is often revealed from the patient's history and review of medications, urinary phosphate excretion can distinguish between renal and nonrenal causes. Phosphate excretion can be determined by a 24-hour urine collection or by calculation of the FEPO$_4$. The normal renal response to hypophosphatemia is to decrease urinary phosphate excretion to < 100 mg/day and FEPO$_4$ $< 5\%$. Renal wasting of phosphate (or increased FEPO$_4$) occurs most commonly with hyperparathyroidism and Fanconi syndrome (Table 24–8). The clinical usefulness of serum FGF23 levels is undetermined except in uncommon diseases.

Other clinical features may be suggestive of hypophosphatemia, such as hemolytic anemia and rhabdomyolysis. Fanconi syndrome may present with any combination of uricosuria, aminoaciduria, normoglycemic glucosuria, normal anion gap metabolic acidosis, and phosphaturia. In chronic hypophosphatemia, radiographs and bone biopsies show changes resembling osteomalacia.

Treatment

Hypophosphatemia can be prevented by including phosphate in repletion and maintenance fluids. Moderate hypophosphatemia (> 1 mg/dL) and asymptomatic patients should be treated with oral phosphate, typically 40–80 mmol divided into three or four doses over 24 hours. Patients with severe hypophosphatemia (below 1 mg/dL), symptomatic patients, and those who cannot tolerate oral therapy should be treated with intravenous replacement. Hypocalcemia, hypotension, hyperphosphatemia, and ECG abnormalities can be seen with intravenous therapy, which can be avoided by providing moderate doses. A typical dose is 15 mmol over 2 hours; the rate should be decreased if hypotension occurs and monitoring of plasma phosphate and calcium every 6 hours is necessary. Magnesium deficiency often occurs concomitantly and should be treated.

Contraindications to phosphate replacement include hypoparathyroidism, advanced CKD, tissue damage and necrosis, and hypercalcemia. When associated hyperglycemia is treated, phosphate accompanies glucose into cells, and hypophosphatemia may ensue.

When to Refer

- Patients with refractory hypophosphatemia with increased urinary phosphate excretion may require evaluation by an endocrinologist (eg, for hyperparathyroidism and vitamin D disorders) or a nephrologist (eg, for renal tubular defects).
- Patients with decreased GI absorption may require referral to a gastroenterologist.

When to Admit

Patients with severe or refractory hypophosphatemia will require intravenous phosphate.

Murray SL et al. Calcium and phosphate disorders: Core Curriculum 2024. Am J Kidney Dis. 2024;83:241. [PMID: 38099870]

HYPERPHOSPHATEMIA

ESSENTIALS OF DIAGNOSIS

- Advanced CKD is the most common cause.
- Hyperphosphatemia in the presence of hypercalcemia imposes a high risk of metastatic calcification.

General Considerations

The two most common etiologies of hyperphosphatemia are decreased renal phosphate clearance from CKD and transcellular shift. Increased dietary intake of phosphates in the setting of advanced CKD can cause hyperphosphatemia. Phosphate-containing laxatives taken as preparation for a GI procedure can cause hyperphosphatemia in patients with impaired kidney function and are therefore less commonly used. Rapid cell breakdown from tumor lysis syndrome, rhabdomyolysis, and massive hemolysis releases intracellular phosphate. Hyperphosphatemia from insulin deficiency can occur in diabetic ketoacidosis (DKA). These patients, however, are typically phosphate depleted and are at risk for developing hypophosphatemia with insulin therapy. Other causes are listed in Table 24–9.

Clinical Findings

A. Symptoms and Signs

Acute hyperphosphatemia is generally asymptomatic, and symptoms are generally associated with concurrent hypocalcemia.

B. Laboratory Findings

In addition to elevated phosphate, blood chemistry abnormalities are those of the underlying disease.

Treatment

Treatment is directed at the underlying cause. Acute hyperphosphatemia with *symptomatic* hypocalcemia and ECG changes (QTc prolongation) can be life-threatening. Intravenous calcium (1–2 g of calcium gluconate over 10–20 minutes) can be given in this situation, though it should be avoided in asymptomatic patients due to the risk of vascular calcification. Hemodialysis may be necessary in patients with impaired kidney function. In chronic hyperphosphatemia, dietary phosphate intake should be decreased and absorption reduced with oral phosphate binders, such as calcium acetate, calcium carbonate, sevelamer, or ferric citrate.

Table 24–9. Causes of hyperphosphatemia.

- **Massive load of phosphate into the extracellular fluid**
  - Exogenous sources
    - Hypervitaminosis D
    - Laxatives or enemas containing phosphate
    - Intravenous phosphate supplement
  - Endogenous sources
    - Rhabdomyolysis (especially if CKD coexists)
    - Tumor lysis by chemotherapy, particularly lymphoproliferative diseases
    - Metabolic acidosis (lactic acidosis, ketoacidosis)
    - Respiratory acidosis (phosphate incorporation into cells is disturbed)
- **Decreased excretion into urine**
  - CKD
  - AKI
  - Hypoparathyroidism
  - Pseudohypoparathyroidism
  - Acromegaly
- **Pseudohyperphosphatemia**
  - Plasma cell myeloma
  - Hyperbilirubinemia
  - Hypertriglyceridemia
  - Hemolysis in vitro

When to Admit

Patients with acute severe hyperphosphatemia require hospitalization for emergent therapy, possibly including dialysis. Concomitant illnesses, such as AKI or cell lysis, may necessitate admission.

Scialla JJ et al. State-of-the-art management of hyperphosphatemia in patients with CKD: an NKF-KDOQI controversies perspective. Am J Kidney Dis. 2021;77:132. [PMID: 32771650]

DISORDERS OF MAGNESIUM CONCENTRATION

Normal plasma magnesium concentration is 1.7–2.1 mg/dL (0.7–0.85 mmol/L). Similar to calcium, only the ionized form is metabolically active. The primary source of magnesium excretion is via the kidney. The physiologic effects of magnesium on the nervous system resemble those of calcium.

Altered magnesium concentration usually provokes an associated alteration of Ca^{2+}. Both hypomagnesemia and hypermagnesemia can decrease PTH secretion or action. Severe hypermagnesemia (> 5 mg/dL [2.1 mmol/L]) suppresses PTH secretion with consequent hypocalcemia; this disorder is typically seen only in patients receiving magnesium therapy for preeclampsia. Severe hypomagnesemia causes PTH resistance in end organs and eventually decreased PTH secretion in severe cases.

HYPOMAGNESEMIA

ESSENTIALS OF DIAGNOSIS

- Serum concentration of magnesium may be normal even in the presence of magnesium depletion. Check urinary magnesium excretion if renal magnesium wasting is suspected.
- Causes neurologic symptoms and arrhythmias.
- Associated with hypocalcemia.

General Considerations

Causes of hypomagnesemia are listed in Table 24–10. Hypomagnesemia and hypokalemia share many etiologies, including diarrhea, alcohol use disorder, and diuretic use. Hypomagnesemia causes renal potassium wasting that is refractory to potassium replacement until magnesium is repleted. Hypomagnesemia also suppresses PTH release and causes end-organ resistance to PTH and low 1,25-dihydroxyvitamin D levels. The resultant hypocalcemia is

Table 24–10. Causes of hypomagnesemia.

- **Diminished absorption or intake**
  - Malabsorption, chronic diarrhea, laxative abuse
  - Malnutrition
  - Alcohol use disorder
  - PPIs
  - Prolonged GI suction
  - Small bowel bypass
  - Total parenteral alimentation with inadequate Mg^{2+} content
- **Increased renal loss**
  - Volume expansion
  - Diuretic therapy (loop diuretics, thiazide diuretics)
  - Hyperaldosteronism, Gitelman syndrome
  - Hyperparathyroidism, hyperthyroidism
  - Hypercalcemia
  - Tubulointerstitial diseases
  - Drugs (aminoglycoside, cetuximab, cisplatin, amphotericin B, pentamidine)
  - Transplant kidney
- **Others**
  - Diabetes mellitus
  - Post-parathyroidectomy (hungry bone syndrome)
  - Respiratory alkalosis
  - Pregnancy

refractory to calcium replacement until the magnesium is normalized. Normomagnesemia does not exclude magnesium depletion because only 1% of total body magnesium is in the extracellular fluid; magnesium repletion should be considered in patients with risk factors for hypomagnesemia and refractory hypokalemia or hypocalcemia. Finally, there is an FDA warning about hypomagnesemia for patients taking PPIs. The presumed mechanism is decreased intestinal magnesium absorption, but it is not clear why this complication develops in only a small fraction of patients taking these medications. The potassium binder patiromer can additionally cause hypomagnesemia by binding magnesium in the colon.

Clinical Findings

A. Symptoms and Signs

Because hypomagnesemia causes hypokalemia and hypocalcemia, it is difficult to determine whether symptoms are from hypomagnesemia or from potassium and calcium depletion. Marked neuromuscular and CNS hyperirritability may produce tremors, cramps, Trousseau and Chvostek signs, confusion, disorientation, and coma. Weakness is common. Cardiovascular manifestations include hypertension, tachycardia, and ventricular arrhythmias, including torsades de pointes.

B. Laboratory Findings

Urinary excretion of magnesium exceeding 10–30 mg/day or a fractional excretion > 3% indicates renal magnesium wasting. Hypocalcemia and hypokalemia are often present. The ECG may show widening of the QRS complex, peaked T waves with ultimate diminution, and a prolonged PR interval. PTH secretion is often suppressed (see Hypocalcemia).

Treatment

Magnesium oxide, 250–500 mg orally once or twice daily, is useful for treating chronic hypomagnesemia. Slow-release formulations such as magnesium chloride or magnesium lactate may be better tolerated. In patients with refractory hypomagnesemia, potassium-sparing diuretics, such as amiloride, may be effective. SGLT-2 inhibitors have emerged as a novel treatment option for refractory hypomagnesemia. Symptomatic hypomagnesemia requires intravenous magnesium sulfate 1–2 g over 5–60 minutes mixed in either dextrose 5% or 0.9% normal saline. Torsades de pointes in the setting of hypomagnesemia can be treated with 1–2 g of magnesium sulfate in 10 mL of dextrose 5% solution pushed intravenously over 15 minutes. Severe, non–life-threatening deficiency can be treated at a rate to 1–2 g/hour over 3–6 hours. Intravenous magnesium inhibits renal reabsorption and patients will demonstrate increased renal wasting during therapy. Serum levels must be monitored daily and dosage adjusted to keep the concentration from rising above 3 mg/dL (1.23 mmol/L). Tendon reflexes may be checked for the hyporeflexia of hypermagnesemia. K^+ and Ca^{2+} replacement may be required, but patients with hypokalemia and hypocalcemia associated with hypomagnesemia do not recover without magnesium supplementation.

Patients with normal kidney function can excrete excess magnesium; hypermagnesemia should not develop with replacement dosages. In patients with CKD, magnesium replacement should be done cautiously to avoid hypermagnesemia. Reduced doses (50–75% dose reduction) and more frequent monitoring of laboratory values are indicated.

Gommers LMM et al. Mechanisms of proton pump inhibitor-induced hypomagnesemia. Acta Physiol (Oxf). 2022;23:e13846. [PMID: 35652564]

Shah CV et al. Sodium/glucose cotransporter 2 inhibitors and magnesium homeostasis. Am J Kidney Dis. 2024;83:648. [PMID: 38372686]

HYPERMAGNESEMIA

ESSENTIALS OF DIAGNOSIS

- Often associated with advanced CKD and chronic intake of magnesium-containing drugs.

General Considerations

Hypermagnesemia is almost always the result of advanced CKD and impaired magnesium excretion. Antacids and laxatives are underrecognized sources of magnesium. Severe hypermagnesemia can develop in pregnant patients who receive intravenous magnesium for preeclampsia and eclampsia. Magnesium replacement should be done cautiously in patients with CKD; dose reductions up to 75% may be necessary to avoid hypermagnesemia.

Clinical Findings

A. Symptoms and Signs

Muscle weakness, decreased deep tendon reflexes, mental obtundation, and confusion are characteristic manifestations of hypermagnesemia. Weakness, flaccid paralysis, ileus, and hypotension can also occur. Severe findings of this condition include respiratory muscle paralysis, complete heart block, and cardiac arrest.

B. Laboratory Findings and ECG

An elevated serum magnesium level is diagnostic. Since CKD is a common risk factor for hypermagnesemia, BUN, creatinine, potassium, phosphate, and uric acid levels may all be elevated. Moreover, the serum calcium level is often low. The ECG may show an increased PR interval, broadened QRS complexes, and QT prolongation.

Treatment

Exogenous sources of magnesium should be discontinued. Calcium antagonizes Mg^{2+} and may be given intravenously as calcium chloride, 500 mg or more at a rate of 100 mg (4.1 mmol) per minute. Hemodialysis may be necessary to remove magnesium, particularly in the context of severe kidney disease. Finally, the long-term use of magnesium hydroxide and magnesium sulfate should be avoided in patients with advanced stages of CKD.

Ribeiro HS et al. Association of magnesium abnormalities at intensive care unit admission with kidney outcomes and mortality: a prospective cohort study. Clin Exp Nephrol. 2022;26:997. [PMID: 35760979]

ACID-BASE DISORDERS

To best evaluate acid-base status, a blood gas and chemistry panel are required. Venous blood pH is typically 0.03–0.04 units lower than arterial blood pH, but still closely approximates arterial blood pH. An ABG should be obtained if more accurate assessment of blood pH and P_{CO_2} is required. Bicarbonate (HCO_3^-) is calculated from the Henderson-Hasselbalch equation below; therefore, the bicarbonate value measured in the electrolyte panel is typically used.

$$pH = 6.1 + \log \frac{HCO_3^-}{0.03 \times P_{CO_2}}$$

Primary acid-base disorders are secondary to changes in either serum bicarbonate or P_{CO_2}. The first step is to look at the pH of a blood gas (venous or arterial). If changes in pH are secondary to changes in HCO_3^-, a metabolic disorder is present. If changes in pH are secondary to changes in P_{CO_2}, a respiratory disorder is present. If the pH is < 7.40, the primary process is acidosis, either respiratory (P_{CO_2} > 40 mm Hg) or metabolic (HCO_3^- < 24 mEq/L). If the pH is > 7.40, the primary process is alkalosis, either respiratory (P_{CO_2} < 40 mm Hg) or metabolic (HCO_3^- > 24 mEq/L). Normally, the kidneys compensate for respiratory acid-base disorders and the lungs compensate for metabolic disorders to maintain pH in a narrow physiologic range. For example, with metabolic acidosis (low pH, low HCO_3^-), alveolar ventilation increases (P_{CO_2} decreases), returning pH close to the normal range. Similarly, with respiratory acidosis (low pH, high P_{CO_2}), the kidneys excrete H^+ (HCO_3^- increase) to return the pH close to normal range. Such compensation can only bring the pH toward normal, though it can never completely correct it. To normalize pH, the primary disorder must be corrected.

One respiratory or metabolic disorder with its appropriate compensatory response is a simple acid-base disorder. A mixed acid-base disorder is when multiple simple disorders are present simultaneously. Diagnosing an acid-base disorder requires a systematic approach (see box Step-by-Step Analysis of Acid-Base Status). Once the primary disorder has been identified, the clinician should assess whether the compensatory response is appropriate (Table 24–11). An inadequate or an exaggerated response indicates the presence of another primary acid-base disturbance.

The serum anion gap should subsequently be calculated (see below) for two reasons. First, it helps identify the cause of a metabolic acidosis, and second, it identifies the presence of a gap metabolic acidosis, which may be present even without a decreased serum bicarbonate concentration. In patients with metabolic acidosis

Table 24–11. Primary acid-base disorders and expected compensation.

Disorder	Primary Defect	Compensatory Response	Magnitude of Compensation
Respiratory acidosis			
Acute	↑ P_{CO_2}	↑ HCO_3^-	↑ HCO_3^- 1 mEq/L per 10 mm Hg ↑ P_{CO_2}
Chronic	↑ P_{CO_2}	↑ HCO_3^-	↑ HCO_3^- 3.5 mEq/L per 10 mm Hg ↑ P_{CO_2}
Respiratory alkalosis			
Acute	↓ P_{CO_2}	↓ HCO_3^-	↓ HCO_3^- 2 mEq/L per 10 mm Hg ↓ P_{CO_2}
Chronic	↓ P_{CO_2}	↓ HCO_3^-	↓ HCO_3^- 5 mEq/L per 10 mm Hg ↓ P_{CO_2}
Metabolic acidosis	↓ HCO_3^-	↓ P_{CO_2}	↓ P_{CO_2} 1.3 mm Hg per 1 mEq/L ↓ HCO_3^-
Metabolic alkalosis	↑ HCO_3^-	↑ P_{CO_2}	↑ P_{CO_2} 0.7 mm Hg per 1 mEq/L ↑ HCO_3^-

STEP-BY-STEP ANALYSIS OF ACID-BASE STATUS

Step 1: Look at the pH on a blood gas to determine the primary disorder, either acidemia or alkalemia.

Step 2: Look at the serum HCO$_3^-$ value to determine if the primary disorder is metabolic.

Step 3: Calculate the anion gap (see Table 24–12).

Step 4: Calculate the Δgap.

Step 5: Evaluate magnitude of compensation (see Table 24–11).

Step 6: Examine the patient to determine whether the clinical signs are compatible with the acid-base analysis.

disorders, clinicians should calculate the **Δgap**, which is the difference between the change in anion gap and the change in bicarbonate, to determine if there is a mixed anion gap or normal anion gap metabolic acidosis. In increased anion gap acidosis disorders, there should be roughly a millimole for millimole decrease in HCO$_3^-$ as the anion gap increases. The corrected serum HCO$_3^-$ should be calculated by adding the change in serum anion gap to the serum HCO$_3^-$. A value higher or lower than normal (24 mEq/L) indicates the concomitant presence of metabolic alkalosis or normal anion gap metabolic acidosis, respectively.

METABOLIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- Decreased HCO$_3^-$ with acidemia (low blood pH).
- Classified into increased anion gap acidosis and normal anion gap acidosis.
- Lactic acidosis, ketoacidosis, and toxins produce metabolic acidosis disorders with the largest anion gaps.
- Normal anion gap acidosis is mainly caused by loss of bicarbonate in the GI tract or RTA.

General Considerations

The hallmark of metabolic acidosis is low serum bicarbonate concentration from loss of bicarbonate or gain of acid (Table 24–12); the anion gap detects an increase in plasma anions other than from measured bicarbonate and chloride.

Many clinicians use 12 mEq/L as the normal serum anion gap (range 4–12 mEq/L) due to differences in analyzer methods).

$$\text{Anion Gap} = \text{Na}^+ - (\text{HCO}_3^- + \text{Cl}^-)$$

Table 24–12. Anion gap in metabolic acidosis.[1]

- **Increased (> 12 mEq/L)**
  - Metabolic anion
    - Diabetic ketoacidosis
    - Alcoholic ketoacidosis
    - Lactic acidosis
    - CKD (advanced stages) (PO$_4^{3-}$, SO$_4^{2-}$)
    - Starvation ketoacidosis
  - Drug or chemical anion
    - Salicylate intoxication
    - Methanol (formic acid)
    - Ethylene glycol (oxalic acid)
  - 5-Oxoproline acidosis from acetaminophen toxicity
- **Normal (4–12 mEq/L)**
  - Loss of HCO$_3^-$
    - Diarrhea
    - Recovery from diabetic ketoacidosis
    - Pancreatic fluid loss, ileostomy (unadapted)
    - Carbonic anhydrase inhibitors
  - Chloride retention
    - Renal tubular acidosis
    - Ileal loop bladder
  - Administration of HCl equivalent or NH$_4$Cl
    - Arginine and lysine in parenteral nutrition
- **Decreased (< 6 mEq/L)**
  - Hypoalbuminemia (decreased unmeasured anion)
  - Plasma cell dyscrasias
    - Monoclonal protein (cationic paraprotein accompanied by chloride and bicarbonate)

[1] Reference ranges for anion gap may vary based on laboratory methods.

The principal unmeasured anion usually responsible for the anion gap is albumin. The expected anion gap must be adjusted for hypoalbuminemia since the anion gap decreases by approximately 2.5 mEq/L for every 1 g/dL reduction in the serum albumin concentration.

$$\text{Corrected serum anion gap} = (\text{measured serium anion gap}) + (2.5 \times [4.0 - \text{serum albumin}])$$

In metabolic acidosis from a gain of acid, the anion gap will increase because the addition of acid includes the addition of anions. In normal anion gap or hyperchloremic metabolic acidosis, the anion gap is normal because the rise in chloride parallels the fall in bicarbonate.

INCREASED ANION GAP METABOLIC ACIDOSIS

A gap metabolic acidosis is secondary to the addition of acid, either exogenous or endogenous. The major causes are lactic acidosis, ketoacidosis, kidney disease, and ingestions (Table 24–12). A useful mnemonic for the differential diagnosis of increased anion gap metabolic acidosis is GOLDMARK (glycols [ethylene glycol and propylene glycol], oxoproline, L-lactate, D-lactate, methanol, aspirin, renal failure, and ketoacidosis) (Table 24–13).

Table 24–13. Common causes and therapy for increased anion gap metabolic acidosis.

Cause	Treatment
Lactic acidosis	Therapy aimed at correcting the underlying cause. Treatment of type A requires improving perfusion and matching oxygen consumption with fluids, packed red cells, vasopressors, and inotropes as needed. Treatment of type B generally requires removal of the offending agent or supplementing key cofactors of anaerobic metabolism.
D-Lactic acidosis	Sodium bicarbonate may be administered in the setting of severe acidemia. Specific antimicrobial agents (metronidazole, neomycin) can be utilized in patients with short gut syndrome. A low-carbohydrate diet can be effective by decreasing substrate delivery to the distal colon. Fecal transplant has been utilized successfully in patients unresponsive to conventional therapies.
Ketoacidosis Diabetes mellitus Starvation Alcoholic	Therapy involves correction of the state of insulin deficiency and glucagon excess. In diabetic ketoacidosis, this requires administration of exogenous insulin, generally with a continuous infusion. In starvation and alcoholic ketoacidosis, dextrose-containing fluids will stimulate endogenous insulin release. In all groups, correction of volume depletion with isotonic fluids as well as judicious repletion of electrolytes (particularly potassium and phosphorous) are imperative.
Kidney failure	Supplemental alkali therapy (sodium bicarbonate or sodium citrate). Hemodialysis when necessary.
Ingestions	
Ethylene glycol Methanol	See Chapter 43.
Salicylic acid	See Chapter 43.
Pyroglutamic acid (5-Oxoproline)	Therapy is directed at the underlying cause. Generally requires withdrawal of the offending agent (acetaminophen) and sodium bicarbonate therapy for severe acidemia. *N*-Acetylcysteine may be effective in restoring glutathione stores.

A. Lactic Acidosis

Lactic acidosis is a common cause of metabolic acidosis, producing an elevated anion gap and decreased serum pH when present without other acid-base disturbances. Lactate is formed from pyruvate in anaerobic glycolysis. Normally, lactate levels remain low (1 mEq/L) because of the metabolism of lactate principally by the liver through gluconeogenesis or oxidation via the Krebs cycle. In lactic acidosis, lactate levels are at least 4–5 mEq/L but commonly significantly higher. There are three types of lactic acidosis summarized below:

Type A (hypoxic) lactic acidosis is the most common, resulting from tissue hypoxia, usually from septic, cardiogenic, or hemorrhagic shock; mesenteric ischemia; respiratory failure; and carbon monoxide poisoning. These conditions increase peripheral lactic acid production and decrease hepatic metabolism of lactate as liver perfusion declines.

Type B lactic acidosis is secondary to impaired mitochondrial oxygen utilization and may be due to metabolic causes (eg, diabetes mellitus, liver disease, kidney disease, thiamine deficiency, D-lactic acidosis, leukemia, or lymphoma) or toxins (eg, ethanol, methanol, ethylene glycol, cyanide, isoniazid, or metformin). Propylene glycol, which is used as a vehicle for intravenous medications (eg, nitroglycerin, etomidate, and diazepam), can cause lactic acidosis by decreasing liver metabolism. Parenteral nutrition without thiamine causes severe refractory lactic acidosis from deranged pyruvate metabolism.

D-Lactic acidosis may develop in patients with short bowel syndrome due to carbohydrate malabsorption and subsequent fermentation by colonic bacteria. Metabolic acidosis occurs after meals and is associated with neurologic changes (confusion, slurred speech, and ataxia). A specific D-lactic acid assay is required as the standard lactic acid assay only detects the L-isomer.

B. Ketoacidosis

All forms of ketoacidosis share the physiologic state of insulin deficiency and glucagon excess, which shifts the body's primary fuel source from glucose to fatty acid metabolism. There are three types of ketones: acetone, acetoacetate, and β-hydroxybutyrate.

1. Diabetic ketoacidosis (DKA)—DKA is characterized by hyperglycemia and metabolic acidosis with an increased anion gap from absolute or relative insulin deficiency

$$H^+ + B^- + NaHCO_3 \leftrightarrow CO_2 + NaB + H_2O$$

where B^- is β-hydroxybutyrate or acetoacetate, the ketones responsible for the increased anion gap. DKA may be accompanied by an additional lactic acidosis from tissue hypoperfusion and increased anaerobic metabolism. The anion gap in DKA is often large (> 20 mEq/L) but is variable. The elevated serum glucose leads to a marked osmotic diuresis with sizeable losses of sodium, water, and potassium.

The correction of ketoacidosis via therapeutic maneuvers can be monitored by the measurement of serum β-hydroxybutyrate, measuring the pH, or by normalization of the anion gap. Urine ketones are detected by nitroprusside testing, results of which are rapidly available.

However, urinary nitroprusside tests detect both acetoacetate and acetone (albeit to a lesser extent) but do not detect β-hydroxybutyrate. Direct measurement of serum β-hydroxybutyrate is preferred and can be used to monitor response to therapy.

2. Fasting ketoacidosis—Hepatic generation of ketones may occur as a normal response to fasting from relative hypoinsulinemia. Mild ketosis often occurs after 12–14 hours of fasting, peaking after 20–30 hours. The level of acidosis is generally small with fasting, albeit overt ketoacidosis can occur in patients who consume very low carbohydrate diets.

3. Alcoholic ketoacidosis—Chronically malnourished patients who consume large quantities of alcohol may develop alcoholic ketoacidosis. Alcohol metabolism decreases gluconeogenesis, resulting in hepatic production of β-hydroxybutyrate and, to a lesser degree, acetoacetate. Mixed acid-base disorders, such as a combination of metabolic alkalosis from vomiting and respiratory alkalosis from alcohol withdrawal, aspiration, or cirrhosis, are common.

With either fasting or alcohol ketoacidosis, insulin release is suppressed by hypoglycemia or stimulation of the sympathetic nervous system, allowing ketosis to occur. Patients with these disorders can sufficiently produce endogenous insulin and therefore do not require exogenous insulin administration. Treatment should commence with glucose administration to stimulate insulin release and suppress ketogenesis. Potassium should be repleted prior to glucose administration as insulin release will cause intracellular potassium shift, risking hypokalemia.

C. Toxins

(See also Chapter 43.) Multiple toxins and drugs increase the anion gap by increasing endogenous acid production. Common examples include methanol (metabolized to formic acid), ethylene glycol (glycolic and oxalic acid), and salicylates (salicylic acid and lactic acid). The latter can cause a mixed disorder of metabolic acidosis with respiratory alkalosis. In toluene poisoning, the metabolite hippurate is rapidly excreted by the kidney, resulting in a normal anion gap acidosis. Isopropanol, which is metabolized to acetone, increases the osmolar gap, but not the anion gap. Long-term acetaminophen use, even at therapeutic doses, can result in an elevated anion gap acidosis from accumulation of 5-oxoproline.

D. Uremic Acidosis

As the GFR drops below 15–30 mL/min/1.73 m^2, the kidneys are increasingly unable to synthesize ammonium (NH_4). The reduced excretion of H^+ (as NH_4Cl) and accumulation of organic anions from decreased excretion (eg, phosphate and sulfate) results in an increased anion gap metabolic acidosis.

NORMAL ANION GAP METABOLIC ACIDOSIS

The two major causes of a normal anion gap metabolic acidosis are bicarbonate loss from the GI tract or defects in renal acidification (RTA) (Table 24–12 and Table 24–14). The compensatory increase in serum chloride (hyperchloremia) maintains electroneutrality and a normal anion gap. Because urine ammonium is not commonly measured, the urinary anion gap is used as a surrogate to differentiate between these causes; however, studies have shown that the urinary anion gap is not a reliable indicator of urine ammonium.

A. GI HCO_3^- Loss

The GI tract secretes bicarbonate at multiple sites. The most common cause of a normal anion gap metabolic acidosis from the GI tract is diarrhea (loss of bicarbonate rich stool fluid). An infrequent cause is a ureterosigmoidostomy, where ureters are implanted into the sigmoid colon for urinary diversion. Unlike the bladder, colonic mucosa secretes bicarbonate in exchange for chloride, resulting in metabolic acidosis. More commonly, a neobladder is created using a loop of bowel (generally ileum or colon), which has significantly decreased the incidence of

Table 24–14. Hyperchloremic, normal anion gap metabolic acidoses.

			Distal H^+ Secretion			
	Renal Defect	Serum [K^+]	Urine pH	Titratable Acid	Urinary Anion Gap	Treatment
GI HCO_3^- loss	None	↓	< 5.5	↑↑	Negative	Na^+, K^+, and HCO_3^- as required
Renal tubular acidosis						
I. Distal	Distal H^+ secretion	↓	> 5.3	↓	Positive	$NaHCO_3$ (1–3 mEq/kg/day)
II. Proximal	Proximal HCO_3^- reabsorption	↓	Variable	Normal	Variable	$NaHCO_3$ or $KHCO_3$ (10–15 mEq/kg/day), thiazide
III. Hyporeninemic hypoaldosteronism	Distal Na^+ reabsorption, K^+ secretion, and H^+ secretion	↑	Variable	↓	Positive	Fludrocortisone (0.1–0.5 mg/day), dietary K^+ restriction, furosemide (40–160 mg/day), $NaHCO_3$ (1–3 mEq/kg/day)

Reproduced, with permission, from Cogan MG. *Fluid and Electrolytes: Physiology and Pathophysiology*. New York: McGraw-Hill, 1991.

metabolic acidosis from diversion, though it can still occur when contact time between urine and mucosa is increased, typically because of an anastomotic stricture.

B. Renal Tubular Acidosis

Hyperchloremic acidosis with a normal anion gap and normal (or near normal) GFR, in the absence of diarrhea, defines RTA. The defect is either an inability to excrete H^+ as ammonium (inadequate generation of new HCO_3^-) or inadequate reabsorption of filtered HCO_3^-. Three major types can be differentiated by the clinical setting, as well as urinary pH, urinary anion gap (or urinary ammonium if available), and serum potassium levels.

1. Distal RTA (type I)—This disorder is characterized by inability to excrete H^+ by the distal nephron. The urine cannot be fully acidified (urine pH remains > 5.5), despite systemic acidosis. Urinary ammonium excretion is therefore decreased, and the urinary anion gap is positive. Distal RTA (dRTA) is usually secondary to a congenital or acquired decrease in the number of functional H^+ pumps, which reduces H^+ secretion. This is associated with hypokalemia due to enhanced K^+ excretion from a lack of competition from H^+ in the tubular fluid. This form of dRTA is commonly due to Sjögren syndrome, SLE, plasma cell myeloma, toluene inhalation (glue sniffing), Wilson disease, and lithium. dRTA can also be caused by destruction of tubular integrity (eg, by the antifungal amphotericin B). In all types of dRTA, buffering of acid by release of bicarbonate and calcium from bone results in hypercalciuria, which in addition to low urinary citrate from increased reabsorption, can result in nephrolithiasis.

2. Proximal RTA (type II)—Proximal RTA (pRTA) is due to a defect in the ability of the proximal tubule to reabsorb filtered HCO_3. The maximal rate of bicarbonate reabsorption is set by the tubular maximum (Tm), which is normally 26–28 mEq/L. The hallmark of pRTA is a decrease in the Tm for bicarbonate, typically to 14–20 mEq/L. Therefore, this is a self-limited disease with serum bicarbonate levels predicated on the severity of the proximal defect and the ability of the distal nephron to reabsorb bicarbonate. This essentially creates a new steady state, in which the Tm is equivalent to the serum HCO_3^- level, the urine is acidic (because there is no impairment of distal H^+ secretion), and the urine anion gap is negative (because there is no impairment of ammonium excretion). Bicarbonaturia, resulting in alkaline urine (> 5.5), only occurs when the bicarbonate level exceeds the Tm, which has implications in treatment. Fanconi syndrome is pRTA with other proximal reabsorption defects resulting in glucosuria, aminoaciduria, phosphaturia, and uricosuria. The most common cause of pRTA is proximal tubular toxicity from the monoclonal immunoglobulin light chains in plasma cell myeloma. Other causes include heavy metals; Sjögren syndrome; cystinosis; Wilson disease; and various medications, such as acetazolamide, topiramate, tenofovir, and ifosfamide. The increased delivery of HCO_3^- to the distal nephron enhances K^+ secretion, and hypokalemia results when a patient is treated with HCO_3^- without adequate K^+ supplementation. Similar to dRTA, bone loss from persistent acidosis is common. Rickets can develop in untreated children, while osteomalacia can develop in untreated adults. Unlike dRTA, nephrolithiasis is uncommon in pRTA because of the increased citrate in the urine, which increases calcium solubility.

3. Hyporeninemic hypoaldosteronemic RTA (type IV)—Type IV is the most common RTA in clinical practice. This is primarily a disorder of hyperkalemia secondary to a decrease in aldosterone, which inhibits ammonium production. The clinical presentation is hyperkalemic normal anion gap metabolic acidosis. Common causes include diabetic nephropathy and tubulointerstitial renal diseases. In patients with these disorders, some medications, such as ACE inhibitors, ARBs, spironolactone, and NSAIDs, can worsen the hyperkalemia and acidosis.

C. Other Causes of Normal Anion Gap Acidosis

A dilutional acidosis may occur when the extracellular volume is rapidly expanded with normal saline since it contains neither bicarbonate nor sodium salts that can be metabolized to bicarbonate. Concerns have been raised regarding potential harm from volume expansion with normal saline. In clinical practice, balanced crystalloid solutions, such as lactated Ringer solution, are more commonly used; however, data regarding optimal fluid choice are conflicting.

1. Urine anion gap—The normal kidney response to a metabolic acidosis is to increase NH_4Cl excretion to enhance H^+ removal. The daily urinary excretion of NH_4Cl can be increased from 30 mEq at baseline to 200–300 mEq in response to acidosis. Urine ammonium excretion can be estimated using the following urine anion gap equation:

$$\text{Urine anion gap} = U_{Na} + U_K - U_{Cl}$$

The urinary anion gap may help differentiate between GI and renal causes of hyperchloremic acidosis, although concerns have been raised regarding the utility of a urinary anion gap as a surrogate for urinary ammonium. If the cause is GI bicarbonate loss (diarrhea), renal acidification remains intact and NH_4Cl excretion increases appropriately (urinary anion gap will be negative). In a dRTA, ammonium excretion is impaired and the urinary anion gap is positive. In pRTA (type II), the primary problem is impaired HCO_3^- reabsorption, leading to increased HCO_3^- excretion rather than decreased NH_4Cl excretion and the urinary anion gap is often negative until treatment is initiated with exogenous bicarbonate therapy.

2. Urine osmolal gap—When large amounts of other anions (eg, hippurate in toluene poisoning, β-hydroxybutyrate, acetoacetate) are present in the urine, the urinary anion gap may not be reliable. In this situation, the urine osmolal gap may be a better indicator of NH_4^+ excretion, which can be estimated as 50% of the urinary osmolal gap where urine concentrations and osmolality are in mmol/L. A urine osmolal gap below 150 mOsmol/kg suggests impaired ammonium excretion, whereas a urine osmolal gap above

400 mOsmol/kg suggests an intact renal response to acidosis.

$$\text{Urine osmolal gap} = U_{osm} - 2(U_{Na} + U_{K}) + U_{area} + U_{glucose}$$

Clinical Findings

A. Symptoms and Signs

Symptoms of metabolic acidosis are mainly those of the underlying disorder. Compensatory hyperventilation is an important clinical sign and may be misinterpreted as a primary respiratory disorder; Kussmaul breathing (deep, regular, sighing respirations) may be seen with severe metabolic acidosis.

B. Laboratory Findings

Blood pH, serum HCO_3^-, and P_{CO_2} are decreased. Anion gap may be normal (hyperchloremic metabolic acidosis) or increased. Hyperkalemia may be present.

Treatment

A. Increased Anion Gap Acidosis

Treatment is aimed at the underlying disorder, such as insulin and fluid therapy for diabetes and appropriate volume resuscitation to restore tissue perfusion (see Table 24–13). $NaHCO_3$ therapy is controversial in the treatment of increased anion gap metabolic acidosis disorders and is usually reserved for severe cases (arterial pH < 7.1–7.2). Large amounts of $NaHCO_3$ may have deleterious effects, including hypernatremia, hyperosmolality, volume overload, and worsening of intracellular acidosis.

B. Normal Anion Gap Acidosis

Treatment of RTA is mainly achieved by administration of alkali (bicarbonate or citrate) to correct metabolic abnormalities and prevent nephrocalcinosis and CKD.

Large amounts of oral alkali ($NaHCO_3$ or $KHCO_3$ 10–15 mEq/kg/day) (Table 24–14) may be required to treat pRTA because much of the administered alkali is excreted into the urine. This can exacerbate hypokalemia and a mixture of sodium and potassium salts is often required. Treatment of type I dRTA requires less alkali (1–2 mEq/kg/day) than pRTA, and potassium supplementation is typically required.

For type IV RTA, dietary potassium restriction may be necessary and potassium-retaining drugs should be withdrawn. Loop diuretics may be beneficial. Fludrocortisone may be effective in some cases without significant volume expansion. In some cases, oral alkali supplementation (1–2 mEq/kg/day) may be required.

When to Refer

Most clinicians will refer patients with RTA disorders to a nephrologist for evaluation and possible alkali therapy.

When to Admit

Patients require emergency department evaluation or hospital admission depending on the severity of the acidosis and underlying conditions.

METABOLIC ALKALOSIS

ESSENTIALS OF DIAGNOSIS

- High HCO_3^- with alkalemia (high pH).
- Evaluate effective circulating volume by physical examination.
- Urinary chloride concentration differentiates saline-responsive alkalosis from saline-unresponsive alkalosis.

General Considerations

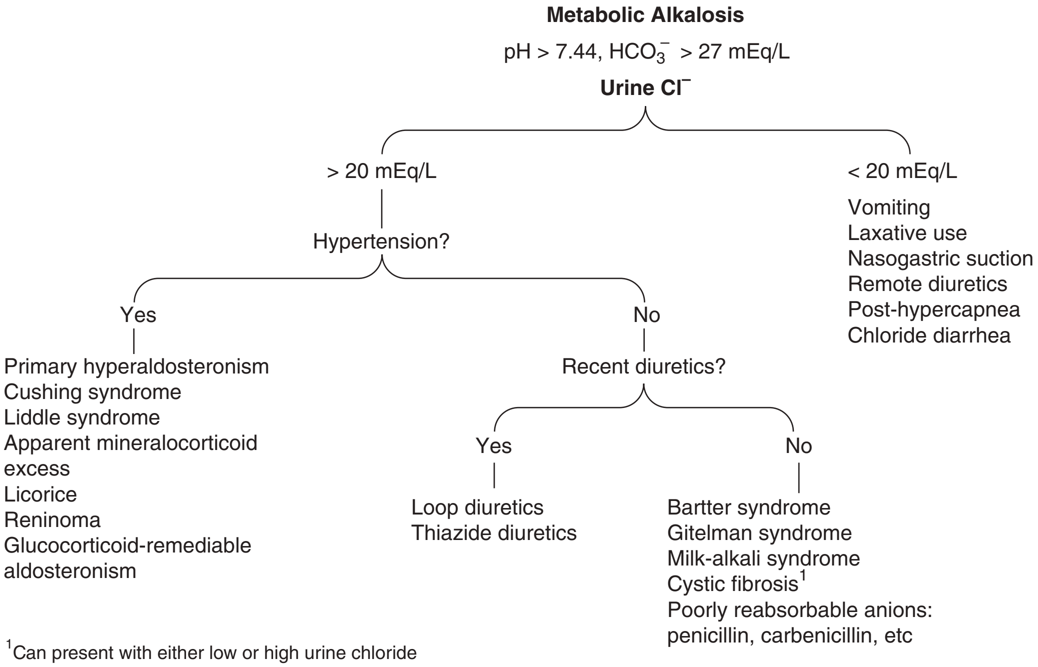
Metabolic alkalosis is characterized by high serum HCO_3^- levels. The development of metabolic alkalosis requires its "generation" from loss of acid or gain of alkali, and its "maintenance" from the kidney's inability to excrete excess bicarbonate.

The causes of metabolic alkalosis are classified into two groups based on chloride responsiveness and are generally distinguished using urine chloride values (Figure 24–3). The compensatory increase in P_{CO_2} rarely exceeds 55 mm Hg; higher P_{CO_2} values imply a superimposed primary respiratory acidosis. However, the disorders of ion transport do not strictly fit in either category.

Bartter and **Gitelman syndromes** are genetic disorders affecting ion transport. Features of both syndromes include metabolic alkalosis, hypokalemia, and normotension. Bartter syndrome is characterized by abnormalities affecting the NKCC channel in the loop of Henle and mimics a persistent loop diuretic effect. Gitelman syndrome is characterized by abnormalities affecting the NCC channel in the distal tubule, which mimics a persistent thiazide diuretic effect.

A. Chloride-Sensitive Metabolic Alkalosis ($U_{Cl}^- < 20$ mEq/L)

Chloride-sensitive metabolic alkalosis involves the loss of chloride and extracellular volume. In vomiting and nasogastric suction, loss of acid (HCl) generates alkalosis and volume contraction from chloride loss maintains the alkalosis. Distally acting diuretics that cause chloride loss, eg, loop and thiazide diuretics, are a common cause of metabolic alkalosis. U_{Cl}^- levels can be unreliable in these settings since these diuretics increase U_{Cl}^-. These disorders cause concurrent hypokalemia, which can exacerbate metabolic alkalosis by stimulating H^+ secretion and ammoniagenesis.



Metabolic Alkalosis
pH > 7.44, HCO3− > 27 mEq/L
Urine Cl−
> 20 mEq/L
Hypertension?
Yes
Primary hyperaldosteronism
Cushing syndrome
Liddle syndrome
Apparent mineralocorticoid excess
Licorice
Reninoma
Glucocorticoid-remediable aldosteronism
No
Recent diuretics?
Yes
Loop diuretics
Thiazide diuretics
No
Bartter syndrome
Gitelman syndrome
Milk-alkali syndrome
Cystic fibrosis1
Poorly reabsorbable anions: penicillin, carbenicillin, etc
< 20 mEq/L
Vomiting
Laxative use
Nasogastric suction
Remote diuretics
Post-hypercapnea
Chloride diarrhea

[1] Can present with either low or high urine chloride

Figure 24–3. Algorithm for metabolic alkalosis on the basis of urine chloride.

In alkalosis, bicarbonaturia causes obligatory sodium excretion as the accompanying cation and U_{Na} levels are unreliable markers of extracellular volume.

B. Chloride-Resistant Metabolic Alkalosis (U_{Cl}^{-} > 20 mEq/L)

1. Excess mineralocorticoid activity—Mineralocorticoids act directly in the collecting duct to stimulate sodium reabsorption and hydrogen and potassium excretion. The effects on hydrogen excretion are important in the generation of metabolic alkalosis. Important causes of excess mineralocorticoid activity include primary hyperaldosteronism, Cushing disease, congenital adrenal hyperplasia (11-β-hydroxylase and 17-α hydroxylase deficiency), reninoma, excess licorice ingestion, apparent mineralocorticoid excess syndrome, and congenital adrenal hyperplasia (11-β-hydroxylase and 17-α hydroxylase) (Figure 24–3). These disorders are typically associated with hypertension, hypokalemia, metabolic alkalosis, and mild hypernatremia.

2. Alkali administration with decreased GFR—The normal kidney has a substantial capacity for bicarbonate excretion; therefore, metabolic alkalosis usually only develops with HCO_3^- intake (eg, intensive antacid therapy) when there is CKD. In milk-alkali syndrome, sustained heavy ingestion of absorbable antacids and milk causes hypercalcemic kidney injury and metabolic alkalosis. Volume contraction from renal hypercalcemic effects exacerbates the alkalosis.

Clinical Findings

A. Symptoms and Signs

There are no characteristic symptoms or signs. However, hypopnea can be present in severe cases. Concomitant hypokalemia may cause weakness and hyporeflexia. Severe alkalosis with a pH > 7.48 is associated with an increased risk of mortality.

B. Laboratory Findings

The arterial blood pH and bicarbonate are elevated. With respiratory compensation, the arterial P_{CO_2} is increased. Serum potassium and chloride are decreased. The urine Cl^- can differentiate between chloride-responsive (< 20 mEq/L) and unresponsive (> 20 mEq/L) causes.

Treatment

Mild alkalosis is generally well tolerated. Severe or symptomatic alkalosis (pH > 7.60) requires urgent treatment.

A. Chloride-Sensitive Metabolic Alkalosis

Therapy for chloride-sensitive alkalosis involves volume expansion with chloride salts, generally in the form of intravenous normal saline, until a euvolemic state has been achieved. This reduces proximal tubular bicarbonate reabsorption and increases distal tubular delivery of chloride, where it is exchanged for bicarbonate by the luminal Cl^-/HCO_3^- pendrin. In edematous patients with a contraindication to volume expansion (eg, HF), options include Cl^- administration in the form of KCl, which has the added benefit of correcting concurrent hypokalemia if present, and the carbonic anhydrase inhibitor acetazolamide, typically given (250–500 mg twice daily) to increase renal bicarbonate excretion.

B. Chloride-Resistant Metabolic Alkalosis

Therapy for chloride-resistant metabolic alkalosis requires therapy targeted to the underlying cause (see Chapter 29).

Emmett M. Metabolic alkalosis: a brief pathophysiologic review. Clin J Am Soc Nephrol. 2020;15:1848. [PMID: 32586924]

RESPIRATORY ACIDOSIS (Hypercapnia)

General Considerations

Respiratory acidosis results from hypoventilation and subsequent hypercapnia. Both pulmonary and extrapulmonary disorders can cause hypoventilation (see Chapter 9, Pulmonary Disorders).

Acute respiratory acidosis is associated with only a modest increase in bicarbonate since serum bicarbonate is an ineffective buffer because of impaired elimination of carbon dioxide. After 6–12 hours, the primary increase in P_{CO_2} evokes a renal compensation to excrete more acid and to generate more HCO_3^-. Complete metabolic compensation by the kidney takes several days. In acute respiratory acidosis, HCO_3^- increases by 1 mEq/L for every 10 mm Hg increase in P_{CO_2}.

Chronic respiratory acidosis is generally seen in patients with underlying lung disease, such as COPD. Renal excretion of acid as NH_4Cl results in compensatory metabolic alkalosis. In this situation, HCO_3^- increases by 3 mEq/L for every 10 mm Hg increase in P_{CO_2}.

Clinical Findings

A. Symptoms and Signs

With acute-onset respiratory acidosis, somnolence, confusion, mental status changes, asterixis, and myoclonus may develop. Severe hypercapnia increases cerebral blood flow, CSF pressure, and intracranial pressure; papilledema and seizures may be seen.

B. Laboratory Findings

Arterial pH is low and P_{CO_2} is increased. Serum HCO_3^- is elevated but does not fully correct the pH. Respiratory etiologies of respiratory acidosis usually have a wide A-a gradient; a relatively normal A-a gradient in the presence of respiratory acidosis is highly suggestive of global hypoventilation.

Treatment

If opioid overdose is a possible diagnosis or there is no other obvious cause for hypoventilation, the clinician should consider a diagnostic and therapeutic trial of intravenous naloxone (see Chapter 43). Noninvasive or mechanical ventilation may be necessary.

Adrogué HJ et al. Alkali therapy for respiratory acidosis: a medical controversy. Am J Kidney Dis. 2020;75:265. [PMID: 31473018]

RESPIRATORY ALKALOSIS

General Considerations

Respiratory alkalosis is always a disorder of hyperventilation, reducing the P_{CO_2} and increasing serum pH (Table 24–15). In pregnancy, progesterone stimulates the respiratory center, producing an average P_{CO_2} of 30 mm Hg and respiratory alkalosis. Salicylates directly stimulate respiration and aspirin toxicity should be suspected when both respiratory alkalosis and an anion gap metabolic acidosis are present, particularly with alkalemia. Symptoms of acute respiratory alkalosis are related to decreased cerebral blood flow induced by the disorder.

Table 24–15. Causes of respiratory alkalosis.

Hypoxia
- Decreased inspired oxygen tension
- High altitude
- Ventilation/perfusion inequality
- Hypotension
- Severe anemia

CNS-mediated disorders
- Voluntary hyperventilation
- Anxiety-hyperventilation syndrome
- Neurologic disease
- Cerebrovascular accident (infarction, hemorrhage)
- Infection
- Trauma
- Tumor
- Pharmacologic and hormonal stimulation
  - Salicylates
  - Nicotine
  - Xanthines
  - Pregnancy (progesterone)
- Liver failure
- Gram-negative septicemia
- Recovery from metabolic acidosis
- Heat exposure

Pulmonary disease
- Interstitial lung disease
- Pneumonia
- PE
- Pulmonary edema

Mechanical overventilation

Reproduced with permission from Gennari FJ. *Respiratory acidosis and alkalosis. In: Maxwell and Kleeman's Clinical Disorders of Fluid and Electrolyte Metabolism*, 5th ed. New York: McGraw-Hill,1994.

Determination of appropriate metabolic compensation may reveal an associated metabolic disorder.

As in respiratory acidosis, the metabolic compensation is greater if the respiratory alkalosis is chronic (see Table 24–11). In acute respiratory alkalosis, HCO_3^- decreases by 2 mEq/L for every 10 mm Hg decrease in P_{CO_2}, whereas in chronic respiratory alkalosis, HCO_3^- decreases by 4 mEq/L for every 10 mm Hg decrease in P_{CO_2}.

Clinical Findings

A. Symptoms and Signs

In acute cases (hyperventilation), there is light-headedness, anxiety, perioral numbness, and paresthesias. Tetany occurs from a low ionized calcium, since severe alkalosis increases calcium binding to albumin.

B. Laboratory Findings

Arterial blood pH is elevated, and P_{CO_2} is low. Serum bicarbonate is decreased in chronic respiratory alkalosis.

Table 24–16. Replacement guidelines for sweat and GI fluid losses.

	Average Electrolyte Composition					Replacement Guidelines per Liter Lost			
	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	HCO_3^- (mEq/L)	0.9% Saline (mL)	0.45% Saline (mL)	D_5W (mL)	KCl (mEq/L)	7.5% $NaHCO_3$ (45 mEq HCO_3^-/amp)
Sweat	30–50	5	30–50			500	500	5	
Gastric secretions	20	10	10			300	700	20	
Pancreatic juice	130	5	35	115		400	600	5	2 amps
Bile	145	5	100	25	600		400	5	0.5 amp
Diarrhea[1]	140	15	110–115	40–45					

[1] In the absence of diarrhea, colonic fluid Na^+ levels are low (40 mEq/L).

Treatment

Treatment is directed toward the underlying cause. In acute hyperventilation syndrome from anxiety, the traditional treatment of breathing into a paper bag should be discouraged because it does not correct Pco_2 and may decrease PO_2. Reassurance may be sufficient for the anxious patient, but sedation may be necessary if the process persists. Hyperventilation is usually self-limited since muscle weakness caused by respiratory alkalemia will suppress ventilation. Rapid correction of chronic respiratory alkalosis may result in metabolic acidosis as Pco_2 is increased with a previous compensatory decrease in HCO_3^-. The severity of hypocapnia in critically ill patients has been associated with adverse outcomes.

FLUID MANAGEMENT

Daily parenteral maintenance fluids and electrolytes for an average adult of 70 kg would include at least 2 L of water in the form of 0.45% saline with 20 mEq/L of potassium chloride. Patients with hypoglycemia, starvation ketosis, or ketoacidosis being treated with insulin may require 5% dextrose-containing solutions. Guidelines for GI fluid losses are shown in Table 24–16.

Weight loss or gain is the best indication of water balance. Insensible water loss should be considered in febrile patients. Water loss increases by 100–150 mL/day for each degree of body temperature over 37°C.

In patients requiring maintenance and possibly replacement of fluid and electrolytes by parenteral infusion, the total daily ration should be administered continuously over 24 hours to ensure optimal utilization.

If intravenous fluids are the only source of water, electrolytes, and calories for longer than a week, parenteral nutrition containing amino acids, lipids, trace metals, and vitamins may be indicated (see Chapter 34).

Balanced crystalloid solutions, such as Ringer lactate, have become the resuscitation fluid of choice, due to concern for metabolic acidosis and reduced GFR associated with normal saline (see Chapter 14). However, studies are conflicting and have not established superiority of one fluid over another, which may reflect an overall paradigm shift favoring conservative fluid administration and earlier use of vasopressors. Excessive fluid resuscitation and maintenance are complications in hospitalized patients, especially those with critical illness or AKI. These complications have been associated with worsened outcomes, such as prolonged mechanical ventilation, dependence on dialysis, and longer hospitalization with increased mortality.

Kidney Disease

25

Tonja C. Dirkx, MD
Tyler B. Woodell, MD, MCR

ASSESSMENT OF KIDNEY DISEASE

Kidneys may incur a variety of injuries (Figure 25–1). Although some patients with kidney disease experience signs or symptoms such as hypertension, edema, gross hematuria, or uremia that may lead to its discovery, kidney disease more often is discovered incidentally or when screening individuals at high risk for kidney disease. The initial approach is to assess the cause and severity of kidney disease. In addition to a careful history and physical examination, evaluation includes (1) eGFR to characterize disease severity and, when previous eGFR values are available, discern kidney disease duration and rate of progression, (2) urine studies, and (3) renal imaging (usually ultrasonography). Select cases may warrant renal biopsy, particularly when glomerular disease is suspected.

Glomerular Filtration Rate

The primary function of the kidneys is removal of waste products and excess solutes from plasma.

The GFR reflects the amount of plasma ultrafiltered across the glomerular filtration barrier per unit time and serves as the primary metric of kidney function. Daily GFR in normal individuals is variable, ranging from 150–250 L/24 hours or 100–120 mL/min/1.73 m^2 of body surface area. Patients with kidney disease usually have decreased GFR; however, a normal or increased GFR (in the case of glomerular hyperfiltration) may also be seen.

GFR can be measured directly or estimated using validated formulae. Direct measurement is performed by determination of the renal clearance of a plasma substance that is not bound to plasma proteins, is freely filterable across the glomerulus, and is neither secreted nor reabsorbed along the renal tubules; it is defined as:

$$C = \frac{U \times \dot{V}}{P}$$

where C is the clearance, U and P are the respective urine and plasma concentrations of the substance, and $\dot{V}$ is volume of urine per unit time (typically mL/min). The gold standard for GFR measurement is by assessment of clearance of exogenously administered inulin; however, in clinical practice, the clearance of endogenous creatinine (termed **creatinine clearance**) is primarily used. The normal creatinine clearance (C_{cr}) is approximately 100 mL/min in healthy young women and 120 mL/min in healthy young men. The creatinine clearance declines by an average of 0.8 mL/min/year after age 40 years as part of the aging process. Creatinine is a useful biomarker because it is produced at a relatively constant rate as a byproduct of muscle metabolism, is freely filtered by the glomerulus, and is not reabsorbed by the renal tubules. (A small amount also is actively secreted by the tubules into the urine.) However, creatinine clearance is an imperfect measurement for several reasons: (1) the small amount eliminated by tubular secretion progressively increases as GFR declines (thus *over* estimating GFR); (2) in more advanced kidney disease, gut microorganisms degrade creatinine; (3) dietary meat intake and muscle mass affect plasma creatinine levels; (4) several medications impair tubular secretion of creatinine, thereby increasing the plasma creatinine concentration and falsely *under* estimating GFR; and (5) GFR measurement assumes a stable plasma creatinine concentration over a 24-hour period; therefore, it is inaccurate when creatinine concentration is changing, as occurs during the development of and recovery from AKI.

Creatinine clearance is measured with a timed urine collection and a simultaneous plasma creatinine level. An incomplete or prolonged urine collection is a common source of error. The completeness of the collection can be estimated by comparing the amount of creatinine excreted in the collection to that expected over a 24-hour period, which should be constant.

$$U_{cr} \times \dot{V} = 15 - 20 \text{ mg/kg for healthy young women}$$
$$U_{cr} \times \dot{V} = 20 - 25 \text{ mg/kg for healthy young men}$$

Because timed urine collections are cumbersome and often inaccurately collected, GFR is more commonly estimated (denoted **eGFR**) using equations that have been validated using patient characteristics (such as age, sex, and weight) and creatinine levels. The Kidney Disease Improving Global Outcomes workgroup recommends eGFR equations as the primary method for determining GFR; the 2021 CKD-Epidemiology (EPI) Collaboration creatinine equation is the preferred formula. the eGFR alongside the plasma or serum creatinine, when needed. eGFR can be estimated by the 2021 CKD-EPI equation using several web-based calculators (eg, https://www.kidney.org/professionals/kdoqi/gfr_calculator). **Cystatin C** is another endogenous marker of GFR that is filtered freely at the glomerulus; it is produced at a relatively constant rate by all nucleated cells, so more accurately estimates GFR in conditions with abnormally low muscle mass. Adding the measurement of cystatin C to serum creatinine improves the accuracy of eGFR, particularly in advanced CKD. A large meta-analysis showed that cystatin C alone or in combination with serum creatinine is a stronger predictor of important clinical events, such as ESKD or death, than serum creatinine alone. However, because most labs in developing countries do not routinely perform cystatin C testing, it remains a complementary rather than primary biomarker for estimating GFR.

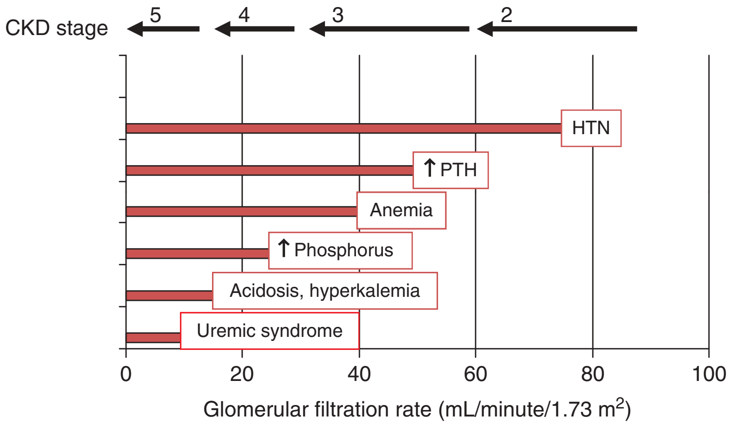
BUN is another index used to assess kidney function. It is synthesized primarily in the liver as a byproduct of protein catabolism. It is freely filtered by the glomerulus, but 30–70% is reabsorbed in the renal tubules. As such, it *under*estimates GFR and varies widely depending on the clinical situation. For example, renal urea reabsorption increases in hypovolemic patients; a normal BUN:creatinine ratio is approximately 10:1 but can increase to 20:1 or higher with volume depletion. Other causes of increased BUN include increased catabolism (GI bleeding, cell lysis, and corticosteroid use), increased dietary protein, and states leading to decreased renal perfusion with resultant increased BUN reabsorption (eg, HF). Reduced BUN levels are seen in advanced liver disease and SIADH.

▶ Disease Duration

Kidney disease can be acute or chronic. AKI is the worsening of kidney function over hours to days, resulting in retention of waste products (termed "azotemia"). If the etiology of kidney injury is mitigated quickly, AKI may be reversible and without lasting damage. Acute kidney disease (AKD) is the persistence of kidney dysfunction for 7–90 days following injury onset and denotes less reversibility to baseline kidney function. CKD is the persistence of kidney dysfunction beyond 3 months (Figure 25–2). Review of previous creatinine values helps to differentiate between AKI, AKD, and CKD. Additional findings may also be helpful; for example, oliguria is only observed in AKI/AKD, and small kidney size is more consistent with CKD.

▶ Urinalysis

Examination of the urine can provide important clues when evaluating kidney disease. A urine specimen should be collected midstream or by bladder catheterization and



▲ **Figure 25–2.** Complications of CKD by stage and GFR. Complications arising from CKD tend to occur at the stages depicted, although there is considerable variability noted in clinical practice. HTN, hypertension; PTH, parathyroid hormone. (Reproduced with permission from William Bennett, MD.)

examined within 1 hour of collection to avoid destruction of formed elements. UA includes dipstick examination followed by microscopy if the dipstick has positive findings. The dipstick examination measures urinary pH, specific gravity, protein (albumin), hemoglobin (blood or myoglobin), glucose, ketones, bilirubin, nitrites, and leukocyte esterase. Microscopy of centrifuged urinary sediment permits examination of formed elements—crystals, cells, casts, and infectious organisms. When urine flow is low, precipitation of Tamm-Horsfall mucoprotein in the renal tubule causes acellular (also called hyaline) cast formation (Table 25–1), which does not necessarily indicate disease. In contrast, casts containing formed elements do signal underlying damage. Granular casts (also called "muddy brown casts") and renal tubular epithelial cells alone or in casts are hallmarks of ATN. Urinary WBCs (including neutrophils and eosinophils) and WBC casts can be seen with pyelonephritis and interstitial nephritis; however, pyuria alone can also be seen in lower tract infections. The presence of protein on dipstick examination suggests underlying glomerular disease. If the glomerular basement membrane (GBM) is damaged (eg, by inflammation), RBCs may leak into the urinary space and appear dysmorphic. Thus, proteinuria, dysmorphic RBCs, and RBCs casts are highly suggestive of glomerulonephritis. Heavy proteinuria (see next section) accompanied by lipiduria may indicate nephrotic syndrome.

Table 25–1. Significance of specific urinary casts.

Type	Significance
Hyaline casts	Not indicative of kidney disease Concentrated urine, febrile disease, diuretic therapy, after strenuous exercise
RBC casts	Glomerulonephritis
WBC casts	Infection or inflammation Pyelonephritis, interstitial nephritis
Renal tubular cell casts	Can be seen in ATN or interstitial nephritis
Granular (muddy brown) casts	ATN
Broad waxy casts	Indicative of stasis in enlarged collecting tubules, CKD

A. Proteinuria

Albumin is the most abundant protein species in the blood and therefore the most abundant urinary protein species. The terms "proteinuria" and "albuminuria" are often used interchangeably, though there are cases for which this is not accurate. The detection of albumin on UA/dipstick should prompt urinary albumin/protein quantification; this may be done with a spot urine specimen for creatine and either albumin or protein. If both species are reported in the same units (eg, mg/dL), then the resulting dimensionless ratio of ($[U_{albumin}]/[U_{creatinine}]$) or ($[U_{protein}]/[U_{creatinine}]$) estimates the daily urinary albumin (or protein) excretion in g/day (Table 25–2); for example, $[U_{protein}]$ of 400 mg/dL and $[U_{creatinine}]$) of 200 mg/dL estimates a daily urinary protein excretion of 2 g. Twenty-four hour urine collections for protein are rarely necessary. Proteinuria > 1–2 g/day is usually a sign of underlying glomerular kidney disease.

There are several reasons proteinuria may develop: (1) **Functional proteinuria** is a benign process due to transient stressors such as acute illness or exercise, and "orthostatic proteinuria." The latter is generally found in people under 30 years of age and usually causes protein excretion < 1 g/day. The orthostatic nature of the proteinuria is confirmed by measuring an 8-hour overnight supine urinary protein excretion, which should be < 50 mg. (2) **Overload proteinuria** occurs when the reabsorptive capacity of tubules is overwhelmed, which can result from excess production of low-molecular-weight plasma proteins. The most common cause is overproduction of immunoglobulin light chains/Bence-Jones proteins by a plasma cell dyscrasia; in these cases, there may be discordance between the urine dipstick, which detects only negatively charged

Table 25–2. Definitions of albuminuria/proteinuria.

	Clinical Results Defining Condition
Normal (with respect to albuminuria)	Albumin < 30 mg/day
Microalbuminuria	Albumin 30–300 mg/day Not detected by urinary dipstick Must evaluate via urinary (micro) albumin:creatinine ratio (ACR)
Albuminuria	Albumin > 300 mg/day Detected by urinary dipstick Should be quantified with ACR or urine protein to creatinine ratio (UPC)
Normal (total) proteinuria	Protein < 150 mg/day
Proteinuria	Protein > 150 mg/day Should be quantified with ACR or UPC Protein > 1 g/day is significant; > 3 g/day is nephrotic-range

albumin, and urine protein quantification, which includes both albumin and positively charged light chains. Qualitative urine protein electrophoresis will exhibit a discrete, monoclonal protein spike. Other examples of overload proteinuria include myoglobinuria in rhabdomyolysis and hemoglobinuria in hemolysis. (3) **Glomerular proteinuria** results from damage-induced increased glomerular permeability with increased filtration of albumin, as classically occurs in diabetic nephropathy. Urine protein electrophoresis will exhibit a large albumin spike. (4) **Tubular proteinuria** occurs due to faulty reabsorption of normally filtered proteins in the proximal tubule, such as β-2-microglobulin. Causes may include ATN, toxic injury (lead, aminoglycosides, and certain antiretrovirals), drug-induced interstitial nephritis, and hereditary metabolic disorders (eg, Wilson disease and Fanconi syndrome).

A kidney biopsy may be indicated to determine the cause of proteinuria, particularly if accompanied by abnormal GFR or hematuria. The clinical sequelae of proteinuria are discussed in the section on Nephrotic Spectrum Glomerular Diseases.

B. Hematuria

Hematuria (ie, blood in the urine) is usually detected incidentally on urine dipstick or following an episode of macroscopic ("gross") hematuria. The diagnosis must be confirmed via microscopic examination, as false-positive dipstick tests can be caused by myoglobin, oxidizing agents, beets and rhubarb, hydrochloric acid, and bacteria. It is considered clinically significant if urine microscopy reveals more than three RBCs per high-power field on at least two occasions.

Hematuria may be due to renal or extrarenal causes. Extrarenal causes are addressed in Chapter 26. Renal causes account for approximately 10% of cases and are classified as either glomerular or extraglomerular. Glomerular causes include glomerulonephritis and heritable abnormalities of the glomerular basement membrane (GBM), thin basement membrane disease, and Alport syndrome. Extraglomerular sources include cysts; calculi; interstitial nephritis; and neoplasms of the kidney, prostate, or bladder (see Chapter 44).

Kidney Biopsy

The kidney is a highly vascular structure, so the primary risk of a percutaneous needle biopsy is bleeding. Thus, while pathologic information is helpful in many cases of kidney disease, biopsy is favored for cases in which the potential benefit outweighs the risk—especially those for whom a precise diagnosis will change management. These include (1) suspected nondiabetic glomerular disease, (2) atypical presentations of AKI, and (3) kidney transplant dysfunction. Relative contraindications include a solitary or ectopic kidney (except for transplant allografts), horseshoe kidney, ESKD, congenital anomalies, and multiple cysts. Absolute contraindications include an uncorrected bleeding disorder; severe uncontrolled hypertension; renal infection or neoplasm; hydronephrosis; or uncooperative patients, including those who are unable to lie prone for the procedure.

Post-biopsy bleeding most commonly occurs within 72 hours post biopsy but may occur later. More than half of patients will have at least a small perinephric hematoma; approximately 1–5% of patients will experience significant bleeding requiring a blood transfusion. Anticoagulation should be held for 5–7 days post biopsy if possible. The risks of nephrectomy and mortality are about 0.06–0.08%. When a percutaneous needle biopsy is technically not feasible and kidney tissue is deemed clinically essential, a closed biopsy via interventional radiologic techniques or open biopsy under general anesthesia can be performed.

ACUTE KIDNEY INJURY

ESSENTIALS OF DIAGNOSIS

- Rapid increase in serum creatinine.
- Oliguria may be present.
- Symptoms and signs depend on cause and severity.

General Considerations

AKI is defined as an acute increase in creatinine occurring over < 7 days, an acute decrease in urine output, or both. It is characterized as oliguric if urine production is < roughly 400–500 mL/day. **Stage 1** AKI is a 1.5- to 1.9-fold increase in serum creatinine or a decline in urinary output to < 0.5 mL/kg/hour for 6–12 hours; **stage 2** is a 2.0- to 2.9-fold increase in serum creatinine or decline in urinary output to < 0.5 mL/kg/hour for 12 hours or longer; **stage 3** is a 3.0-fold or greater increase in serum creatinine, an increase in serum creatinine to ≥ 4 mg/dL, a decline in urinary output to < 0.3 mL/kg/hour for 24 hours or longer, anuria for 12 hours or longer, or initiation of kidney replacement therapy. If the kidneys are completely nonfunctioning (ie, GFR virtually 0) serum creatinine will typically increase by 1–1.5 mg/dL daily, although in certain conditions such as rhabdomyolysis serum creatinine can increase more rapidly. AKI is estimated to occur in approximately 20% of all hospitalized patients and 65% of patients in the ICU. AKI may pose a risk for the development and more rapid progression of CKD, and patients with AKI from any cause are at higher risk for all-cause mortality, even if there is substantial renal recovery.

Clinical Findings

A. Symptoms and Signs

Most patients will not experience any symptoms or exhibit any signs of AKI; however, profound accumulation of waste products can cause nonspecific symptoms and signs collectively termed **uremia**: nausea, vomiting, malaise, and altered sensorium. More commonly, patients experience symptoms and signs of the underlying disease causing their AKI (eg, volume depletion, sepsis, lupus). Hypovolemia can cause states of low blood flow to the kidneys, sometimes termed **prerenal azotemia,** whereas hypervolemia due to impaired sodium excretion can result from intrinsic or postrenal disease. Hyperkalemia may occur, with attendant risk of heart block and ventricular tachycardia. Uremia may cause prolonged bleeding time due to platelet dysfunction may be seen with uremia. Progressive uremia may also cause neurologic signs such as asterixis, encephalopathy, and seizures. Rarely, it may cause hemorrhagic pericarditis with a friction rub on auscultation and possible tamponade if the effusion is large.

B. Laboratory Findings

By definition, elevated serum creatinine levels are present. Decreased clearance of organic and inorganic acids may lead to metabolic acidosis. Hyperkalemia can occur from impaired renal potassium excretion or from shifting of potassium from cells into the blood as a result of inorganic metabolic acidosis. With hyperkalemia, ECG can reveal peaked T waves, PR prolongation, and QRS widening. A long QT segment can occur with hypocalcemia. Hyperphosphatemia is common. Anemia can occur as a result of decreased erythropoietin production over weeks.

Classification & Etiology

AKI is diagnostically organized into three anatomic categories: prerenal causes (kidney hypoperfusion), intrinsic kidney disease, and postrenal causes (obstruction to urinary outflow) (Figure 25–1A) (Table 25–3).

A. Prerenal Causes

Prerenal causes are the most common etiology of outpatient AKI, accounting for 40–80% of cases. Prerenal

Table 25–3. Classification and differential diagnosis of AKI.

	Prerenal Azotemia	Postrenal Azotemia	Intrinsic Renal Disease		
			ATN	Acute Glomerulonephritis	Acute Interstitial Nephritis
Etiology	Poor renal perfusion	Obstruction of the urinary tract	Ischemia, nephrotoxins, sepsis	Immune complex–mediated, pauci-immune, anti-GBM–related, monoclonal immunoglobulin–mediated, C3 glomerulopathy	Allergic reaction; drug reaction; infection; autoimmune disease
Serum BUN:Cr ratio	> 20:1	> 20:1	< 20:1	> 20:1	< 20:1
U_{Na} (mEq/L)	< 20	Variable	> 20	< 20	Variable
FE_{Na} (%)	< 1	Variable	> 1 (when oliguric)	< 1	Variable
Urine osmolality (mOsm/kg)	> 500	< 400	250–300	Variable	Variable
Urinary sediment	Benign or hyaline casts	Normal or red cells, white cells, or crystals	Granular (muddy brown) casts, renal tubular cell casts	Red cells, dysmorphic red cells, and red cell casts	White cells, white cell casts, with or without eosinophils

BUN:Cr, blood urea nitrogen:creatinine ratio; FE_{Na}, fractional excretion of sodium; GBM, glomerular basement membrane; U_{Na}, urinary concentration of sodium.

azotemia is a physiologic response to renal hypoperfusion; if reversed quickly (eg, fluid resuscitation), renal parenchymal damage often does not occur. If hypoperfusion persists, prerenal azotemia can develop into intrinsic kidney injury/ATN.

Decreased renal perfusion can occur due to a decrease in intravascular volume, a change in vascular resistance, or low cardiac output. Causes of volume depletion include hemorrhage, GI losses, excessive diuresis, burns, and extravascular fluid sequestration (eg, pancreatitis). In states of hypovolemia or decreased effective circulating volume (including poor cardiac output, cirrhosis, and reduced systemic vascular resistance due to sepsis, anaphylaxis, and anesthesia), autoregulation of renal blood flow and maintenance of GFR becomes dependent on prostaglandin-mediated afferent arteriolar vasodilation and angiotensin II-mediated efferent arteriolar vasoconstriction. Blockade of the renin-angiotensin system, as with ACE inhibitors or ARBs, and blockade of prostaglandin production, as with NSAIDs, impair this autoregulation and increase risk for more profound AKI in susceptible states. Renal blood flow may also be impaired due to vasoconstricting agents such as epinephrine, norepinephrine, high-dose dopamine, anesthetic agents, hypercalcemia, and calcineurin inhibitors. Renal artery stenosis causes increased resistance and decreased renal perfusion. Hepatorenal syndrome, a serious complication of decompensated cirrhosis, is another prerenal cause of AKI that results from low effective circulating volume (see Chapter 18).

History, physical examination, and laboratory data are important in the initial evaluation. In prerenal AKI, the BUN:creatinine ratio often exceeds 20:1 due to increased urea reabsorption by functioning tubules. In oliguric patients, a useful index is the fractional excretion of sodium (FE_{Na}). With decreased GFR, the kidney reabsorbs salt and water avidly if there is no intrinsic tubular dysfunction. Thus, oliguric patients with prerenal AKI should have a low fractional excretion of sodium (< 1%). In contrast, oliguric patients with intrinsic kidney dysfunction typically have a high FE_{Na} (> 1–2%), indicating loss of tubular cells' ability to reabsorb sodium. The FE_{Na} is calculated as follows: FE_{Na} = clearance of Na^+/GFR = clearance of Na^+/C_{cr}:

$$FE_{Na} = \frac{Urine_{Na}/Serum_{Na}}{Urine_{cr}/Serum_{cr}} \times 100\%$$

The equation was created and validated to differentiate *oliguric* ATN and prerenal AKI; its utility in nonoliguric patients is limited. Because diuretics act by increasing sodium excretion, a high FE_{Na} within 12–24 hours after diuretic administration cannot be meaningfully interpreted. In contrast, a low FE_{Na} *despite* receiving diuretics offers strong evidence of prerenal states in oliguric patients.

Urine microscopy is a valuable tool in the evaluation of AKI. Prerenal azotemia results in a bland urine sediment; hyaline casts may be present. In contrast, renal tubular epithelial cells or muddy brown casts are indicative of ATN.

Treatment of prerenal AKI depends on the underlying cause, but achievement of euvolemia, attention to serum electrolytes, and avoidance of nephrotoxic drugs are fundamentals of therapy.

B. Postrenal Causes

Postrenal causes of AKI are the least common, accounting for approximately 5–10% of cases; these occur when urinary flow from both kidneys, or a single functioning kidney, is obstructed. Obstruction leads to elevated intraluminal pressure and resultant kidney parenchymal damage, with marked effects on renal blood flow and tubular function.

Postrenal AKI can occur from obstruction at the level of the urethra, bladder, ureters, or renal pelvises. In men, benign prostatic hyperplasia is the most common cause. Patients taking anticholinergic drugs are at risk for urinary retention. Obstruction can also be caused by bladder, prostate, and cervical cancers; retroperitoneal fibrosis; and neurogenic bladder (eg, from diabetes mellitus). Less common causes include blood clots, bilateral ureteral stones, urethral stones or strictures, and bilateral papillary necrosis.

Obstruction can be constant or intermittent, and partial or complete. Obstruction may cause anuria but can also cause polyuria in the setting of partial obstruction with resultant tubular dysfunction and inability to reabsorb salt and water. Patients may have lower abdominal or back pain, and on examination may have an enlarged prostate, distended bladder, or palpable abdominal mass.

Laboratory examination may initially reveal high urine osmolality, low urine sodium, high BUN:creatinine ratio, and low FE_{Na} (ie, tubular function may not be compromised). These indices are similar to prerenal AKI because extensive intrinsic renal damage has not yet occurred. After several days, however, the urine sodium increases as the kidneys fail and are unable to concentrate urine (isosthenuria). Urine sediment is generally bland, though hematuria may be seen if the obstruction is due to stones, blood clots, or papillary necrosis.

Patients with AKI due to suspected postrenal causes should undergo bedside or formal ultrasonography to assess for hydroureter, hydronephrosis, or large bladder volume (despite recent attempted voiding). Prompt treatment of obstruction within days by catheters, stents, or surgical procedures can result in partial or complete reversal of AKI. After treatment of the obstruction, some patients experience significant increased urinary output (called postobstructive diuresis). In such settings, care should be taken to avoid volume depletion and electrolyte derangements.

C. Intrinsic Acute Kidney Injury

Intrinsic renal disorders account for up to 50% of all cases of AKI. Intrinsic dysfunction is considered after prerenal and postrenal causes have been excluded. The potential sites of injury are the tubules, interstitium, vasculature, and glomeruli. Intrinsic AKI is discussed in greater detail in the following sections.

When to Refer

- AKI that has not reversed over 1–2 weeks, or when the degree of AKI is concerning (eg, doubling of creatinine) and without an immediately reversible cause such as obstruction (Table 25–7).
- Patients with signs of urinary tract obstruction should be referred to a urologist.

When to Admit

Patients should be admitted if there is sudden loss of kidney function resulting in abnormalities that cannot be appropriately addressed in an outpatient setting (eg, hyperkalemia, volume overload, uremia) or if an acute intervention is needed, such as emergent urologic procedures or dialysis.

ACUTE TUBULAR NECROSIS

ESSENTIALS OF DIAGNOSIS

- AKI.
- Ischemic or toxic insult, or underlying sepsis.
- Urine sediment may reveal granular (muddy brown) casts, renal tubular epithelial cells, or both.

General Considerations

AKI due to tubular damage is called **acute tubular necrosis (ATN)**; it accounts for 85% of intrinsic AKI and the majority of hospitalized cases. ATN may be caused by prolonged renal ischemia, nephrotoxin exposure, or sepsis (even in patients who are normotensive).

A. Exogenous Nephrotoxins

Aminoglycosides are a common cause of ATN, even at therapeutic levels. Nonoliguric AKI typically occurs after 5–10 days of exposure. Predisposing factors include underlying kidney disease, volume depletion, and advanced age. Monitoring drug levels is important, and troughs are helpful in predicting renal toxicity.

Amphotericin B is typically nephrotoxic after a total dose of 2–3 g. This causes a type 1 (distal) renal tubular acidosis with severe vasoconstriction and tubular damage, which can lead to hypokalemia and nephrogenic diabetes insipidus. **Vancomycin**, intravenous **acyclovir**, and **cephalosporins** are also known to cause or be associated with ATN.

Radiographic contrast media may be nephrotoxic; contrast nephropathy refers to a rise in creatinine that occurs 24–48 hours after contrast administration. AKI in association with contrast exposure results from the synergistic combination of direct renal tubular epithelial cell toxicity and renal medullary ischemia in susceptible individuals. The combination of preexisting diabetes mellitus and CKD is associated with the greatest risk; other risk factors include advanced age, volume depletion, HF, multiple myeloma, repeated doses of contrast, and recent exposure to agents which impair renal autoregulation, including NSAIDs, ACE inhibitors/ARBs, and SGLT-2 inhibitors. Prevention of contrast nephropathy in patients who have high risk for injury includes using lower contrast volumes with the lowest osmolality. Other prophylactic measures include infusion of intravenous fluids—usually normal saline given at 3 mL/kg/hour for 1 hour before and 1 mL/kg/hour for 4–6 hours after contrast administration in patients who can tolerate this volume; increasing oral intake of fluids is an alternative, though is likely less protective. If tolerated, diuretics may be held prior to contrast administration. Alternative prophylactic strategies including *N*-acetylcysteine, sodium bicarbonate, mannitol, and furosemide have not shown benefit over normal saline administration.

Calcineurin inhibitor (tacrolimus or cyclosporine) toxicity is usually dose-dependent. It causes distal tubular dysfunction (a type 4 renal tubular acidosis) and severe vasoconstriction. Regular blood level monitoring is important to prevent both acute and chronic nephrotoxicity. Acute kidney dysfunction usually improves after reducing the dose or stopping the drug.

Other exogenous agents that can cause ATN include chemotherapeutic agents such as cisplatin; organic solvents; and heavy metals such as mercury, cadmium, and arsenic. ACE inhibitors, ARBs, and SGLT-2 inhibitors have many long-term benefits for patients with CKD but may cause or contribute to ischemic ATN at times of prolonged hypotension or volume depletion or when administered in combination with NSAIDs. Some herbal or traditional medicines may also be nephrotoxic.

B. Endogenous Nephrotoxins

Endogenous nephrotoxins include pigments (myoglobin and hemoglobin), uric acid, and paraproteins. These products can cause direct tubular toxicity, resulting in ATN. The most common type of pigment nephropathy is rhabdomyolysis, caused by release of myoglobin from muscle. Massive intravascular hemolysis with release of hemoglobin is seen in transfusion reactions and in certain hemolytic anemias. Remission of the underlying disorder and volume resuscitation are mainstays of treatment.

Hyperuricemia can occur in the setting of rapid cell turnover and lysis. Chemotherapy for germ cell and hematologic malignancies (leukemia and lymphoma) is the primary cause; spontaneous tumor lysis syndrome can also occur, though is less common. When serum uric acid levels exceed 15–20 mg/dL, ATN can result from intratubular precipitation of uric acid crystals. Allopurinol or rasburicase can be used prophylactically, and rasburicase with or without dialysis is often used for treatment in established cases.

Paraproteins seen in plasma cell myeloma can cause direct tubular toxicity and tubular obstruction. Other renal complications from plasma cell myeloma include hypercalcemia and renal tubular dysfunction, including type 2 (proximal) renal tubular acidosis (see Plasma Cell Myeloma below).

Clinical Findings

A. Symptoms and Signs

See Acute Kidney Injury.

B. Laboratory Findings

Hyperkalemia and hyperphosphatemia are commonly present. The BUN:creatinine ratio is usually < 20:1 because tubular function is not intact, as described in the general section on AKI (Table 25–3). Urine sodium concentration and FE_{Na} are usually (but not invariably) elevated, indicative of tubular dysfunction. Urine microscopy may show evidence of acute tubular damage; the presence of two or more granular casts or renal tubular epithelial cells is strongly predictive of ATN but has a low negative predictive value (see Table 25–1). Kidney biopsy is not performed in cases of suspected ATN but is sometimes helpful in cases of diagnostic uncertainty.

Treatment

Treatment of ATN is aimed at hastening recovery and avoiding complications. Preventive measures should be taken to avoid volume overload and hyperkalemia. A prospective RCT did not show benefit of loop diuretics on either recovery from AKI or death. Use of diuretics in critically ill patients with AKI should be used only when otherwise clinically indicated (eg, in states of volume overload); nonresponsiveness to a trial of high-dose diuretics (called "furosemide stress test") has been shown to predict future need for acute dialysis in this population. Ultrafiltration is generally reserved for patients with AKI in need of volume removal who are unresponsive to diuretics; however, this has not been shown to improve survival. Hyperkalemia and hyperphosphatemia can be treated with dietary restriction and phosphate-binding agents (see section on CKD) taken with meals. Hypocalcemia should not be treated in patients with rhabdomyolysis unless they are symptomatic. Magnesium-containing antacids and laxatives should be avoided. Dosages of all medications eliminated by the kidney must be adjusted.

Indications for dialysis in AKI from ATN or other intrinsic diseases include life-threatening "AEIOUs" (Acid-base or Electrolyte disturbances [eg, hyperkalemia] refractory to medical management; Intoxications from certain drugs; volume; Overload unresponsive to diuretics; and Uremic complications [eg, encephalopathy, pericarditis, and/or seizures]). In critically ill patients, less severe but worsening abnormalities may also be indications for dialytic support. Unfortunately, there is no evidence that more intensive or earlier initiation of renal replacement therapy for patients with AKI confers survival benefit.

Course & Prognosis

The clinical course of ATN is often divided into three phases: initial injury, maintenance, and recovery. The maintenance phase is expressed as either oliguric (urinary output < 500 mL/day) or nonoliguric. Nonoliguric ATN is associated with better outcomes than oliguric ATN; conversion from oliguric to nonoliguric states with the use of diuretics does not alter prognosis. Likewise, other agents thought to have favorable effects on renal hemodynamics such as low-dose dopamine or fenoldopam have been shown to be ineffective in numerous studies for preventing ATN or hastening the recovery. Average duration of the maintenance phase is 1–3 weeks, but some cases last several months, during which time cellular repair and removal of tubular debris begin to occur. The recovery phase can be heralded by diuresis, due to the inability of recovering renal tubules to reabsorb salt and water appropriately, and solute-induced diuresis from accumulated BUN.

The mortality rate associated with AKI in hospitalized patients is 20–50% and up to 70% in ICU patients requiring dialysis. Increased mortality is associated with advanced age, severe underlying disease, and multisystem organ failure. Leading causes of death are infections, fluid and electrolyte disturbances, and worsening of underlying disease.

When to Refer

- When uncertainty exists as to the cause of or treatment for AKI.
- For fluid, electrolyte, and acid-base abnormalities that are recalcitrant to interventions.
- Nephrology referral improves outcomes in AKI.

When to Admit

A patient with symptoms or signs of AKI that require immediate intervention, such as administration of intravenous fluids or dialytic therapy, or that require a team approach that cannot be coordinated as an outpatient.

RHABDOMYOLYSIS

ESSENTIALS OF DIAGNOSIS

- Associated with crush injuries to muscle, immobility, drug toxicities, and hypothermia.
- Characterized by serum elevations in muscle enzymes, including creatine kinase, and marked electrolyte abnormalities.
- Release of myoglobin leads to direct renal toxicity.

General Considerations

Rhabdomyolysis is a syndrome of acute skeletal muscle necrosis resulting in markedly elevated plasma creatine kinase levels and myoglobinuria. Excessive urinary myoglobin can cause intrarenal vasoconstriction and pigmented tubular cast formation, leading to intrarenal obstruction and ATN. Rhabdomyolysis can result from crush injuries, prolonged immobility, seizures, substance use (eg, cocaine), and medications; concomitant volume depletion in these settings increases risk of rhabdomyolysis and associated ATN. In patients taking statins, the risk of rhabdomyolysis is increased in the presence of kidney or liver disease, diabetes, hypothyroidism, concurrent use of niacin and fibrate-containing therapy. With the exception of rosuvastatin and pravastatin, risk with statins is also increased with concomitant therapy with drugs that inhibit cytochrome P450 (including protease inhibitors, erythromycin or clarithromycin, itraconazole, diltiazem, and verapamil).

Clinical Findings

A. Symptoms and Signs

Patients with rhabdomyolysis may have myalgia, weakness, or both, though it is not uncommon for them to be asymptomatic. Urine may appear dark due to the presence of myoglobin.

B. Laboratory Findings

Rhabdomyolysis of clinical importance commonly occurs when serum creatine kinase exceeds 16,000–50,000 IU/L. Often, there are elevated serum levels of other skeletal muscle enzymes including AST, ALT, and LD. The acute muscle enzyme elevations peak quickly and usually resolve within days once the inciting injury has resolved.

The classic laboratory finding in rhabdomyolysis is a urine dipstick test that is positive for “blood” but without RBCs on microscopy; the false-positive result is due to detection of myoglobin rather than hemoglobin. Additionally, rhabdomyolysis causes injured muscle cells to release intracellular components, leading to electrolyte derangements (including hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia).

Treatment

The mainstay of treatment is aggressive volume repletion with 0.9% normal saline (ie, > 4 L/day) and removal of offending medications thought to have caused or contributed to the disorder. Adjunctive treatments with mannitol and alkalization of the urine have not been proven to change outcomes. As patients recover, calcium can translocate from tissues to plasma, so early exogenous calcium administration for hypocalcemia is not recommended unless the patient is symptomatic or the level becomes exceedingly low in an unconscious patient; calcium repletion can cause precipitation of calcium phosphate given the frequently concurrent hyperphosphatemia.

Myopathic complications of statins usually resolve within several weeks of discontinuing the drug.

When to Refer

Clinically meaningful rhabdomyolysis requires immediate attention and inpatient management. Referral to outpatient nephrology clinics may be appropriate following hospital discharge.

When to Admit

Patients whose serum creatine kinase levels are > 15,000–20,000 IU/L or patients with AKI or electrolyte derangements should be admitted for fluid repletion and serial monitoring of creatine kinase and electrolytes.

INTERSTITIAL NEPHRITIS

ESSENTIALS OF DIAGNOSIS

- Acute or chronic in nature.
- Pyuria, WBC casts, and proteinuria.
- Fever, transient maculopapular rash, or eosinophilia may occur in acute disease.

General Considerations

Acute interstitial nephritis accounts for 10–15% of cases of intrinsic AKI. An interstitial inflammatory response with edema is the typical pathologic finding; tubular damage may be present as well.

Although drugs account for over 70% of cases, acute interstitial nephritis may also be caused by infectious diseases and autoimmune disorders. The most common causative drugs are penicillins and cephalosporins, immune checkpoint inhibitors, sulfonamides and sulfonamide-containing diuretics, NSAIDs, PPIs, rifampin, and allopurinol. Infectious causes include streptococcal infections, leptospirosis, cytomegalovirus, histoplasmosis, and Rocky Mountain spotted fever. SLE, Sjögren syndrome, sarcoidosis, and cryoglobulinemia can also cause interstitial nephritis, though they are more classically associated with glomerulonephritis (Table 25–4).

Clinical Findings

Features of drug-induced acute interstitial nephritis may include fever, rash, arthralgias, and peripheral blood eosinophilia. However, the classic triad of fever, rash, and arthralgias is present in only 10–15% of cases and many have no signs or symptoms. Urine microscopy often reveals white cells and white cell casts; red cells may also be present. Proteinuria is often present, particularly in NSAID-induced interstitial nephritis, but is usually modest (< 2 g/day). Evaluation for eosinophiluria is not advised as it is neither sensitive nor specific for interstitial nephritis. Although the clinical history and laboratory data often suggest the diagnosis, kidney biopsy is sometimes needed.

Table 25–4. Causes of acute tubulointerstitial nephritis (abbreviated list).

Drug Reactions
Antibiotics
β-Lactam antibiotics: methicillin, penicillin, ampicillin, cephalosporins
Ciprofloxacin
Erythromycin
Sulfonamides (trimethoprim-sulfamethoxazole, loop and thiazide diuretics)
Tetracycline
Vancomycin
Ethambutol
Rifampin
NSAIDs
Diuretics
Thiazides
Furosemide
Other
Allopurinol
Cimetidine
Phenytoin
PPIs
Systemic Infections
Bacteria
Streptococcus
Corynebacterium diphtheriae
Legionella
Viruses
Epstein-Barr
Other
Mycoplasma
Rickettsia rickettsii
Leptospira icterohaemorrhagiae
Toxoplasma
Idiopathic
Tubulointerstitial nephritis-uveitis

Treatment & Prognosis

Acute interstitial nephritis often carries a good prognosis, with recovery occurring over weeks to months. Urgent dialytic therapy may be necessary in up to one-third of patients before resolution, but patients rarely progress to ESKD. Those with prolonged oliguria and advanced age have a worse prognosis. Treatment consists of supportive measures and prompt removal of the inciting agent. If kidney injury persists despite removal of the culprit drug, corticosteroids should be considered, although data to support their use are limited, and their efficacy is diminished if started more than 1–2 weeks after onset of AKI. Short-term, high-dose methylprednisolone (0.25–0.5 g/day intravenously for 1–4 days) or prednisone (60 mg/day orally for 4–6 weeks) followed by a prednisone taper can be used in severe cases of drug-induced interstitial nephritis, including disease due to immune checkpoint inhibitors.

GLOMERULONEPHRITIS

ESSENTIALS OF DIAGNOSIS

- Hematuria and proteinuria.
- Red cell casts may be seen.
- Dependent edema and hypertension.
- AKI.

General Considerations

Acute glomerulonephritis is an uncommon cause of AKI, accounting for about 5% of cases. In these cases, glomerular inflammation often incites a proliferative response by mesangial cells, glomerular capillary endothelial cells, or both. Glomerular crescents may be seen when severe damage causes breaks in the glomerular walls with exudation of inflammatory cells into the urinary space. Generally, the development of crescents portends a poorer prognosis and increases the urgency for treatment, if appropriate.

Glomerulonephritides (detailed later in this chapter) are classified into five pathophysiologic processes.

Immune complex glomerulonephritis occurs when autoantibodies combine with antigens to form immune complexes that deposit within glomeruli. There are several distinct immune complex glomerulonephritides, including IgA nephropathy, infection-related glomerulonephritis, lupus nephritis, and cryoglobulinemic glomerulonephritis (often associated with hepatitis C virus [HCV]).

Anti-GBM–associated acute glomerulonephritis is either confined to the kidney or associated with pulmonary hemorrhage. The latter is called "Goodpasture syndrome." Injury is related to autoantibodies against type IV collagen in the GBM.

Pauci-immune acute glomerulonephritis is a form of small-vessel ANCA-associated vasculitis in which there is kidney damage without direct immune complex deposition or antibody binding. Tissue injury is believed to be due to neutrophil-mediated immune processes. The two most common ANCA vasculitides are granulomatosis with polyangiitis (GPA) and microscopic polyangiitis. GPA is a systemic necrotizing vasculitis of small arteries and veins associated with intravascular and extravascular granuloma formation; in addition to glomerulonephritis, these patients can have upper airway, pulmonary, and skin manifestations. ANCA subtype testing for proteinase 3 (which is more common in GPA) and myeloperoxidase (which is more common in microscopic polyangiitis) may be helpful indistinguishing these two vasculitides.

ANCA- and anti-GBM–associated acute glomerulonephritides have poor outcomes unless treatment is started early.

Monoclonal immunoglobulin–mediated glomerulonephritis is characterized by the deposition of a monoclonal immunoglobulin in glomeruli, the tubular basement membrane, or both. Immunofluorescent or immunohistochemical staining of kidney biopsies detects monotypic immunoglobulin deposits. Many cases occur in the setting of an identifiable monoclonal gammopathy, but this is not always the case. Serum protein electrophoresis, immunofixation, and free light chain analysis are important diagnostic tests to perform when monoclonal immunoglobulin–mediated glomerulonephritis is suspected or confirmed.

C3 glomerulopathy results from predominant C3 deposition in the glomeruli with or without minimal deposition of immunoglobulins. It is also identified by immunofluorescence or immunohistochemistry. The pathogenesis of C3 glomerulonephropathy stems from abnormalities in regulation of the alternative pathway of complement. Measurement of serum C3 levels may be helpful, but normal levels do not rule out C3 glomerulopathy.

Other vascular causes of glomerulonephritis include hypertensive emergencies and the thrombotic microangiopathies such as hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (see Chapter 16).

Clinical Findings

A. Symptoms and Signs

Patients with acute glomerulonephritis may be hypertensive and edematous. Extrarenal signs that reflect systemic manifestations of their disease (eg, rash in patients with lupus; cough or sinus congestion in patients with ANCA glomerulonephritis, or subacute fatigue and weight loss in patients with infection or vasculitis) may be present. Macroscopic hematuria is uncommon but may occur in select cases (eg, IgA nephropathy).

B. Laboratory Findings

Serum creatinine can rise over days to months, depending on the rapidity of the underlying process. Urine dipstick shows blood and protein, with urine microscopy demonstrating dysmorphic RBCs. Heavy glomerular bleeding, if present, may result in red cell casts in the urinary sediment that, when present, are specific for glomerulonephritis.

Serum complement levels (C3, C4) may be low in immune complex glomerulonephritis (except for IgA nephropathy) and in C3 glomerulopathy, but normal in pauci-immune, anti-GBM–related, and most monoclonal immunoglobulin–mediated glomerulonephritides. Other serologic evaluations include ASO titers, anti-GBM antibody levels, ANCAs, ANA titers, cryoglobulins, HIV, hepatitis B and C serologies, serum protein electrophoresis, immunofixation, serum free light chains, and blood cultures. Renal ultrasound should be done to ensure there are no anatomic contraindications for renal biopsy. A kidney biopsy is usually necessary to confirm the diagnosis prior to treatment.

Treatment

Treatment is tailored to the specific type and severity of glomerulonephritis. It may include high-dose corticosteroids, rituximab, cytotoxic agents (such as cyclophosphamide), antiproliferative agents (eg, mycophenolate), and calcineurin inhibitors (eg, tacrolimus). Plasma exchange can be used in Goodpasture syndrome as a temporizing measure until chemotherapy can take effect. Treatment and prognosis for specific diseases are discussed below.

COVID-19 & THE KIDNEY

ESSENTIALS OF DIAGNOSIS

- Broad array of clinical presentations and kidney pathology.

Clinical Findings & Treatment

In the early stages of the COVID-19 pandemic, nearly 30% of infected patients who were hospitalized patients and 50% who were critically ill patients had AKI. Over time, the incidence and severity of AKI in the setting of severe COVID-19 infection has decreased. ATN is the most common cause of AKI in those with COVID-19, which is secondary to a high inflammatory state (termed "cytokine storm") and to prolonged hypotension and volume depletion in susceptible patients. UA may reveal hematuria due to endothelial injury and fibrin thrombi that may accompany tubular damage. Patients who carry high-risk *APOL1* alleles (see section on Nephrotic Spectrum Glomerular Diseases below) may develop COVID-19–associated collapsing glomerulopathy—a type of focal segmental glomerulosclerosis that presents with nephrotic syndrome. Treatment of COVID-19–related AKI is largely supportive; approximately 20% of patients require kidney replacement therapy. Corticosteroids have been used in COVID-19–associated collapsing glomerulopathy with reported success, but there is a lack of trial data or long-term follow-up to date to confirm efficacy.

HEPATORENAL SYNDROME

See Chapter 18.

CARDIORENAL SYNDROME (Cardiovascular-Kidney-Metabolic Syndrome)

ESSENTIALS OF DIAGNOSIS

- **Cardiac dysfunction:** acute or chronic HF, ischemic injury, or arrhythmias.
- **Kidney disease:** acute or chronic, depending on the type of cardiorenal syndrome.

General Considerations

Cardiorenal syndrome is a pathophysiologic disorder of the heart and kidneys wherein acute or chronic deterioration of one organ results in the acute or chronic deterioration of the other. Recently, the focus has turned to the common metabolic dysfunction affecting both organ systems, which is more aptly termed “cardiovascular-kidney-metabolic syndrome.” Achieving euvolemia, addressing cardiovascular and metabolic risk factors, and implementing guideline-directed medical therapy as tolerated are the overarching therapeutic goals (see Heart Failure section in Chapter 11).

The need for decongestion and diuresis may be urgent and take clinical precedence. Consideration for sequential nephron blockade (ie, adding a thiazide to a loop diuretic) may be needed to overcome diuretic resistance. Medical diuresis achieves similar decongestion, possibly with lower rates of adverse events compared to extracorporeal therapies (eg, ultrafiltration). While guideline-directed medical therapy is crucial, caution is required in those with advanced CKD due to increased risk with some agents (alone or in combination) for hyperkalemia or excessive blood-pressure lowering (alone or in combination).

CHRONIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- Reduced GFR, urinary abnormalities (eg, proteinuria), or both present for at least 3 months.
- Hypertension is commonly present.
- Bilateral small or echogenic kidneys on ultrasound in advanced disease.
- Symptoms and signs of uremia when nearing end-stage disease.

General Considerations

CKD affects about 14% of Americans and 850 million persons worldwide. Many are unaware of their CKD as it is asymptomatic until it becomes advanced. The National Kidney Foundation’s staging system helps clinicians formulate practice plans according to stage or severity of CKD (Table 25–5). Over 70% of cases of ESKD in the United States are due to diabetes mellitus or hypertension/vascular disease. Glomerulonephritis, cystic diseases, chronic tubulointerstitial diseases, and other urologic diseases account for the remainder (Table 25–6). Genetic polymorphisms of the *APOL-1* gene are associated with an increased risk of developing CKD in persons of sub-Saharan African ancestry.

CKD is typically characterized by progressive decline in kidney function even if the inciting cause can be identified and treated. Destruction of nephrons leads to compensatory hypertrophy and supranormal GFR of the remaining nephrons in order to maintain overall homeostasis. As a result, serum creatinine may appear normal even in the face of significant loss of renal mass, making it an insensitive marker for early renal damage and scarring. In addition, compensatory hyperfiltration leads to overwork injury in the remaining nephrons, which over time leads to glomerular sclerosis and interstitial fibrosis. ARBs, ACE inhibitors, SGLT-2 inhibitors, and mineralocorticoid receptor antagonists (MRA) help reduce hyperfiltration, which can slow progression of CKD.

CKD is an independent risk factor for CVD, particularly if proteinuria is present. Many patients at earlier stages of CKD will die of underlying CVD prior to progression to ESKD.

Table 25–5. Stages of CKD: a clinical action plan.[1,2]

Stage[3]	Description	GFR (mL/min/1.73 m²)	Action
1	Kidney damage with normal or ↑↑ GFR	≥ 90	Diagnosis and treatment of underlying etiology if possible. Treatment of comorbid conditions. Estimate progression, work to slow progression. CVD risk reduction.
2	Kidney damage with mildly ↓ GFR	60–89	
3a	Mildly-moderately ↓ GFR	45–59	As above, and evaluating and treating complications.
3b	Moderately-severely ↓ GFR	30–44	
4	Severely ↓ GFR	15–29	Preparation for ESKD.
5	ESKD	< 15 (or dialysis)	Dialysis, transplant, or palliative care.

[1] Based on National Kidney Foundation, KDOQI, and KDIGO Chronic Kidney Disease Guidelines.

[2] CKD is defined as either kidney damage or GFR < 60 mL/min/1.73 m² for 3 or more months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

[3] At all stages, persistent albuminuria confers added risk for CKD progression and CVD in the following gradations: < 30 mg/day = lowest added risk, 30–300 mg/day = mildly increased risk, > 300–1000 mg/day = moderately increased risk, > 1000 mg/day = severely increased risk.

Reproduced with permission from Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease. *Kidney Int.* 2013;3(1)(Suppl):1–150.

Clinical Findings

A. Symptoms and Signs

Stages 1–4 CKD usually are asymptomatic. As GFR declines, symptoms develop slowly, are nonspecific, and often do not manifest until GFR is < ~10 mL/min/1.73 m², at which time the accumulation of metabolic waste products (uremic toxins) may cause **uremia**. Uremia is a syndrome characterized by fatigue, anorexia, nausea, and a metallic taste in the mouth. Neurologic symptoms such as memory impairment, insomnia, restless legs, and twitching may develop. Generalized pruritus (without rash) may occur, as may decreased libido and menstrual irregularities. Pericarditis, a rare complication of ESKD, may present with pleuritic chest pain. Medications cleared by the kidneys will accumulate as kidney function worsens and toxicity may ensue; an important example is insulin, which carries risk of precipitating hypoglycemia if its dose is not appropriately reduced.

Table 25–6. Causes of CKD.

Glomerular Diseases[1]
Diabetic nephropathy Focal segmental glomerulosclerosis IgA nephropathy Lupus nephritis Membranous nephropathy Infection-related glomerulonephritis
Tubulointerstitial Nephritis
Medication hypersensitivity Heavy metals NSAIDs/analgesic nephropathy Reflux/chronic pyelonephritis Sickle cell nephropathy Idiopathic
Cystic Diseases
Polycystic kidney disease Medullary cystic disease
Obstructive Nephropathies
Bladder outlet obstruction Nephrolithiasis Retroperitoneal fibrosis Congenital/reflux
Vascular Diseases
Hypertensive nephrosclerosis Renal artery stenosis

[1] Most common glomerular diseases worldwide.

The most common physical exam finding in CKD is hypertension, due in part to impaired sodium excretion, which often presents in early stages of CKD and worsens as disease progresses. In later stages of CKD, sodium retention may lead to clinically apparent volume overload. When GFR falls below 10 mL/min/1.73 m², signs of mild uremia such as slowed cognition and halitosis (uremic fetor) may be seen. More severe uremic presentations may include a generally sallow and ill appearance, decreased mental status, asterixis, myoclonus, and, rarely, seizures.

The presence of uremia warrants immediate consultation with a nephrologist; those with severe signs and symptoms should be hospitalized for urgent dialysis initiation. Because AKI can often be superimposed on CKD, it is important to identify and correct potentially reversible insults or exacerbating factors (Table 25–7). Urinary obstruction, hypovolemia, hypotension, nephrotoxins (such as NSAIDs, aminoglycosides, or PPIs), hypertensive emergency, and HF exacerbation should be excluded.

B. Laboratory Findings

CKD is defined by the presence of at least one of the following for a minimum of 3 months: reduced eGFR; urinary abnormalities such as proteinuria or hematuria; electrolyte abnormalities (eg, renal tubular acidosis); or imaging abnormalities (eg, polycystic kidneys or a single kidney). Multiple estimates of GFR over time are used to determine the rate and pattern of progression. Although progression rates can

Table 25–7. Reversible causes of kidney injury.

Reversible Factors	Diagnostic Clues
Obstruction	Post-void residual, bladder catheterization, renal ultrasound
Significant hypotension relative to baseline	Blood pressure and pulse
Extracellular fluid volume depletion	Orthostatic vitals, weight, volume status exam
Hypercalcemia	Serum electrolytes, calcium, phosphate
Nephrotoxic agents	Medication/supplement history
Severe/urgent hypertension	Blood pressure, CXR
HF exacerbation	Physical examination, CXR

vary (eg, a smooth linear slope, or stair-stepping pattern), any acute decline in eGFR should prompt an evaluation for potentially reversible causes (see “AKI” above). Anemia, hyperphosphatemia, hypocalcemia, hyperkalemia, and metabolic acidosis are common complications of advanced CKD. The urinary sediment may show broad waxy casts as a result of dilated, hypertrophic nephrons. If proteinuria is present, it should be quantified as described above. This can help elucidate the etiology of CKD (Table 25–6). For example, glomerular diseases typically present with protein excretion of > 0.5 g/day. Quantifying proteinuria also informs prognosis (ie, higher rates are associated with more rapid progression of CKD and increased risk of cardiovascular mortality) and guides management (eg, antiproteinuric therapy aimed at slowing disease progression).

C. Imaging

Findings of small, echogenic kidneys bilaterally (< 9–10 cm) by ultrasonography suggest chronic scarring of advanced CKD. Large kidneys can be seen with polycystic kidney disease, diabetic nephropathy, HIV-associated nephropathy, plasma cell myeloma, amyloidosis, and obstructive uropathy.

Complications

Complications of CKD tend to occur at relatively predictable stages of disease as noted in Figure 25–2.

A. Cardiovascular Complications

CKD confers increased morbidity and mortality risk compared to the general population. Roughly 80% of patients with CKD die before reaching ESKD, primarily of CVD. Of those undergoing dialysis, over 50% will die of a cardiovascular cause. The mechanisms for increased cardiovascular mortality in CKD are complex and include abnormal phosphorus and calcium homeostasis, increased burden of oxidative stress and inflammation, increased vascular reactivity, LVH, and coexistent conditions such as hypertension and diabetes mellitus. The presence of proteinuria is a marker for increased CVD risk.

1. Hypertension—Hypertension is the most common complication of CKD; it tends to be progressive and salt-sensitive. As with other patient populations, control of hypertension is achieved through both pharmacologic and nonpharmacologic therapy (eg, low-salt diet, exercise, weight loss, treatment of obstructive sleep apnea). CKD results in disturbed sodium homeostasis such that the ability of the kidney to adjust to variations in sodium and water intake becomes limited as GFR declines. A low-salt diet (2 g/day) is often essential to control blood pressure and prevent volume overload. Diuretics are commonly needed to help control hypertension as disease progresses (see Table 13–9). Thiazides work well through stage 4 CKD. Loop diuretics are often used in those with more overt signs of volume overload; they are more effective at blood pressure control when administered twice daily. Recommendations for initial drug therapy in nonproteinuric patients are no different than for the general population. For proteinuric patients, first-line therapy includes ACE inhibitors or ARBs (see Table 13–6); and then MRAs if proteinuria persists. Serum creatinine and potassium should be checked 7–14 days after starting these drugs or increasing their dose. A rise in serum creatinine > 30% from baseline warrants consideration of dose reduction or drug cessation and continued following of the creatinine trajectory. Strategies to mitigate hyperkalemia include addition of a diuretic (loop inhibitor or thiazide), a low-potassium diet, potassium-binding resins, or a combination of these. Patients in whom hyperkalemia develops and who are not able to adhere to recommended mitigation strategies with close follow-up should not be treated with ACE inhibitors, ARBs, or MRAs. An ACE inhibitor and ARB should not be used in combination. CKD is a common cause of resistant hypertension for which agents from multiple classes are often needed. Guidelines differ with respect to blood pressure goals in CKD; the American Heart Association recommends < 130/80 mm Hg, whereas the Kidney Diseases Improving Global Outcomes (KDIGO) committee recommends < 120/80 mm Hg. Patients with CKD are at risk for renal hypoperfusion and AKI with overtreatment of hypertension; it is prudent to individualize the approach to blood pressure control based on patient characteristics and risk factors.

2. Cardiovascular disease—Patients with CKD are at higher risk for death from CVD than the general population. Uremic vascular calcification involving disordered phosphorus homeostasis and other mediators may contribute. Traditional modifiable risk factors for CVD, such as hypertension, diabetes mellitus, tobacco use, and dyslipidemia, should be aggressively treated.

3. Heart failure—CKD complications result in increased cardiac workload due to hypertension, volume overload, and anemia. Patients may also have accelerated rates of atherosclerosis and vascular calcification resulting in vessel stiffness. These factors contribute to LVH and HF with preserved EF, which is common in CKD. Over time, HF with decreased EF may develop. Loop diuretic therapy, in addition to fluid and salt restriction, is often necessary; diuretic dose escalation may be needed as kidney function declines. ACE inhibitors and ARBs can be used for patients with advanced CKD with close monitoring of blood pressure and potassium; MRAs may be used with similar precautions as long as eGFR is > 30 mL/min/1.73 m^2. SGLT-2 inhibitors improve outcomes for both HF and CKD and, therefore, are recommended by both nephrology and cardiology society guidelines.

4. Atrial fibrillation—Patients with advanced CKD and ESKD have increased rates of atrial fibrillation, which approach 20% in patients receiving dialysis. Those with pre-ESKD should be treated as the general population. For patients with ESKD, anticoagulation for prevention of thromboembolic events is challenging due to increased risks of bleeding and limited data supporting the benefit of anticoagulation for stroke reduction. For nonvalvular atrial fibrillation, DOACs may be safer and more effective than vitamin K antagonists for thromboembolic prophylaxis.

5. Aortic valvular calcification and stenosis—CKD may lead to aortic valvular calcification with valvular stenosis, which may progress rapidly in those with advanced CKD and ESKD.

6. Pericarditis—Pericarditis rarely develops in uremic patients; typical findings include pleuritic chest pain and a friction rub. Because cardiac tamponade can occur with uremic pericarditis, hospitalization and initiation of hemodialysis are mandatory.

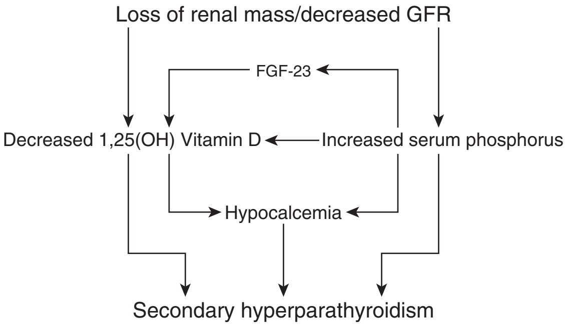
B. Mineral Bone Disorders

Mineral bone disorders of CKD refer to the complex disturbances of calcium and phosphorus metabolism, parathyroid hormone (PTH), active vitamin D (calcitriol), and fibroblast growth factor-23 (FGF-23) homeostasis (see Chapter 30 and Figure 25–3). A typical pattern seen in advanced CKD is relative hyperphosphatemia and hypocalcemia with low active vitamin D, resulting in secondary hyperparathyroidism. These abnormalities contribute to bone disease and excess fracture risk, as well to vascular calcification that is partly responsible for the accelerated CVD and excess mortality seen in CKD. Epidemiologic studies associate elevated phosphorus levels with increased risk of cardiovascular mortality in early CKD through ESKD. Data regarding how best to manage mineral bone disorders in these patients are limited; control of mineral and PTH levels per guidelines is discussed below.

Bone disease, or renal osteodystrophy, in advanced CKD is common and manifests in a variety of lesions. The gold standard for diagnosing renal osteodystrophy is bone biopsy, but this is not widely available. The most common bone disease, osteitis fibrosa cystica, is a result of secondary hyperparathyroidism and the osteoclast-stimulating effects of PTH. This is a high-turnover disease with bone resorption and subperiosteal lesions, which can cause bone pain and proximal muscle weakness. Adynamic bone disease, or low bone turnover, is becoming more common and may occur iatrogenically from suppression of PTH or via spontaneously low PTH production. Osteomalacia is characterized by lack of bone mineralization. Although historically associated with aluminum toxicity, osteomalacia is now most commonly due to vitamin D deficiency. Bisphosphonate administration in advanced CKD also may result in osteomalacia.

Management involves correction of calcium, phosphorus, and 25-OH vitamin D levels toward normal values, and mitigation of hyperparathyroidism. Understanding the interplay between these abnormalities can help target therapy (Figure 25–3). Declining GFR leads to phosphorus retention. Loss of renal mass and low 25-OH vitamin D levels often seen in CKD patients result in low 1,25(OH) vitamin D production by the kidney. Hypocalcemia can result from poor gut calcium absorption due to hypovitaminosis D as well as excess phosphate, which complexes with calcium and leads to vascular, valvular and soft tissue calcification. Hyperphosphatemia, hypocalcemia, and hypovitaminosis D are all stimuli for PTH production, and, over time, parathyroid gland hyperplasia.

The foundational step in treating mineral bone disorders is management of serum phosphorus levels. Patients should be instructed to avoid intake of highly bioavailable phosphorus—usually in the form of cola beverages, highly-processed foods, or both. If phosphorus targets are not achieved, further dietary phosphorus restriction may be



Loss of renal mass/decreased GFR
FGF-23
Decreased 1,25(OH) Vitamin D
Increased serum phosphorus
Hypocalcemia
Secondary hyperparathyroidism

Figure 25–3. Mineral abnormalities of CKD. Decline in GFR and loss of renal mass lead directly to increased serum phosphorus and hypovitaminosis D. Both of these abnormalities result in hypocalcemia and hyperparathyroidism. Many CKD patients also have nutritional 25(OH) vitamin D deficiency. PTH, parathyroid hormone. (From Tonja Dirkx, MD.)

necessary (see section on dietary management), followed by oral phosphate binders. Oral phosphate binders block absorption of dietary phosphorus and thus are taken with meals. Although target phosphorus levels are not strongly evidenced-based, standard treatment goals in ESKD are levels < 5.5 mg/dL. Calcium-containing binders are relatively inexpensive but may contribute to positive calcium balance and vascular calcification; overt hypercalcemia may also occur. Because of this, guidelines suggest limiting their use in favor of non–calcium-containing binders (sevelamer carbonate; or lanthanum carbonate) and iron-based binders (ferric citrate and sucroferric oxyhydroxide). Ferric citrate should be avoided in patients with iron overload. Aluminum hydroxide is a highly effective phosphorus binder. It can be used in the acute setting for severe hyperphosphatemia or for short periods (eg, 3 weeks) in dialysis patients, but generally should not be used long-term because it can cause osteomalacia and neurologic complications.

Once serum phosphorus levels are controlled and 25-OH vitamin D stores are repleted, active vitamin D (1,25[OH] vitamin D, or calcitriol) or other vitamin D analogs may be used to treat secondary hyperparathyroidism in advanced CKD and ESKD. Monitoring for calcitriol-induced hypercalcemia and hyperphosphatemia is important; therapy should be dose-reduced or discontinued if either occurs. Calcimimetics such as cinacalcet or etelcalcetide target the calcium-sensing receptors of the parathyroid gland and suppress PTH production. Cinacalcet can be used if elevated serum phosphorus or calcium levels prohibit the use of vitamin D analogs; etelcalcetide is only available intravenously and is administered at hemodialysis units. Because calcimimetics can cause serious hypocalcemia, close monitoring is required. Optimal PTH levels in CKD are not known, but because skeletal resistance to PTH develops with uremia, relatively high levels are targeted in advanced CKD to avoid adynamic bone disease. Expert guidelines suggest goal PTH levels near or just above the upper limit of normal for moderate CKD, and 2- to 9-fold the upper limit of normal for ESKD.

C. Hematologic Complications

1. Anemia—Anemia of CKD is primarily due to decreased erythropoietin production. It often becomes clinically significant at stage 3b–4 disease. The approach to a patient with CKD and anemia begins with ensuring that the bone marrow can respond to erythropoietin. Thus, thyroid function tests, serum vitamin B_{12} levels, reticulocyte count, and iron stores (ferritin and iron saturation) should be checked in the initial evaluation. CKD is also associated with high levels of hepcidin, which blocks GI iron absorption and mobilization of iron from body stores; this results in a functional iron deficiency or "anemia of chronic disease." In patients with CKD and anemia, KDIGO guidelines recommend offering iron supplementation if serum ferritin is below 500 ng/mL and iron saturation is < 30%. Iron therapy usually is withheld if the serum ferritin is > 700 ng/mL, even if iron saturation is < 20%. Oral therapy with ferrous sulfate, gluconate, or fumarate, 325 mg once every other day, is typically prescribed in pre-dialysis CKD; higher doses may result in increasing hepcidin levels. For those who do not respond due to poor GI absorption or intolerance, intravenous iron (eg, iron sucrose or iron gluconate) can be considered.

Erythropoiesis-stimulating agents (ESAs, eg, recombinant erythropoietin [epoetin alfa or beta] and darbepoetin) are used to treat anemia of CKD if other treatable causes are excluded. Initiation of an ESA is usually considered when hemoglobin (Hgb) values are 9–10 g/dL. Typical ESA starting doses are epoetin alfa 50–100 U/kg once or twice weekly; darbepoetin 0.45 mcg/kg every 2–4 weeks; or epoetin beta 60–100 mcg every 2–4 weeks. These agents can be given intravenously (eg, during hemodialysis) or subcutaneously; subcutaneous dosing of epoetin alfa is roughly 30% more effective than intravenous dosing. ESAs should be titrated to an Hgb of 10–11 g/dL for optimal safety; studies show that targeting a higher Hgb increases the risk of stroke and possibly other cardiovascular events. When titrating doses, Hgb levels should rise no more than 1 g/dL every 3–4 weeks. Other concerns regarding ESA use include possible exacerbation of HTN and acceleration of underlying malignancy growth. For this reason, daprodustat, a hypoxia-inducible factor prolyl hydroxylase inhibitor, has emerged as an alternative to ESAs in treating anemia; however, it is not widely available to date.

2. Coagulopathy—Bleeding diathesis may occur in stage 4–5 CKD due to platelet dysfunction or severe anemia.

Treatment of bleeding diathesis is required only in patients who are symptomatic. Raising the Hgb to 9–10 g/dL can reduce risk of bleeding via improved clot formation. Desmopressin is a short-lived but effective treatment for platelet dysfunction and can be used in preparation for surgery or kidney biopsy; hyponatremia is a potential adverse effect of this treatment. Dialysis improves platelet function in uremic patients.

D. Hyperkalemia

Potassium balance generally remains intact in CKD until stages 4–5. However, hyperkalemia may occur at earlier stages when certain conditions are present, such as type 4 renal tubular acidosis (seen in patients with diabetes mellitus), high-potassium diets, or medications that decrease renal potassium secretion (amiloride, triamterene, spironolactone, eplerenone, finerenone, NSAIDs, ACE inhibitors, ARBs) or block cellular potassium uptake (β-blockers). Other causes include acidemic states and any process causing release of intracellular contents, such as hemolysis and rhabdomyolysis.

Treatment of acute hyperkalemia is discussed in Chapter 24 (see Table 24–5). Cardiac monitoring is indicated for any ECG changes seen with hyperkalemia or a serum potassium level > 6.0–6.5 mEq/L. Chronic hyperkalemia is best treated with dietary potassium restriction (2 g/day) and minimization or elimination of any medications that may impair renal potassium excretion, as noted above. Diuretics may help control potassium levels; SGLT-2 inhibitors and thiazides are less potent kaliuretics than loop diuretics. Oral potassium-binding resins (patiromer and sodium zirconium cyclosilicate) may permit the continued use of cardio- and reno-protective medications contributing to hyperkalemia, but this strategy should only be utilized in highly adherent patients with routine lab monitoring.

St-Jules DE et al. Etiology-based dietary approach for managing hyperkalemia in people with chronic kidney disease. Nutr Rev. 2022;80:2198. [PMID: 35482610]

E. Acid-Base Disorders

Damaged kidneys are unable to excrete the 1 mEq/kg/day of acid generated by metabolism of dietary animal protein intake. The resultant non-anion gap metabolic acidosis is primarily due to impaired ammonia production; proximal or distal tubular defects also may contribute to or worsen the acidosis. Excess hydrogen ions are buffered by bone; the consequent leaching of calcium and phosphorus from the bone contributes to the mineral bone disorders described above. Chronic acidosis can increase muscle protein catabolism and accelerate CKD progression. Reduction of dietary animal protein, increase in fruit and vegetable intake, and the administration of oral sodium bicarbonate (in titrated doses of 0.5–1.0 mEq/kg/day divided twice daily) may bring serum bicarbonate levels toward normal and is recommended when serum consistently are below 18 mmol/L. Citrate salts increase the absorption of dietary aluminum and should be avoided in CKD.

Raphael K. Metabolic acidosis in CKD: pathogenesis, adverse effects, and treatment effects. Int J Mol Sci. 2024;25:5187. [PMID: 38791238]

F. Neurologic Complications

Uremic encephalopathy, resulting from the accumulation of uremic toxins, typically does not occur until GFR falls below 5–10 mL/min/1.73 m^2. Symptoms begin with difficulty in concentrating and can progress to lethargy, confusion, seizure, and coma. Physical findings may include altered mental status, weakness, and asterixis. These findings improve with dialysis.

Other neurologic complications of advanced CKD may include peripheral neuropathies (stocking-glove or isolated mononeuropathies), erectile dysfunction, autonomic dysfunction, sleep disorders, restless leg syndrome, and pruritus. These may not improve with dialysis therapy.

G. Endocrine Disorders

Hypothyroidism is common in CKD. Men with advanced CKD may experience decreased libido and erectile dysfunction; women may have menstrual disturbances and anovulatory cycles. During pregnancy, a serum creatinine > 1.4 mg/dL is associated with more rapid CKD progression. However, poor outcomes of pregnancy are not increased in women with creatinine < 1.4 mg/dL and fetal survival is not compromised unless CKD is advanced.

▶ Treatment

A. Slowing Progression

Slowing CKD progression is a multipronged task that includes (1) treatment of the underlying cause, (2) blood pressure control, (3) therapy with antiproteinuric agents (ACE inhibitor or ARB, MRA, SGLT-2-inhibitor, or a combination of these) if appropriate, (4) weight loss if a patient has obesity, (5) avoidance of possible nephrotoxins (iodinated contrast agents, NSAIDs, PPIs), and (6) management of cardiovascular risk factors. Treatment of metabolic acidosis is recommended. GLP-1 agonists have emerged as a promising class of medications to help slow disease progression in patients with diabetes. Laboratory results should be monitored after starting or titrating antiproteinuric agents. An initial fall in eGFR within the first several weeks may be seen, but as long as further testing demonstrates stabilization of kidney function and there is no concerning hyperkalemia, the agent should be continued.

B. Dietary Management

Patients with CKD should be evaluated by a renal dietitian. Patient-specific recommendations should be made concerning protein, salt and water, potassium, and phosphorus intake to help mitigate CKD progression and complications.

1. Protein restriction—Limiting protein intake to 0.6–0.8 g/kg/day may slow CKD progression; plant-based sources of protein are thought to be better than animal sources for long-term kidney health. Restricting beyond these amounts is not advisable and should be avoided in those with cachexia or low serum albumin.

2. Salt and water restriction—Efforts should prioritize sodium restriction over water restriction; patients should be encouraged to drink water to thirst so long as they are following guidance on sodium intake appropriately. In advanced CKD, the kidney is unable to adapt to large changes in sodium intake. Intake of > 3–4 g/day can lead to hypertension and hypervolemia, whereas intake of < 1 g day can lead to volume depletion and hypotension. A goal of 2 g/day of sodium is reasonable for most patients.

3. Potassium restriction—Restriction is needed once the GFR falls below 10–20 mL/min/1.73 m^2, or earlier if the patient is hyperkalemic. Patients should receive detailed lists describing potassium content of foods and should limit their intake to < 50–60 mEq/day (2 g/day). Constipation can contribute to hyperkalemia in CKD, since a higher percentage of potassium is excreted through the GI tract as GFR declines.

4. Phosphorus restriction—Guidelines suggest lowering elevated serum phosphorus levels toward normal in advanced CKD and to a level of < 5.5 mg/dL in ESKD. Initial dietary phosphate restriction should include avoidance of highly bioavailable phosphorus (fast foods and highly processed foods, and cola beverages), and subsequently moderation of intake of other phosphorus-rich foods such as eggs, dairy products, nuts, beans, and meat. Care must be taken to avoid protein malnutrition. When ESKD is reached, dietary restriction alone rarely is sufficient to reach target levels, and phosphorus binders are often required (see section on Mineral Bone Disorders).

MacLaughlin HL et al. Nutrition in kidney disease: Core Curriculum 2022. Am J Kidney Dis. 2022;79:437. [PMID: 34862042]

C. Medication Management

Many drugs are excreted by the kidney; dosages should be adjusted for GFR. As CKD advances, patients with diabetes using insulin or sulfonylureas may face increased risk of hypoglycemia due to decreased renal elimination of insulin; patient education and dose appropriate reductions are vital to avoid harm. The risk of lactic acidosis with metformin is due to both dose and eGFR; its dose should be reduced when eGFR is < 45 mL/min/1.73 m^2, and it should be discontinued when eGFR is < 30 mL/min/1.73 m^2.

Magnesium-containing medications, such as laxatives or antacids, and phosphorus-containing medicines (eg, enemas) should be avoided. Active morphine metabolites can accumulate in advanced CKD and should be avoided; this problem is not encountered with other opioid agents. Drugs with potential nephrotoxicity (NSAIDs, intravenous contrast, as well as others noted in the Acute Kidney Injury section) should be avoided. PPIs should be used only when medically necessary and for short courses.

D. Treatment of ESKD

When GFR declines to 5–10 mL/min/1.73 m^2, kidney replacement therapy (hemodialysis, peritoneal dialysis, or kidney transplantation) may extend life. Patient evaluation and education are crucial for timely preparation for the chosen therapy. Referral to a nephrologist has been shown to improve clinical outcomes. Practice guidelines recommend referral to a nephrologist when the GFR falls below 30 mL/min/1.73m^2, declines rapidly (> 5 mL/min/1.73 m^2 per year), or when > 300 mg/day of albuminuria is present. Preparation for ESKD treatment requires a team approach with the involvement of dietitians, social workers, primary care clinicians, and nephrologists. For older adults (over 80 years), or those with multiple debilitating or life-limiting comorbidities, dialysis may not meaningfully prolong life, and the option of medical management without dialysis should be discussed with the patient and family. Conversely, for patients who are otherwise relatively healthy, evaluation for preemptive kidney transplantation should be considered.

1. Dialysis—Dialysis initiation should be considered when GFR is near 10 mL/min/1.73 m^2 and uremic symptoms are present. Other indications for dialysis, which may occur when GFR is 10–15 mL/min/1.73 m^2, are fluid overload unresponsive to diuresis and refractory hyperkalemia.

A. Hemodialysis—Vascular access for hemodialysis can be an arteriovenous fistula (the preferred method) or prosthetic graft; creation of dialysis access should be considered well before dialysis initiation. A tunneled dialysis catheter is used when there is no usable vascular access. Because catheters confer a high risk of bloodstream infection, they should be considered a temporary measure. Fistulae typically last longer than prosthetic grafts but require a longer time after surgical construction for maturation (6–8 weeks for a fistula versus 2 weeks for a graft). Infection, thrombosis, and aneurysm formation are complications seen more often in grafts than fistulae.

Treatment at a hemodialysis center typically occurs three times a week. Sessions last 3–4.5 hours, depending on body habitus and patient habits. Home hemodialysis is often performed more frequently (4–6 days per week for shorter sessions) and often requires a trained helper. Clinical trials comparing quotidian modalities (nocturnal and frequent home hemodialysis) to conventional in-center dialysis have not shown significant mortality differences, but there may be improvements in blood pressure control, mineral metabolism, and quality of life.

B. Peritoneal dialysis—With peritoneal dialysis, the peritoneal membrane is the "dialyzer."

There are two primary approaches to peritoneal dialysis: continuous ambulatory peritoneal dialysis (CAPD), in which the patient manually exchanges the dialysate four to six times daily; and continuous cyclic peritoneal dialysis (CCPD), which utilizes a cycler machine that automatically perform exchanges at night during sleep.

2. Kidney transplantation—Many patients with ESKD are otherwise healthy enough to undergo transplantation, although standard criteria for recipient selection are lacking between transplant centers. Two-thirds of kidney allografts come from deceased donors, with the remainder from living related or unrelated donors. Over 100,000 patients are on the waiting list for a deceased donor transplant in the United States; the average wait is 3–7 years, depending on geographic location and recipient blood type.

3. Medical management of ESKD—As noted above, some patients are not candidates for kidney transplantation and may not benefit from dialysis. Frail older adults may die soon after dialysis initiation; those who do not may rapidly lose functional status in the first year of treatment. The decision to initiate dialysis in those with limited life expectancy should be weighed against probable deterioration in quality of life. For patients with ESKD who elect not to undergo dialysis or who withdraw from dialysis, progressive uremia with gradual suppression of sensorium results in a typically painless death within days to months. Hyperkalemia may intervene with a fatal cardiac dysrhythmia. Diuretics, volume restriction, and opioids, as described in Chapter 5, may help decrease the symptoms of volume overload. Involvement of a palliative care team is essential.

Prognosis in ESKD

Compared with kidney transplant recipients and age-matched controls, mortality is higher for patients undergoing dialysis. There is likely little difference in survival for well-matched peritoneal versus hemodialysis patients.

Patients undergoing dialysis have an average life expectancy of 3–5 years, but survival for as long as 25 years may be achieved depending on comorbidities, age at which dialysis is initiated, and underlying cause of kidney disease. Overall 5-year survival is estimated at 40%. Five-year Kaplan-Meier survival rates vary from 37% for patients with diabetes to 54% for patients with glomerulonephritis. The most common cause of death is cardiac disease (> 50%). Other causes include infection, cerebrovascular disease, and malignancy.

When to Refer

- A patient should be referred to a nephrologist for management in conjunction with the primary care provider when GFR falls below 30 mL/min/1.73m^2 or declines rapidly (> 5 mL/min/1.73 m^2 per year).
- A patient with other forms of CKD such as those with proteinuria > 300 mg/day or polycystic kidney disease should be referred to a nephrologist at earlier stages.

When to Admit

- Admission should be considered for decompensation of problems related to CKD, such as worsening of acid-base status, electrolyte abnormalities, and volume overload, that cannot be appropriately treated in the outpatient setting.
- Admission is appropriate when a patient needs to start dialysis and is not stable for outpatient initiation.

RENAL ARTERY STENOSIS

ESSENTIALS OF DIAGNOSIS

- Secondary to atherosclerotic occlusive disease (80–90% of patients) or fibromuscular dysplasia (10–15%).
- Hypertension, may be resistant or refractory.
- AKI may occur in patients with bilateral stenosis when ACE inhibitor or ARB therapy is initiated.

General Considerations

Renal artery stenosis is a relatively common cause of secondary hypertension and can lead to CKD and ESKD. It typically occurs among persons over 45 years of age with atherosclerotic risk factors such as diabetes mellitus, hyperlipidemia, and tobacco use; disease in other vessels is common. Fibromuscular dysplasia, a less common cause of renal artery stenosis, usually occurs in young women.

Clinical Findings

A. Symptoms and Signs

Patients with atherosclerotic renovascular disease may have refractory hypertension, new-onset hypertension, acute pulmonary edema with poorly controlled blood pressure, and/or AKI upon starting an ACE inhibitor or ARB. Physical examination may reveal an audible abdominal bruit on the affected side. Unexplained hypertension in a woman younger than 40 years should raise suspicion for fibromuscular dysplasia.

B. Laboratory Findings

Serum creatinine may be elevated if there is significant renal ischemia. Patients with bilateral renal artery stenosis may have hypokalemia, a finding that reflects activation of the renin-angiotensin-aldosterone system in response to reduced blood flow (a "prerenal" state). Plasma renin concentration or activity is elevated.

C. Imaging

Abdominal ultrasound can reveal either asymmetric kidney size (> 1.5 cm difference) if one renal artery is primarily affected, or small hyperechoic kidneys if both are affected.

Screening with Doppler ultrasonography, CT angiography, or magnetic resonance angiography (MRA) is recommended if a corrective procedure would be performed when a positive test result is found. **Doppler ultrasonography** of the renal arteries can be both sensitive and specific but is extremely operator- and patient habitus–dependent.

CT angiography consists of intravenous contrast injection with digital subtraction arteriography and offers good sensitivity and specificity.

MRA is an excellent but expensive way to screen for renal artery stenosis, particularly in those with atherosclerotic disease. The newer-generation gadolinium contrast agents seem to carry little to no risk for nephrogenic systemic fibrosis in those with advanced CKD or ESRD.

Renal angiography is the gold standard for diagnosis but is invasive, requiring femoral artery catheterization. Thus, it is usually performed after a positive screening test in order to confirm the anatomy and to provide interventions when high grade, hemodynamically significant stenotic lesions are identified. Atherosclerotic lesions are most commonly found in the proximal third or ostial region of the renal artery. There is risk of atheroembolic phenomena after angiography. Fibromuscular dysplasia has a characteristic "beads-on-a-string" appearance on angiography.

Treatment

Treatment of atherosclerotic renovascular disease is controversial. Options include medical management and angioplasty with stenting. Two large randomized trials showed that mechanical intervention is no better than optimal medical management (including ACE inhibitor or ARB and lipid control) in most patients. Angioplasty and stenting should be considered for those with high-grade stenosis (> 70%) and any of the following: acute ("flash") pulmonary edema or recurrent episodes of volume overload, refractory HTN, ACEi or ARB intolerance, increased rate of eGFR decline, or stenosis in a transplanted kidney artery.

Treatment of fibromuscular dysplasia with percutaneous transluminal angioplasty is often curative, which is in stark contrast to treatments for atherosclerotic disease.

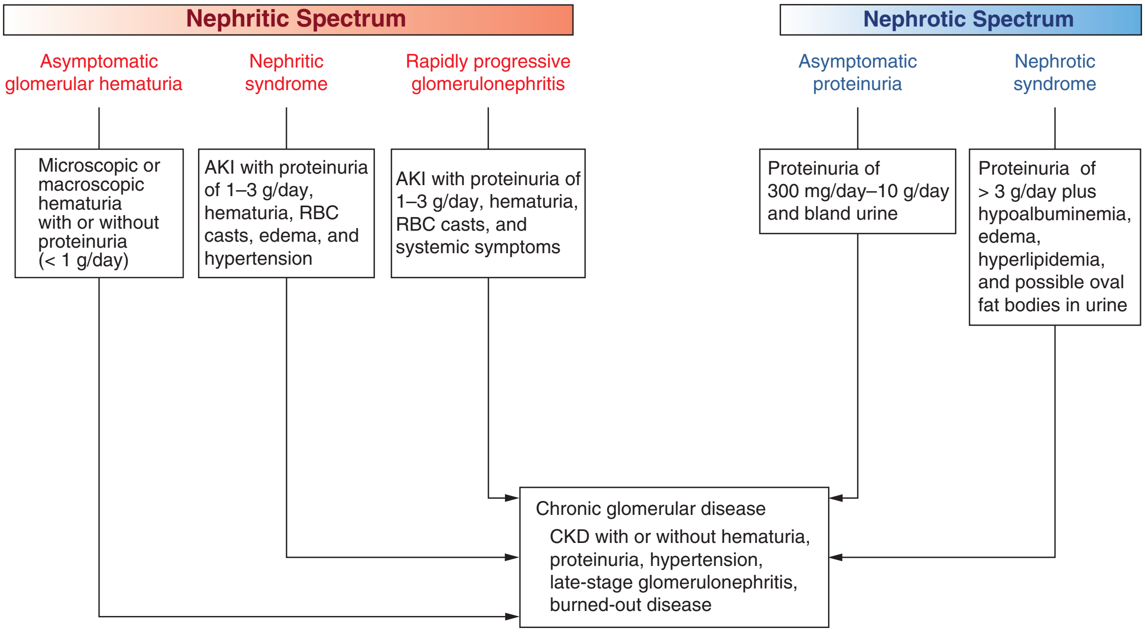
GLOMERULAR DISEASES

The glomerulus is a histologically complex structure consisting of the epithelial cells (podocytes), basement membrane, capillary endothelium, and mesangium. A variety of different insults can occur within these structures causing different patterns of injury. Examples of injuries that can affect any or all of the constituents of the glomerulus are (1) overwork injury, as in CKD or obesity; (2) an inflammatory process, such as SLE; (3) a podocyte protein mutation, as in hereditary focal segmental glomerulosclerosis (FSGS); or (4) a deposition disease, as in diabetes or amyloidosis. Different glomerular patterns of injury tend to cause different clinical syndromes or findings, which may help narrow the differential diagnosis, but a kidney biopsy is often needed to confirm the diagnosis.

Classification

Glomerular diseases are clinically classified as either nephritic or nephrotic (Figure 25–4). These are distinguished by the amount of proteinuria, as well as the presence (nephritic) or absence (nephrotic) of significant glomerular hematuria. Differentiation is important because it helps narrow the differential diagnosis of the



Nephritic Spectrum
Asymptomatic glomerular hematuria
Nephritic syndrome
Rapidly progressive glomerulonephritis
Microscopic or macroscopic hematuria with or without proteinuria (< 1 g/day)
AKI with proteinuria of 1–3 g/day, hematuria, RBC casts, edema, and hypertension
AKI with proteinuria of 1–3 g/day, hematuria, RBC casts, and systemic symptoms
Nephrotic Spectrum
Asymptomatic proteinuria
Nephrotic syndrome
Proteinuria of 300 mg/day–10 g/day and bland urine
Proteinuria of > 3 g/day plus hypoalbuminemia, edema, hyperlipidemia, and possible oval fat bodies in urine
Chronic glomerular disease
CKD with or without hematuria, proteinuria, hypertension, late-stage glomerulonephritis, burned-out disease

Figure 25–4. Glomerular diseases present within one of the clinical spectra shown; the exact presentation is determined by the severity of the underlying disease and the pattern of injury. Nephritic diseases are characterized by the presence of an active urine sediment with glomerular hematuria and often with proteinuria. Nephrotic spectrum diseases are proteinuric with bland urine sediments (no cells or cellular casts). All glomerular diseases may progress to a chronic, scarred state. (Reproduced with permission from Megan Troxell, MD, PhD.)

underlying glomerular disease and guide further serologic evaluation prior to possible kidney biopsy (Tables 25–8 and 25–9).

Nephritic diseases are characterized by proteinuria < 3.5 g/day and glomerular hematuria. At the "least severe" end of the nephritic spectrum, asymptomatic glomerular hematuria (ie, dysmorphic RBCs) with or without subnephrotic proteinuria is characteristic. The mid-portion of the spectrum is the nephritic *syndrome*, where additional features accompany hematuria and proteinuria, such as edema, hypertension, and creatinine elevation. The "most severe" and clinically urgent end of the spectrum are the rapidly progressive glomerulonephritides (RPGNs).

Nephrotic spectrum diseases demonstrate greater proteinuria with a typically bland urine sediment (no cells or cellular casts). The relatively rare nephrotic *syndrome* is the most severe end of the spectrum, encompassing heavy proteinuria (> 3.5 g/day) in addition to hypoalbuminemia, edema, and hyperlipidemia.

Glomerular diseases can also be classified according to whether they cause renal abnormalities alone (primary renal disease) or represent manifestations of a systemic disease (secondary renal disease), such as diabetes.

NEPHRITIC SPECTRUM GLOMERULAR DISEASES

ESSENTIALS OF DIAGNOSIS

- **Mild cases: asymptomatic glomerular hematuria**
  - Hematuria with dysmorphic RBCs
  - Proteinuria typically < 1 g/day
- **More severe cases: nephritic syndrome**
  - Glomerular hematuria (and RBC casts if glomerular bleeding is heavy)
  - Proteinuria typically 1–3.5 g/day
  - Hypertension
  - Edema
  - Rising creatinine over days to months
- **Most severe cases: rapidly progressive glomerulonephritis**
  - AKI with rising creatinine over days to months
  - Glomerular hematuria and RBC casts
  - Proteinuria typically 1–3.5 g/day

Table 25–8. Nephritic spectrum glomerular diseases.

	Typical Presentation	Association/Notes	Serology
Postinfectious or infection-related glomerulonephritis	Children: abrupt onset of nephritic syndrome and AKI but can present anywhere in nephritic spectrum	Streptococci, other bacterial infections (eg, staphylococci, endocarditis, shunt infections)	Rising ASO titers, low complement levels, blood cultures
IgA nephropathy (Berger disease) and Henoch-Schönlein purpura, systemic IgA vasculitis	Classically: gross hematuria with respiratory tract infection, but can present anywhere in nephritic spectrum; Henoch-Schönlein purpura with vasculitic rash and GI hemorrhage	Abnormal IgA glycosylation in both primary (familial predisposition) and secondary disease (associated with cirrhosis, HIV, celiac disease) Henoch-Schönlein purpura in children after an inciting infection	No serologic tests helpful; complement levels are normal
Cryoglobulin-associated glomerulonephritis	Often acute nephritic syndrome; often with systemic vasculitis including rash and arthritis	Most commonly associated with chronic hepatitis C; may occur with other chronic infections or some connective tissue diseases	Cryoglobulins positive; rheumatoid factor may be elevated; complement levels low
Lupus nephritis	Anywhere in nephritic spectrum, depending on pattern/severity of injury	Treatment depends on clinical course and International Society of Nephrology and Renal Pathology Society classification on biopsy	High ANA and anti-double-stranded DNA titers; low complement levels
Pauci-immune (granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, polyarteritis)	Classically: crescentic or RPGN, but can present anywhere in nephritic spectrum; may have respiratory tract/sinus symptoms in granulomatosis with polyangiitis	May be related to environmental exposures including infection	ANCAs: MPO or PR3 titers high; complement levels normal
Anti-GBM glomerulonephritis; Goodpasture syndrome	Classically: crescentic or RPGN, but can present anywhere in nephritic spectrum; pulmonary hemorrhage in Goodpasture syndrome	May develop as a result of respiratory irritant exposure (chemicals or tobacco use)	Anti-GBM antibody titers high; complement levels normal
C3 glomerulopathies (and idiopathic immune-complex MPGN)	Classically: acute nephritic syndrome, but can also have nephrotic syndrome	Most patients are < 30 years old; dysregulation of alternative complement pathway resulting in overactivation	Low complement levels, may have findings of underlying infection or paraproteinemia
Monoclonal immunoglobulin glomerulonephritis (monoclonal gammopathy of renal significance)	Anywhere in nephritic spectrum	Can cause different patterns of renal injury	SPEP with monoclonal protein; serum light chain ratio > 3

ANCAs, antineutrophil cytoplasmic antibodies; ASO, antistreptolysin O; GBM, glomerular basement membrane; MPGN, membranoproliferative glomerulonephritis; MPO, myeloperoxidase; PR3, proteinase 3; RPGN, rapidly progressive glomerulonephritis.

General Considerations

"Glomerulonephritis" is a term given to nephritic diseases and usually signifies an inflammatory process causing kidney dysfunction. Glomerulonephritis is further classified according to one of five pathogenic subtypes: immune-complex (eg, lupus nephritis), pauci-immune, anti-GBM, C3 glomerulopathy, or monoclonal immunoglobulin–mediated. Presentation may be acute (developing over days to weeks), with or without resolution, or may be chronic and indolent with progressive scarring. As noted above, nephritic diseases may present with glomerular hematuria and proteinuria, with nephritic syndrome, or with RPGN.

Clinical Findings

A. Symptoms and Signs

Nephritic syndrome usually presents with an acute decrease in GFR. The resultant sodium retention can lead to hypertension and edema, which is first seen in regions of low tissue pressure such as the periorbital and scrotal areas. Heavy bleeding from glomerular inflammation may result in gross hematuria ("cola-colored urine").

B. Laboratory Findings

1. Serologic testing—Serologic tests (selected based on the history and physical examination) help narrow the

Table 25–9. Classification and findings in glomerulonephritis: nephrotic spectrum presentations.

Disease	Typical Presentation	Association/Notes
Minimal change disease	Child with sudden onset of nephrotic syndrome	Children: associated with allergy or viral infection Adults: associated with Hodgkin disease, NSAIDs, bee stings
Focal and segmental glomerulosclerosis	Anywhere in nephrotic spectrum; children with congenital disease have nephrotic syndrome	Children: congenital disease with podocyte gene mutation, or in spectrum of disease with minimal change disease Adults: associated with heroin use, HIV infection, reflux nephropathy, obesity, pamidronate, podocyte protein mutations, *APOL1* mutations
Membranous nephropathy	Anywhere in nephrotic spectrum, but nephrotic syndrome not uncommon; particular predisposition to hypercoagulable state	Serologic PLA$_2$R Ab positivity strongly suggestive of primary MN (may eliminate need for renal biopsy) Secondary may be associated with non-Hodgkin lymphoma, carcinoma (GI, renal, bronchogenic, thyroid), gold therapy, penicillamine, SLE, chronic hepatitis B or C infection
Diabetic kidney disease	High GFR (hyperfiltration) → microalbuminuria → frank proteinuria → decline in GFR	Diabetes diagnosis precedes diagnosis of nephropathy by years
HIV-associated nephropathy	Heavy proteinuria, often nephrotic syndrome, progresses to ESKD relatively quickly	Usually seen in antiviral treatment-naïve patients (rare in antiretroviral therapy era), and in those with 2 *APOL1* risk alleles
Amyloidosis	Usually nephrotic syndrome; may have signs of amyloid deposition in other organs	AL: plasma cell dyscrasia with Ig light chain overproduction and deposition; check SPEP/UPEP, serum light chains AA: serum amyloid protein A overproduction and deposition in response to chronic inflammatory disease (rheumatoid arthritis, IBD, chronic infection)

PLA$_2$R, phospholipase A$_2$ receptor; SPEP/UPEP, serum and urine protein electrophoresis.

differential diagnosis. These include C3 and C4 complement levels, ANA, cryoglobulins, hepatitis serologies, serum/urine protein electrophoreses and immunofixation, serum free light chains, ANCAs, anti-GBM antibodies, and anti-pathogen antibodies (eg, antistreptolysin O titers) (Table 25–8).

2. UA—The urine dipstick is positive for protein and blood. Urinary microscopy reveals RBCs that are dysmorphic from traversing a damaged glomerular basement membrane. RBC casts are seen with heavy glomerular bleeding and tubular stasis. When quantified, proteinuria is usually subnephrotic range (< 3.5 g/day).

3. Biopsy—Definitive diagnosis of the underlying glomerular disease cannot be made without a kidney biopsy. Candidates for biopsy are patients for whom test results would influence management or inform prognosis; exceptions include those with advanced underlying CKD, those who cannot adhere to medical therapy, those for whom immunosuppressive therapy is not appropriate, or those for whom the clinical presentation is "classic" for a particular disease (eg, poststreptococcal glomerulonephritis, childhood minimal change disease, and diabetic nephropathy). The major risk of biopsy is bleeding. Contraindications include a bleeding diathesis, thrombocytopenia, and uncontrolled hypertension.

Treatment

General measures include treatment of hypertension and fluid overload, if present. Antiproteinuric therapy with an ACE inhibitor or ARB should be considered for those without AKI. For those with profound AKI, dialysis may be needed. The inflammatory glomerular injury may require immunosuppressive agents (see specific diseases discussed below).

When to Refer

Any patient in whom glomerulonephritis is suspected should be immediately referred to a nephrologist.

When to Admit

Any suspicion for acute nephritic syndrome or RPGN warrants consideration of immediate hospitalization.

Romagnani P et al. The five types of glomerulonephritis classified by pathogenesis, activity and chronicity (GN-AC). Nephrol Dial Transplant. 2023;38:ii3. [PMID: 37218714]
Rovin BH et al. Executive summary of the KDIGO 2021 guideline for the management of glomerular diseases. Kidney Int. 2021;100:753. [PMID: 34556300]

1. Immune Complex Glomerulonephritis: Infection-Related & Postinfectious Glomerulonephritis

ESSENTIALS OF DIAGNOSIS

- Proteinuria.
- Glomerular hematuria.
- Symptoms occur during course of some infections (eg, pneumonia, endocarditis) or 1–3 weeks after some infections (often pharyngitis or impetigo).

General Considerations

Infection-related glomerulonephritis (IRGN) is characterized by glomerular injury during active or recent infection. Although more common in the setting of staphylococcal infections (eg, bloodstream infections, abscesses, endocarditis), IRGN can occur in a variety of infections including viral, fungal, and parasitic causes of glomerulonephritis; these include hepatitis B or C, HIV, cytomegalovirus infection, infectious mononucleosis, coccidioidomycosis, malaria, mycobacteria, syphilis, and toxoplasmosis. Post-infectious glomerulonephritis specifically refers to those cases that arise due to infection with nephritogenic group A β-hemolytic streptococcal infections (pharyngitis or impetigo), and 1–3 weeks after infection (average 7–10 days).

Clinical Findings

A. Symptoms and Signs

Disease presentation varies across the nephritic spectrum from asymptomatic glomerular hematuria with preserved kidney function, to nephritic syndrome with hypertension, edema, and gross glomerular hematuria (“cola-colored urine”); the most severe cases may result in oliguric AKI requiring dialysis.

B. Laboratory Findings

Serum C3 and C4 are low, with C3 levels classically being “disproportionately” lower than C4. In postinfectious glomerulonephritis due to group A streptococcal infection, anti-streptolysin O (ASO) titers may be high. Glomerular hematuria and proteinuria are present. In children with recent streptococcal infection and nephritic features, a diagnosis may be made empirically without a biopsy. When performed, kidney biopsy shows a diffuse proliferative pattern of injury on light microscopy. Immunofluorescence demonstrates granular deposition of IgG and C3 in the mesangium and along the capillary basement membrane. Electron microscopy shows large, dense subepithelial deposits or “humps.” Kidney biopsy findings in IRGN are similar, though some may demonstrate IgA deposition rather than IgG, and others may appear similar to C3 glomerulopathy.

Treatment

Any active infection should be identified and treated appropriately; otherwise, treatment for IRGN is supportive. Although steroids are sometimes considered, evidence does not support their use. Antihypertensives, salt restriction, and diuretics should be used if needed. Prognosis depends on the severity of the glomerular injury and age of the patient. Children are more likely to fully recover; adults are more prone to the development of severe disease (RPGN with crescent formation) and CKD.

2. Immune Complex Glomerulonephritis: IgA Nephropathy

ESSENTIALS OF DIAGNOSIS

- Proteinuria: minimal to nephrotic-range.
- Glomerular hematuria: microscopic is common; macroscopic (gross) can occur after infection.
- Positive IgA staining on kidney biopsy.

General Considerations

IgA nephropathy results from glomerular mesangial deposition of immune complexes made up of aberrantly glycosylated IgA (a heritable condition) and IgG autoantibodies against these abnormal molecules. IgA nephropathy can be a primary (renal-limited) disease or secondary to cirrhosis, celiac disease, and infections such as HIV and cytomegalovirus.

IgA nephropathy is the most common primary glomerular disease worldwide, particularly in Asia. It is most often seen in children and young adults and affects males two to three times more commonly than females.

Clinical Findings

The classic presentation of IgA nephropathy is an episode of gross hematuria associated with a mucosal viral infection, often of the upper respiratory tract 1–2 days after illness onset (in contrast to the longer latent period seen in post-infectious glomerulonephritis). IgA nephropathy can present anywhere along the nephritic spectrum from asymptomatic microscopic hematuria with minimal proteinuria and preserved eGFR to RPGN (Figure 25–4). Rarely, nephrotic syndrome can also develop.

There are no serologic tests that aid in this diagnosis; serum complements are normal. The typical pattern of injury seen on kidney biopsy is a focal glomerulonephritis with mesangial proliferation; immunofluorescence demonstrates diffuse mesangial IgA and C3 deposits.

Treatment

Treatment recommendations for IgA nephropathy are changing rapidly in recent years, and many new therapies have emerged. In general, patients at lowest risk for progression (no hypertension, normal GFR, minimal proteinuria) can be monitored expectantly. Patients at higher risk (proteinuria > 1.0 g/day, decreased GFR, hypertension, or any combination of these three conditions) should be treated with an ACE inhibitor or ARB. Therapy should be titrated to reduce proteinuria to < 0.5 g/day and to control blood pressure to 120/80 mm Hg. SGLT-2 inhibitors are standard care in proteinuric patients. Sparsentan, a dual-acting endothelin and angiotensin II antagonist, is superior to ACE inhibitors or ARBs for proteinuria reduction, but its use may be limited by high cost.

Immunosuppressive therapy is considered for patients at the highest risk, defined as persistent proteinuria > 1.0 g/day despite 90 days of optimized antiproteinuric therapy. Guidelines recommend consideration of systemic corticosteroids to reduce proteinuria reduction and slow progression, but their use must be weighed against risk of adverse effects, including infection. By targeting intestinal mucosal immunogenicity, enteric-coated budesonide therapy reduces proteinuria with fewer adverse effects compared with systemic corticosteroids and can be considered. Additionally, iptacopan, which inhibits factor B in the alternative pathway of complement, has been shown to reduce proteinuria without increasing risk of infection. Small studies support the consideration of mycophenolate mofetil. For the rare patient with IgA nephropathy and a rapidly progressive clinical course with diffuse crescent formation on biopsy, cyclophosphamide and corticosteroid therapy should be considered (see section on ANCA-associated vasculitis below). Kidney transplantation is an excellent option for patients with ESKD, but recurrent disease develops in 30% of patients 5–10 years posttransplant.

Prognosis

Patients with IgA nephropathy are at risk for progression to ESKD, particularly when presenting with proteinuria of > 0.5 g/day, lower GFR, and/or biopsy finding of tubulointerstitial fibrosis and glomerulosclerosis.

3. Immune Complex Glomerulonephritis: IgA Vasculitis (Henoch-Schönlein Purpura)

IgA vasculitis, or Henoch-Schönlein purpura, is a systemic small-vessel leukocytoclastic vasculitis associated with IgA subclass 1 deposition in vessel walls. It is most common in children and is often associated with an inciting infection or medication exposure. It classically presents with palpable purpura in the lower extremities and buttocks, arthralgias, abdominal symptoms (nausea, colic, and melena), and AKI with nephritic urine sediment. The renal pattern of injury is the same as IgA nephropathy. Most patients with microscopic hematuria and minimal proteinuria recover fully over several weeks. Progressive CKD is more likely to develop in adults and in those with both nephritic and nephrotic syndromes. Although several treatment regimens of various immunosuppressive agents have been clinically tested, none is proven to alter the course of severe nephritis. Rituximab treatment and plasma exchange have been successful for severe disease according to several case reports, but clinical trials are lacking. Rapidly progressive disease with crescent formation on biopsy should be treated as in ANCA-associated vasculitis (see section below). Further details about IgA vasculitis are provided in Chapter 23.

4. Immune Complex Glomerulonephritis: Cryoglobulin-Associated Glomerulonephritis

A systemic vasculitis due to cryoglobulinemia (cold-precipitable immunoglobulins) can result in glomerular disease. The majority of cases are caused by HCV infection. Immune complexes of rheumatoid factor, HCV antigen, and polyclonal anti-HCV IgG deposit in vessels and incite inflammation. Additional causes of polyclonal cryoglobulinemic vasculitis include other overt or occult infections (eg, viral, bacterial, and fungal) and autoimmune diseases. Disease without an identifiable cause is termed “essential” cryoglobulin-associated glomerulonephritis.

Patients exhibit purpuric and necrotizing skin lesions in dependent areas, arthralgias, fever, and hepatosplenomegaly. Serum complement levels (particularly C4) are low, and rheumatoid factor is often elevated. Kidney biopsy may show different patterns of injury: crescent formation, glomerular capillary thrombi, or a membranoproliferative pattern of injury (“MPGN”). Treatment consists of aggressively targeting the cause, if known. Viral eradication with direct-acting antiviral agents is the cornerstone of treatment of HCV-associated cryoglobulinemic glomerulonephritis (see Chapter 18). Therapy with rituximab and possibly corticosteroids and plasmapheresis should be initiated in patients with severe vasculitis prior to the initiation of antiviral therapy.

Sohal A et al. Renal manifestations of chronic hepatitis C: a review. J Clin Med. 2024;13:5536. [PMID: 39337023]

5. Immune Complex Glomerulonephritis: Lupus Nephritis

Lupus nephritis occurs in 35–90% of patients who have SLE, with higher estimates encompassing subclinical disease. Rates of lupus nephritis are highest in non-White patients. The pathogenesis is complex and in part due to autoantibody response to exposed nuclear antigens, ultimately resulting in immune complex glomerulonephritis. See Chapter 23 for further discussion of SLE.

The term "lupus nephritis" encompasses many patterns of injury; however, most present within the nephritic spectrum (eg, class IV). Non-glomerular syndromes include tubulointerstitial nephritis and vasculitis. All patients with SLE should have routine UAs to monitor for hematuria or proteinuria. If urinary abnormalities are detected, kidney biopsy is often recommended. The International Society of Nephrology and Renal Pathology Society classification of renal glomerular lesions is class I, minimal mesangial nephritis; class II, mesangial proliferative nephritis; class III, focal (< 50% of glomeruli affected with capillary involvement) proliferative nephritis; class IV, diffuse (> 50% of glomeruli affected with capillary involvement) proliferative nephritis; class V, membranous nephropathy (discussed below); and class VI, advanced sclerosis without residual disease activity. Classes III and IV, the most severe forms of lupus nephritis, are further classified as active or chronic, and global or segmental, which confers additional prognostic value.

Treatment

Individuals with **class I** and **class II lesions** generally require antiproteinuric therapy with ACE inhibitors or ARBs. Hydroxychloroquine is recommended in all patients with lupus nephritis, regardless of histological class. Transformation into a more active lesion may occur and is usually accompanied by an increase in lupus serologic activity (eg, rising titers of anti–double-stranded DNA antibodies, and falling C3 and C4 levels) and increasing proteinuria or falling GFR. Repeat biopsy in such patients is recommended.

Patients with active **class III** and **IV lesions** should receive prompt, aggressive immunosuppression. Poor prognostic indicators include elevated serum creatinine, lower complement levels, male sex, presence of antiphospholipid antibodies, nephrotic-range proteinuria, sub-Saharan African descent (unclear association with *APOL1* risk alleles), and poor response to therapy. Immunosuppression for class V lupus nephritis is indicated if superimposed proliferative lesions exist, or if nephrotic syndrome is present. Class VI lesions represent irreversible patterns of injury and do not respond to treatment.

Treatment of class III or IV lupus nephritis consists of approximately 6 months of induction therapy, followed by maintenance therapy. For induction therapy, revised 2024 practice guidelines call for a combination of corticosteroids in combination with one of the following: (1) mycophenolate mofetil; (2) intravenous cyclophosphamide; (3) belimumab (anti-B cell therapy) with either mycophenolate or cyclophosphamide; or (4) mycophenolate mofetil with a calcineurin inhibitor. The decision on which approach to take is based on severity of clinical presentation and patient factor; three-drug regimens are considered for more severe presentation. Induction is followed by maintenance therapy with daily oral mycophenolate mofetil (preferred) or azathioprine for at least 3 years. With standard therapy, remission rates with induction vary from 80% for partial remission to 50–60% for full remission. Relapse is common and higher in those who do not experience complete remission. Progression to ESKD is more common in those who relapse more frequently or fail to achieve remission. Some patients may respond to newer steroid-sparing regimens of obinutuzumab in combination with mycophenolate mofetil. Pure class V disease can be treated similarly to classes III/IV, though calcineurin inhibitors appear especially effective.

The levels of various disease activity markers (double-stranded DNA antibodies, serum C3, C4 levels), proteinuria, and sediment activity can be useful in monitoring response to treatment, though repeat renal biopsy yields more reliable information regarding disease activity and may be used to guide maintenance therapy withdrawal. Patients with SLE who undergo dialysis have a favorable prospect for long-term survival; SLE symptoms often become quiescent with the development of ESKD. Patients with SLE undergoing kidney transplants can have recurrent renal disease, although relapse rates are relatively low.

6. Pauci-Immune Glomerulonephritis (ANCA-Associated)

Pauci-immune necrotizing glomerulonephritis is caused by the following ANCA-associated vasculitides (AAVs): granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (see Chapter 23). ANCA-associated glomerulonephritis can also present as a kidney-limited disease without systemic vasculitis. The pathogenesis of these entities appears to involve cytokine-primed neutrophils that present the cytoplasmic antigens proteinase-3 or myeloperoxidase on their surfaces. Circulating ANCAs bind to these antigens and activate a neutrophil respiratory burst with consequent vascular damage; primed neutrophils also appear to activate the alternative complement pathway. Immunofluorescence of kidney biopsy specimens demonstrates lack of or scant immunoglobulin/complement deposition, hence the term "pauci-immune." Renal involvement classically presents as RPGN, but more indolent presentations can be seen. Most cases of AAV are idiopathic, but others may be linked to an infection (including COVID-19), environmental exposure (eg, silica), or drug exposure (eg, levamisole).

Clinical Findings

A. Symptoms and Signs

Symptoms of a systemic inflammatory disease, including fever, malaise, and weight loss, may be present, sometimes for months prior to diagnosis. In addition to the glomerular inflammatory signs of hematuria and proteinuria, vasculitic involvement of dermal capillaries and nerve arterioles may result in purpura and mononeuritis multiplex, respectively. Ninety percent of patients with granulomatosis with polyangiitis have upper (especially sinus) or lower respiratory tract symptoms with nodular lesions that can cavitate and bleed. Hemoptysis is suggestive of alveolar hemorrhage and usually warrants hospitalization and aggressive immunosuppression.

B. Laboratory Findings

Serologically, ANCA subtype analysis is done to determine whether antiproteinase-3 antibodies (PR3-ANCA) or antimyeloperoxidase antibodies (MPO-ANCA) are present. Most patients with granulomatosis with polyangiitis are PR3 positive; the remainder are MPO positive or, more rarely, do not demonstrate circulating ANCA. Microscopic polyangiitis is generally associated with MPO-ANCA. Renal biopsy reveals necrotizing lesions and crescents on light microscopy; immunofluorescence is negative for immune complex deposition.

Treatment

Prompt initiation of treatment is essential. A 3–6-month induction therapy course with corticosteroids and cyclophosphamide or rituximab is followed by long-term rituximab (preferred) or azathioprine. The oral complement inhibitor avacopan can be considered in place of corticosteroids during induction. The role of plasma exchange in ANCA vasculitis is controversial; it may be considered in cases of diffuse alveolar hemorrhage with hypoxemia or severe kidney disease (creatinine > 3.4 mg/dL [> 300 mcmol/L]), and it is standard of care if anti-GBM antibodies are also present (see below).

Prognosis

Without treatment, prognosis is extremely poor. With aggressive treatment, complete remission can be achieved in the majority of patients. Prognosis depends on the extent of renal involvement before treatment is started. ANCA titers may be monitored to follow treatment efficacy, though they are only modestly predictive of future disease relapse and should be interpreted in the context of additional clinical data including the urine sediment.

7. Anti-Glomerular Basement Membrane Glomerulonephritis & Goodpasture Syndrome

Autoantibodies to epitopes of the GBM cause glomerulonephritis (anti-GBM disease); concomitant immune attack on alveolar basement membranes results in pulmonary hemorrhage as well (Goodpasture syndrome). Anti-GBM–associated glomerulonephritis accounts for 10–20% of patients with acute RPGN. The incidence has a bimodal distribution, peaking in the third decade of life during which time men are predominantly affected and lung involvement is more common, and again in the sixth and seventh decades with less sex specificity and pulmonary involvement. Goodpasture syndrome is associated with pulmonary infection, tobacco use, and exposure to hydrocarbon solvents or alemtuzumab; HLA-DR2 and -B7 antigens may predispose as well.

Clinical Findings

A. Symptoms and Signs

The onset of disease may be preceded by an upper respiratory tract infection; hemoptysis, dyspnea, and respiratory failure may ensue. Kidney laboratory findings are almost always consistent with RPGN, although cases may rarely present more mildly (eg, glomerular hematuria and proteinuria with minimal kidney dysfunction).

B. Diagnostic Findings

Imaging may demonstrate pulmonary infiltrates if pulmonary hemorrhage is present. Serum complement levels are normal. Circulating anti-GBM antibodies are present in over 90% of patients. A small percentage of patients have elevated ANCA titers. Kidney biopsy typically shows crescent formation with light microscopy, with linear IgG staining along the GBM on immunofluorescence.

Treatment

Patients with pulmonary hemorrhage and strong clinical suspicion of Goodpasture syndrome should be treated emergently—often prior to confirming the diagnosis with serology and kidney biopsy. Treatment is a combination of therapeutic plasma exchange daily for up to 2 weeks to remove circulating antibodies, and administration of corticosteroids and cyclophosphamide to prevent formation of new antibodies and control the inflammatory response. Rituximab has been used in a small number of patients with refractory disease. Patients with oliguric AKI or who require dialysis upon presentation have a poor prognosis.

Anti-GBM antibody titers should decrease as the clinical course improves.

8. C3 Glomerulopathies

C3 glomerulopathy is caused by several inherited or acquired abnormalities in the alternative complement pathway; this diagnosis encompasses two disease expressions/patterns of injury—C3 glomerulonephritis and dense deposit disease. Both frequently result in low circulating C3 levels. Renal biopsy of C3 glomerulonephritis shows varying degrees of mesangial hypercellularity, endocapillary proliferation and capillary wall remodeling resulting in double contours of the GBM (“tram track” appearance) that are characterized as a membranoproliferative pattern of injury (MPGN). While other glomerulonephritides can also display an MPGN pattern of injury on light microscopy, the defining histopathologic characteristic in C3 glomerulonephritis is a lack or paucity of immunoglobulin staining on immunofluorescence. The rare variant of dense deposit disease is characterized by thick ribbon-like deposits on electron microscopy. Evaluation for viral infection, cancer screening, and genetic testing are standard diagnostic tests for C3 glomerulopathy.

Treatment of C3 glomerulopathies is evolving as novel therapies targeting the dysregulated alternative complement cascade are explored. Small, uncontrolled series suggest a benefit of eculizumab in some patients; others may respond to mycophenolate mofetil. Risk of ESKD is relatively high. Less favorable prognostic findings include dense deposit disease, early decline in GFR, hypertension, and persistent disease. C3 glomerulopathy recurs with high frequency after kidney transplantation.

9. Monoclonal Immunoglobulin Glomerulonephritis

Monoclonal gammopathies which do not otherwise meet criteria for hematologic therapy may nonetheless result in glomerular injury, termed MIg glomerulonephritis or monoclonal gammopathy of renal significance (MGRS). Clinical presentation is varied, ranging from asymptomatic glomerular hematuria and proteinuria to RPGN. Laboratory studies typically reveal some combination of abnormal serum free light chain ratios, signifying accumulation of either kappa or lambda light chains; abnormal serum or urine protein electrophoresis, which determines the concentration of an abnormal monoclonal protein; or abnormal serum or urine immunofixation, which determines the type of monoclonal protein present (eg, IgG kappa). If MIg glomerulonephritis is suspected and the patient is not already on therapy for systemic disease (eg, myeloma), a kidney biopsy is warranted to define the disease process and guide treatment. Although light microscopic findings are variable, all MIg glomerulonephritis have the monotypic presence of immunoglobulins on immunofluorescence.

Treatment of MIg glomerulonephritis is aimed at identifying and targeting the underlying clone of monoclonal immunoglobulin. If the clone derives from plasma cells, then a bortezomib-based regimen is recommended (see section on Plasma Cell Myeloma). B-cell clones are responsive to rituximab. Daratumumab, a monoclonal anti-CD38 antibody, has proven effective in certain subtypes of MIg glomerulonephritis. Prognosis in MIg glomerulonephritis is dependent upon the eradication of the clone and is favorable if remission is achieved.

NEPHROTIC SPECTRUM GLOMERULAR DISEASES

ESSENTIALS OF DIAGNOSIS

- Persistent proteinuria with bland urine sediment (few if any cells).
- Nephrotic *syndrome* (if present):
- Hypoalbuminemia.
- Peripheral edema.
- Hyperlipidemia.
- Oval fat bodies may be seen in the urine.

General Considerations

In developed countries, the most common cause of nephrotic disease is diabetes mellitus. Other causes include minimal change disease, FSGS, membranous nephropathy, and amyloidosis. Clinical presentations along the nephrotic spectrum vary based on etiology, with diabetic nephropathy and secondary FSGS typically on the less severe end (bland UA and proteinuria); minimal change disease, membranous nephropathy and amyloidosis tend to present with the full nephrotic *syndrome*. Serum creatinine may be abnormal at the time of presentation, depending on the severity and chronicity of the disease.

Clinical Findings

A. Symptoms and Signs

Patients with isolated proteinuria do not manifest symptoms of kidney disease. In those with the nephrotic *syndrome*, peripheral edema is present—likely due to sodium retention and hypoalbuminemia-induced low plasma oncotic pressure. Edema may develop solely in dependent regions, such as the lower extremities, or it may become generalized and include periorbital edema. Dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise due to ascites can occur.

B. Laboratory Findings

1. UA—Proteinuria occurs due to podocyte injury and variable damage to the glomerular filtration barrier. The urine dipstick is a good screening test for albuminuria; if positive, urinary protein excretion should be quantified (see earlier Proteinuria section, Table 25–2). A spot urine protein to urine creatinine ratio gives a reasonable approximation of grams of protein excreted per day; a 24-hour urine sample for protein excretion is more precise but not routinely needed.

The urinary sediment has few cellular elements. However, if marked hyperlipidemia is present, urinary oval fat bodies may be seen. They appear as "grape clusters" under light microscopy and "Maltese crosses" under polarized light.

2. Blood chemistries—Nephrotic *syndrome* results in hypoalbuminemia. Hyperlipidemia occurs in over 50% of patients with nephrotic syndrome, due to falling oncotic pressure that triggers increased hepatic lipid production and to decreased clearance of VLDLs with resultant hypertriglyceridemia. An elevated ESR may be seen as a result of increased levels of fibrinogen. Heavy urinary excretion of binding proteins may result in deficiencies of vitamin D, zinc, and copper.

Laboratory testing to help elucidate the underlying cause of the glomerular disease includes complement levels, serum/urine protein electrophoresis and immunofixation, serum free light chains, ANA, PLA_2R antibody titers, HbA_{1c}, and serologic testing for hepatitis B and C, HIV, and syphilis (Table 25–9).

3. Kidney biopsy—Kidney biopsy is often performed in adults with new-onset nephrotic syndrome if a primary renal disease that may require immunosuppressive therapy is suspected. Chronically and significantly decreased GFR suggests irreversible kidney disease which may decrease the utility of kidney biopsy. In the setting of long-standing (> 12 years) diabetes mellitus type 1 or 2, proteinuric kidney disease is not commonly biopsied unless atypical features (eg, significant glomerular hematuria or cellular casts) are also present, or if there is reason to suspect an additional or alternative kidney lesion.

Treatment

A. Proteinuria

In those with isolated proteinuria, dietary protein restriction may be helpful in slowing progression of kidney disease (see CKD section). Anti-proteinuric medications, including ACE inhibitors, ARBs, mineralocorticoid receptor antagonists, and SGLT-2 inhibitors, can help slow progression. They can be used in patients with reduced GFR as long as significant hyperkalemia (potassium > 5.5 mEq/L) does not occur and serum creatinine rises < 30% after drug initiation or dose titration; patients should be counseled on preventive practices to reduce risk of AKI and hyperkalemia. Combination therapy of an ARB and an ACE inhibitor is not recommended. MRA is not recommended when eGFR is < 30 mL/min.

B. Edema

Dietary sodium restriction is essential for managing edema; most patients also require diuretic therapy. Refractory fluid retention can occur due to hypoalbuminemia or decreased delivery of diuretics to the kidney tubule. Higher doses or combination diuretic therapy (multiple classes) may be required.

C. Hyperlipidemia

Hypercholesterolemia and hypertriglyceridemia can occur as noted above. Dietary modification and exercise should be encouraged, but pharmacologic treatment is usually required (see Chapter 33).

D. Hypercoagulable State

Patients with nephrotic *syndrome* have urinary losses of antithrombin, protein C and protein S, and increased platelet activation. Patients with serum albumin < 2.5 g/dL (25 g/L) are at higher risk for thrombosis and may develop DVT, renal vein thrombosis, or PE, particularly in cases of membranous nephropathy. Anticoagulation therapy is warranted for at least 3–6 months in patients with evidence of thrombosis in any location and may be required indefinitely for renal vein thrombosis, PE, recurrent thromboemboli, or when ongoing nephrotic syndrome poses a risk of thrombosis recurrence.

When to Refer

Any patient with the nephrotic *syndrome* should be referred immediately to a nephrologist for volume and blood pressure management, assessment for kidney biopsy, and treatment of the underlying disease. Nephrotic range proteinuria without the nephrotic syndrome also merits nephrology referral, though with less urgency.

When to Admit

Patients with edema refractory to outpatient therapy or rapidly worsening kidney function that requires inpatient interventions should be admitted.

NEPHROTIC SPECTRUM DISEASE IN PRIMARY KIDNEY DISORDERS

MINIMAL CHANGE DISEASE

ESSENTIALS OF DIAGNOSIS

- Usually presents with nephrotic syndrome.
- Kidney biopsy shows no changes on light microscopy.
- Diffuse foot-process effacement on electron microscopy.

General Considerations

Minimal change disease is the most common cause of proteinuric kidney disease in children, accounting for approximately 80% of cases. It often remits upon treatment with corticosteroids. Children with nephrotic syndrome are often treated for minimal change disease empirically without a biopsy diagnosis. Minimal change disease is less common in adults, accounting for 20–25% of cases of primary nephrotic syndrome in those over age 40 years. This entity can be idiopathic but also occurs following viral upper respiratory infections (especially in children), in association with neoplasms such as Hodgkin disease, with drugs (lithium), and with hypersensitivity reactions (especially to NSAIDs and bee stings).

Clinical Findings

A. Symptoms and Signs

Patients usually present with nephrotic syndrome, which confers susceptibility to infection, thrombotic events, hyperlipidemia, and protein malnutrition. Minimal change disease can also present with AKI due to renal tubular damage and interstitial edema.

B. Laboratory and Histologic Findings

There is no helpful serologic testing. When kidney biopsy is performed, glomeruli appear normal on light microscopy and immunofluorescence. On electron microscopy, there is a characteristic diffuse effacement of podocyte foot processes. Mesangial cell proliferation may be seen in a subgroup of patients; this finding is associated with more hematuria and hypertension and poor response to standard corticosteroid treatment.

Treatment

First-line treatment is with prednisone, 1 mg/kg/day; remission in steroid-responsive minimal change disease often occurs within 4–8 weeks, though treatment up to 16 weeks is sometimes needed. Treatment should be continued for at least 2 weeks after complete remission, and dosing tapers should be individualized. Roughly half of patients with minimal change disease relapse and require repeated corticosteroid treatment. Patients with frequent relapses or corticosteroid resistance may require cyclophosphamide, a calcineurin inhibitor (tacrolimus, cyclosporine), or rituximab to induce subsequent remissions. Progression to ESKD is rare. Complications most often arise from prolonged corticosteroid use.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS (FSGS)

General Considerations

FSGS is a relatively common pattern of injury resulting from damage to podocytes. It can be a primary/kidney-limited disorder or may be secondary to another underlying disease. Etiologies of primary FSGS fall into three categories: (1) heritable abnormalities in any one of several podocyte proteins or underlying type 4 collagen mutations; (2) polymorphisms in the *APOL1* gene in those of sub-Saharan African ancestry; or (3) increased levels of a circulating permeability factor that has yet to be identified. Secondary causes include kidney overwork injury (eg, history of nephrectomy), obesity, hypertension, chronic urinary reflux, HIV or SARS-CoV-2 infection, or analgesic or bisphosphonate exposure. Genetic testing in primary cases is increasingly available, especially in the pediatric population.

Clinical Findings

Decreased GFR is present in 25–50% of those with FSGS at time of diagnosis. Nephrotic syndrome is commonly seen in those with FSGS caused by a genetic disorder or putative circulating permeability factor; nephrotic syndrome is uncommon in secondary and *APOL1*-associated FSGS.

Diagnosis requires kidney biopsy, and genetic testing may be helpful. Light microscopy shows sclerosis of segments of some, but not all, glomeruli. On immunofluorescence, IgM and C3 are seen in the sclerotic lesions, although it is presumed that these immune components are simply trapped in the sclerotic glomeruli and not pathogenetic. As in minimal change disease, electron microscopy shows foot process effacement.

Treatment

Treatment for all forms of FSGS includes ACE inhibitors, ARBs, or MRAs to control proteinuria and hypertension, and statins for hyperlipidemia; SGLT-2 inhibitors may be considered for those not receiving immunosuppression. Immunosuppression (oral prednisone, 1 mg/kg/day for 4–16 weeks followed by a slow taper) is recommended if nephrotic syndrome is present, as this suggests primary FSGS. In those with steroid-resistance or intolerance, calcineurin inhibitors, rituximab, and mycophenolate mofetil can be considered. Kidney transplantation in this subgroup of FSGS patients is complicated by a relatively high relapse rate and risk of graft loss. Those with *APOL1*-associated and hereditary primary FSGS do not appear to benefit from immunosuppression. Patients with secondary FSGS do not benefit from immunosuppressive therapy; treatment should be directed at the underlying cause.

MEMBRANOUS NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- Varying degrees of proteinuria.
- Most common cause of primary adult nephrotic syndrome.
- Significant risk for hypercoagulable state if nephrotic syndrome present.
- “Spike and dome” pattern on kidney biopsy from subepithelial deposits.
- Secondary causes include hepatitis B virus and cancer.

General Considerations

Membranous nephropathy is the most common cause of nephrotic syndrome in adults, most often presenting in the fifth and sixth decades. Primary membranous nephropathy is an autoimmune disease with reactivity against several possible podocyte antigens. Secondary disease is associated with infections, (such as hepatitis B and C, endocarditis, and syphilis); underlying cancer; SLE (class V); and certain drugs (such as NSAIDs, captopril, and possibly traditional indigenous medicines). The course of primary disease is highly variable, with spontaneous remission in approximately 30% of patients and progression to ESKD over 3–10 years in 50%. Poorer outcome is associated with concomitant tubulointerstitial fibrosis, male sex, elevated serum creatinine on presentation, hypertension, and proteinuria > 10 g/day.

Compared to other causes of nephrotic syndrome, patients with membranous nephropathy have a higher risk of hypercoagulability, including a predisposition to renal vein thrombosis.

Clinical Findings

A. Symptoms and Signs

Patients may be asymptomatic or may have edema or frothy urine. Symptomatic venous thrombosis may be an initial sign. There may be symptoms or signs of an underlying infection or neoplasm (especially lung, stomach, breast, and colon cancers) in secondary membranous nephropathy.

B. Laboratory Findings

Hypoalbuminemia and hyperlipidemia are characteristic laboratory findings in the nephrotic syndrome. Evaluation for secondary causes including serologic testing for SLE, syphilis, and viral hepatitides, and age- and risk-appropriate cancer screening should be performed. The presence of circulating PLA_2R antibodies is considered diagnostic for primary membranous nephropathy and eliminates the need for kidney biopsy. Kidney biopsy findings in membranous nephropathy include increased capillary wall thickness without inflammatory changes or cellular proliferation; when stained with silver methenamine, a “spike and dome” pattern results from projections of excess GBM between the subepithelial immune complex deposits. Immunofluorescence shows IgG, C3, and possibly PLA_2R Ab staining along capillary loops. Electron microscopy reveals deposits along the subepithelial surface of the basement membrane.

Treatment

Secondary causes must be considered prior to consideration of treatment. Primary disease treatment depends on the risk of disease progression. Roughly 30% of patients present with subnephrotic proteinuria (< 3.5 g/day), which portends a favorable prognosis with conservative management, including antiproteinuric therapy with ACE inhibitor or ARB. Spontaneous remission may develop even in those with heavy proteinuria (about 30% of cases). Thus, immunosuppression should be reserved for those at highest risk for progression, including nephrotic syndrome, and with salvageable kidney function and serum creatinine < 3 g/dL. Rituximab or corticosteroids and cyclophosphamide are given for 6 months. Calcineurin inhibitors with or without corticosteroids may be considered as well, though risk of relapse is higher with this drug regimen. Reduction in proteinuria may take up to 6 months, especially with rituximab-based regimens. Patients with primary membranous nephropathy who progress to ESKD are excellent candidates for transplant.

NEPHROTIC SPECTRUM DISEASE FROM SYSTEMIC DISORDERS

DIABETIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- Evidence of diabetes mellitus, typically over 10 years.
- Albuminuria usually precedes decline in GFR.
- Other end organ damage, such as retinopathy, is common.

General Considerations

Diabetic kidney disease is the most common cause of ESKD in the United States. The incidence of CKD is approximately 30% in both type 1 and type 2 diabetes mellitus. ESKD is much more likely to develop in persons with type 1 diabetes mellitus, in part due to fewer comorbidities and deaths before ESKD ensues. With the current epidemic of obesity and type 2 diabetes mellitus, rates of diabetic nephropathy continue to increase. Those with a family history of kidney disease are at higher risk. Mortality rates are higher for patients with diabetes who have comorbid kidney disease compared to those without CKD.

Clinical Findings

Kidney disease develops about 10 years after the onset of diabetes mellitus but may be present at the time type 2 diabetes mellitus is diagnosed. The first stage is hyperfiltration with an increase in GFR, followed by the development of moderate albuminuria (30–300 mg/day). Over time, albuminuria becomes severe (> 300 mg/day) and can be detected on urine dipstick as overt proteinuria. GFR subsequently declines over time. Yearly screening for moderate albuminuria is recommended for all patients with diabetes to detect disease at its earliest stage, though diabetic kidney disease less commonly can present as nonproteinuric CKD.

The most common lesion in diabetic kidney disease is diffuse glomerulosclerosis, but nodular glomerulosclerosis (Kimmelstiel-Wilson nodules) is pathognomonic. The kidneys are usually enlarged until disease becomes advanced. Kidney biopsy is not required in most patients unless atypical findings are present, such as sudden onset of proteinuria, nephritic features (see above), massive proteinuria (> 10 g/day), urinary cellular casts, or rapid decline in GFR.

Patients with diabetes are prone to other kidney diseases. These include papillary necrosis, chronic interstitial nephritis, and type 4 (hyporeninemic hypoaldosteronemic) renal tubular acidosis. Patients are more susceptible to AKI from many insults, including intravenous contrast material and concomitant use of an ACE inhibitor or ARB with NSAID.

Treatment

At the onset of moderate albuminuria, treatment is necessary. Strict glycemic control should be emphasized early in diabetic nephropathy, with recognition of risk of hypoglycemia as CKD becomes advanced (see CKD section). Recommended blood pressure goals should be tailored to the individual patient. In the BPROAD trial, targeting blood pressure below 120/80 mm Hg conferred a composite benefit of reduced risk of death from cardiovascular cause or nonfatal stroke, MI, or hospitalization for HF in patients with diabetes with increased risk of CVD. The 2021 Kidney Disease Improving Global Outcomes (KDIGO) practice guideline on blood pressure management recommends targeting blood pressure below 120/80 mm Hg in patients with diabetes who have CKD, regardless of degree of albuminuria. ACE inhibitors and ARBs in those with moderate albuminuria decrease rate of progression to overt proteinuria and slow progression to ESKD by reducing intraglomerular pressure and via antifibrotic effects; these agents are not absolutely indicated in patients without albuminuria who have diabetes. Patients with diabetes, especially with advanced CKD, are at relatively high risk for AKI and hyperkalemia with inhibition of the renin-angiotensin system, so monitoring for hyperkalemia or a decline in GFR > 30% within ~2 weeks of the initiation or uptitration of this therapy is prudent, with dose reduction or discontinuation of therapy if these complications are encountered. Combination ARB and ACE inhibitor therapy is not recommended due to lack of efficacy and increased adverse events of hyperkalemia and AKI. In addition to their cardioprotective effects, SGLT-2 inhibitors, including canagliflozin, empagliflozin, and dapagliflozin, slow progression of diabetic nephropathy in patients with type 2 diabetes mellitus. Although their use is FDA-authorized only when eGFR is > 30 mL/min/1.73 m^2, dapagliflozin and empagliflozin have been shown to be safe and effective at eGFRs of 25 and 20 mL/min/1.73 m^2, respectively. Mineralocorticoid receptor antagonism can be considered for blood pressure and proteinuria management in type 2 DM with careful monitoring for hyperkalemia; non-steroidal MRAs are less likely to cause hyperkalemia. GLP1 agonists, such as dulaglutide or semaglutide, are effective treatment options as additional therapy, or for those with more advanced CKD or who are intolerant of SGLT-2 inhibitors. Metformin may have kidney-specific benefits but should be discontinued when eGFR is < 30 mL/min/1.73 m^2. Treatment of obesity and other cardiovascular risk factors is vital. Many with diabetes have multiple comorbid conditions, and mortality is high among those who progress to ESKD. Patients who are relatively healthy, however, benefit from kidney transplantation.

HIV-ASSOCIATED NEPHROPATHY

HIV-associated nephropathy usually presents with nephrotic syndrome and declining GFR in patients with active HIV infection. Most who present with HIV-associated nephropathy are of sub-Saharan African descent with *APOL1* risk alleles (see section on Focal Segmental Glomerulosclerosis). HIV-associated nephropathy is usually associated with low CD4 counts and AIDS, but it can also be the initial presentation of HIV disease. Persons living with HIV are at risk for other kidney diseases, such as toxicity from antiretroviral medications (eg, tenofovir disoproxil fumarate), vascular disease, and diabetes, or immune complex–mediated glomerular disease (HIV-immune complex disease).

Classic HIV-associated nephropathy is characterized by an FSGS pattern of injury with glomerular collapse; severe tubulointerstitial damage may also be present.

HIV-associated nephropathy is less common in the era of HIV screening and more effective antiretroviral therapy. Small, uncontrolled studies have shown that antiretroviral therapy slows progression of disease. ACE inhibitors or ARBs can be used to control blood pressure and proteinuria. Kidney biopsy is necessary for diagnosis and to rule out other causes of kidney dysfunction. Patients who progress to ESKD and are otherwise healthy are good candidates for kidney transplantation.

RENAL AMYLOIDOSIS

Amyloidosis is a relatively rare cause of nephrotic syndrome. It is caused by tissue deposition of an overproduced and misfolded protein (amyloid). Different proteins can form amyloid fibrils with renal deposition. Primary amyloidosis, or AL amyloidosis, is the most common form and is due to a plasma cell dyscrasia causing overproduction and deposition of monoclonal Ig light chains (see Chapter 15). Secondary amyloidosis, or AA amyloidosis, rarely occurs in chronic inflammatory disease such as rheumatoid arthritis, IBD, or chronic infection due to deposition of an acute phase reactant, serum amyloid A protein.

Renal involvement in amyloidosis is characterized by proteinuria, decreased GFR, and nephrotic syndrome. Evidence of other organ involvement, such as the heart, is common. Serum and 24-hour urine protein electrophoresis and immunofixation, and serum free light chains (kappa and lambda) should be quantified. Amyloid-affected kidneys are often larger than 10 cm. Pathologically, glomeruli display nodular sclerosis and are filled with amorphous deposits that show green birefringence with Congo red staining; EM reveals fibril deposition.

AL amyloidosis with renal involvement progresses to ESKD in an average of 2–3 years. Five-year overall survival is < 20%, with worse prognosis in those with advanced cardiac involvement. Standard treatment is a combination of melphalan, corticosteroids, and the proteosome inhibitor bortezomib; addition of daratumumab may improve remission rates. Melphalan and autologous stem cell transplantation are associated with a high (45%) mortality rate but can induce remission in 80% of survivors; however, few patients are eligible for this treatment. In AA amyloidosis, remission can occur if the underlying disease is successfully treated. Renal transplantation is an option.

TUBULOINTERSTITIAL DISEASES

Tubulointerstitial disease may be acute or chronic. Acute disease is most commonly associated with medications, infectious agents, and systemic rheumatologic disorders. Interstitial edema, infiltration with polymorphonuclear neutrophils, and accompanying ATN can be seen. (See Acute Kidney Injury, above, and Table 25–4.) Chronic disease may result from clinically apparent acute disease that was not fully reversible or, more commonly, may develop insidiously over time without a known inciting factor. Interstitial fibrosis and tubular atrophy are present, with a mononuclear cell predominance. The chronic disorders are described below.

CHRONIC TUBULOINTERSTITIAL DISEASES

ESSENTIALS OF DIAGNOSIS

- Kidney size is small.
- Decreased urinary concentrating ability.
- CKD.

General Considerations

There are many causes of chronic tubulointerstitial disease (also called chronic interstitial nephritis [CIN]). Most are the sequelae of chronic obstruction or toxic exposures; however, hereditary forms are increasingly recognized.

Obstructive uropathy is a common cause of CIN. It is the result prolonged or recurrent obstruction, most commonly from prostate disease; bilateral ureteral calculi, or calculus in a single functioning kidney; carcinoma of the cervix, colon, or bladder; and retroperitoneal tumors or fibrosis.

Vesicoureteral reflux, generally a childhood disorder, occurs when an incompetent vesicoureteral sphincter allows urine from the bladder to reflux to the kidney during voiding. Urine can extravasate into the interstitium, triggering an inflammatory response that leads to fibrosis over time.

Analgesic nephropathy can occur in patients who ingest large quantities of anti-inflammatory pain medications such as paracetamol, aspirin, and other NSAIDs; acetaminophen is a possible but less certain culprit. Ingestion of these analgesics of at least 1 g/day for several years is considered necessary for kidney dysfunction to develop; however, many patients underestimate their analgesic use. Female sex, older age, and malnutrition are risk factors for analgesic nephropathy. Aspirin and other NSAIDs can cause damage through intermediate metabolites, which can lead to cell necrosis. These drugs also decrease medullary blood flow (via inhibition of prostaglandin synthesis) and decrease glutathione levels, which are necessary for detoxification. Renal papillary tip and inner medullary concentrations of some analgesics are 10-fold higher than in the renal cortex; all of which may result in papillary necrosis in addition to chronic interstitial inflammation and scarring.

Long-term **lithium** use, usually > 10 years, can result in CIN with slowly progressive CKD and renal parenchymal microcysts.

Environmental exposure to **heavy metals**—such as lead, cadmium, mercury, and bismuth—can cause CIN. Individuals at risk for lead-induced tubulointerstitial disease are those with occupational exposure (eg, those who weld, or work with lead-based paint or leaded-gasoline) or who drink alcohol distilled in automobile radiators ("moonshine" whiskey).

CIN in agricultural communities is a form of chronic tubulointerstitial disease seen in workers in tropical and subtropical agricultural communities that can lead to ESKD.

Clinical Findings

A. General Findings

Polyuria may occur if tubular damage leads to nephrogenic diabetes insipidus, possibly from vasopressin insensitivity. This is especially common in those with lithium exposure. Volume depletion can rarely occur due to salt-wasting defects in some individuals.

Renal tubular acidosis is common and can develop through three mechanisms: (1) reduced ammoniagenesis in the proximal tubules, (2) inability to reabsorb bicarbonate in the proximal tubules, and (3) inability to secrete protons in the distal tubules, which is needed for urinary acidification. Type 1 (hypokalemic) or type 4 (hyperkalemic) renal tubular acidoses may be seen in tubulointerstitial disease; heavy metal exposures tend to damage the proximal tubule and may result in proximal (type 2) renal tubular acidosis. In contrast to *acute* interstitial nephritis, the UA in CIN disease is often bland, either with no findings or a few cells or broad waxy casts. Proteinuria may be present, owing to inability of the proximal tubule to reabsorb freely filtered proteins, but is typically < 2 g/day.

B. Specific Findings

1. Obstructive uropathy—In partial obstruction, patients can exhibit polyuria (from tubular damage) or oliguria (due to decreased GFR). Renin-mediated hypertension may be present. Abdominal, rectal, and genitourinary examinations may be helpful in detecting a distended bladder or large prostate. UA is often bland, but may show hematuria, pyuria, or bacteriuria. Bedside ultrasound for elevated post-void residual bladder volume can be helpful in cases of bladder outlet obstruction. Abdominal ultrasound usually detects hydroureter, and hydronephrosis but may miss obstruction due to retroperitoneal fibrosis. CT scanning or MRI can be considered if suspicion remains despite a normal ultrasound.

2. Vesicoureteral reflux—Vesicoureteral reflux is typically diagnosed in young children with a history of recurrent UTIs but can also develop after kidney transplantation. Renal ultrasound can show renal scarring and hydronephrosis. Most damage occurs before age 5, and progressive deterioration to ESKD is common.

3. Analgesics—Patients can exhibit hematuria, mild proteinuria, polyuria (from tubular damage), anemia (from GI bleeding or erythropoietin deficiency), and sterile pyuria. Sloughed papillae can be found in the urine when papillary necrosis occurs and can lead to obstruction. Although classically diagnosed by IVP, papillary necrosis is more commonly detected by CT imaging or cystoureteroscopy.

4. Heavy metals—Proximal tubular damage from lead exposure can cause decreased secretion of uric acid, resulting in hyperuricemia and saturnine gout. Hypertension is common. Diagnosis of lead nephropathy is established with a calcium disodium edetate (EDTA) chelation test—24-hour urine excretion of > 600 mg of lead following 1 g of EDTA indicates excessive lead exposure. The proximal tubular dysfunction from cadmium can cause hypercalciuria and nephrolithiasis.

5. Chronic interstitial nephritis in agricultural communities— In addition to low-grade proteinuria, hyperuricemia and hypokalemia are often identified among affected individuals. Although not pathognomonic, areas of glomerular ischemia (despite mild vascular disease) that accompany chronic tubulointerstitial injury on kidney biopsy are highly suggestive of CINAC.

Treatment

Treatment depends first on identifying the disorder responsible for kidney dysfunction. Interstitial fibrosis on biopsy reflects irreversible damage, the degree of which is directly associated with the likelihood of progression to ESKD. Treatment of hypertension may slow progression. Tubular dysfunction may require bicarbonate supplementation to treat metabolic acidosis or potassium restriction to mitigate hyperkalemia.

If hydronephrosis is present, the obstruction should be promptly relieved. Prolonged obstruction leads to further tubular damage—particularly in the distal nephron—which may become irreversible. Although surgical correction of reflux may be indicated in select instances, this will unlikely prevent deterioration toward ESKD if fibrosis is extensive.

Patients in whom lead nephropathy is suspected should continue chelation therapy with EDTA if there is minimal evidence of irreversible renal damage; continued exposure to lead should be avoided.

Treatment of analgesic nephropathy requires cessation of all analgesics. Stabilization of or improvement in kidney function may occur if significant interstitial fibrosis is not present. Ensuring volume repletion during exposure to analgesics may also have some beneficial effects.

Patients with chronic interstitial nephritis in agricultural communities should be counseled to remain adequately hydrated and, if possible, minimize heat exposure. NSAIDs should be avoided due to their hemodynamic effects (reduced renal blood flow and glomerular filtration), which may exacerbate renal injury in states of volume depletion and hot climates.

When to Refer

- Patients with stage 3–5 CKD should be referred to a nephrologist. Earlier referral may be appropriate if management of tubular dysfunction, such as renal tubular acidosis, is necessary.
- Patients with urologic abnormalities should be referred to a urologist.

SIMPLE OR SOLITARY CYSTS

Renal cysts are tubular epithelium-lined cavities filled with fluid or semisolid material. Cysts are described as “simple” if they are anechoic by ultrasound, uncalcified and have smooth walls. Simple cysts account for 65–70% of all renal masses and may be noted incidentally on abdominal imaging in 50% of persons over 50 years of age. They are generally found at the outer cortex and contain fluid that is consistent with an ultrafiltrate of plasma. They are typically asymptomatic but rarely can become infected or cause hematuria. Ultrasound or CT scanning is recommended for evaluation. Simple cysts must display three sonographic features to be considered benign: (1) echo-free, (2) sharply demarcated with smooth walls, and (3) an enhanced back wall (indicating good transmission through the cyst). On contrasted CT scan, simple cysts should not enhance. Simple benign cysts do not require any specific follow-up, though changes in clinical presentation should prompt repeat imaging. Renal parenchymal scarring and remodeling can lead to simple cyst formation (known as “acquired” cysts) in CKD and ESKD; these cysts carry a small risk of malignant transformation to renal cell carcinoma.

Simple cysts must be differentiated from malignancy, abscess, or heritable cystic diseases. Complex cysts can have thick walls, calcifications, solid components, and mixed echogenicity. Renal cell carcinoma usually demonstrates vascular enhancement, although a small number are avascular. If a cyst has questionable imaging characteristics or is of uncertain significance, periodic reevaluation is recommended, and urologic consultation should be considered. Heritable cystic diseases are associated with many cysts in both kidneys and, depending on type, can progress to ESKD (Table 25–10).

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- Multiple cysts in both kidneys; number of cysts depends on patient age.
- Hypertension and (over time) large palpable kidneys.
- Autosomal dominant pattern of inheritance, although sporadic cases may occur.

General Considerations

Autosomal dominant polycystic kidney disease (ADPKD) is the most common monogenic kidney disease. It has a

Table 25–10. Clinical features of renal cystic disease.

	Simple Renal Cysts	Acquired Renal Cysts	Autosomal Dominant Polycystic Kidney Disease	Medullary Sponge Kidney	Medullary Cystic Kidney
Prevalence	Common	Dialysis patients	1:1000	1:5000	Rare
Inheritance	None	None	Autosomal dominant	None	Autosomal dominant
Age at onset	…	…	20–40 years	40–60 years	Adulthood
Kidney size	Normal	Small	Large	Normal	Small
Cyst location	Cortex and medulla	Cortex and medulla	Cortex and medulla	Collecting ducts	Corticomedullary junction
Hematuria	Occasional	Occasional	Common	Rare	Rare
Hypertension	None	Variable	Common	None	None
Associated complications	None	Adenocarcinoma in cysts	Hepatic cysts, UTIs, renal calculi, cerebral aneurysms	Renal calculi, UTIs	Polyuria, salt-wasting
Kidney failure	Never	Always	Frequently	Never	Always

prevalence of 1:1000 and accounts for 5–10% of all ESKD cases globally. ADPKD is primarily caused by mutations in genes encoding polycystins (*PKD1* for polycystin 1, or *PKD2* for polycystin 2). Affected individuals with the more common *PKD1* mutations tend to develop ESKD by age 50, although disease penetration is variable. Those with the less common *PKD2* mutations (15–20% of patients) have slower progression of disease, with median age at ESKD of 75 years. Sporadic cases without identifiable polycystin gene mutations may occur.

Clinical Findings

Hematuria (either microscopic or gross) is present in most patients. A family history of ADPKD is present in 75% of cases. Cyst development and growth over time eventually results in large kidneys that may be palpable on abdominal examination; massively enlarged kidneys can cause early satiety, shortness of breath, or pain. Spontaneous cyst rupture can cause severe intermittent flank pain; gross hematuria episodes may result from bleeding into cysts. Cysts may become infected, causing pain and fever. Roughly half of patients have concurrent hepatic cysts; pancreatic and splenic cysts may occur. UA often shows hematuria and subnephrotic proteinuria. In patients with an established family history of ADPKD, ultrasonography confirms the diagnosis—two or more cysts in patients under age 30 years, two or more cysts in each kidney in patients aged 30–59 years, and four or more cysts in each kidney in patients aged 60 years or older are diagnostic for ADPKD. Importantly, these criteria do *not* apply to individuals without a known family history; these individuals should be evaluated with CT, which is more sensitive. If found, the presence of multiple hepatic cysts helps support the diagnosis. In some cases, genetic testing for *PKD1* and *PKD2* mutations may be required.

Complications & Treatment

A. Pain

Abdominal or flank pain may be caused by cyst infection, rupture or hemorrhage, or nephrolithiasis. Cyst decompression can help with chronic pain.

B. Hematuria

Gross hematuria is most commonly due to cystic rupture into the renal pelvis, but it can also be caused by a kidney stone or UTI. If due to cyst rupture, hematuria typically resolves within 7 days with bed rest and hydration.

C. Renal Infection

An infected renal cyst should be suspected in patients who have flank pain, fever, and leukocytosis. UA may be normal if the cyst does not communicate directly with the urinary tract. CT evaluation demonstrating increased wall thickness is suggestive of infection, but PET CT provides the greater sensitivity. Adequate antibiotic treatment is limited by poor cyst penetration, but fluoroquinolones (ciprofloxacin or levofloxacin) or trimethoprim-sulfamethoxazole are the agents of choice.

D. Nephrolithiasis

Up to 20% of patients have kidney stones, primarily calcium oxalate. Hydration (2–3 L/day) is recommended in order to prevent precipitation of stones.

E. Hypertension

At time of presentation, 50% of patients have hypertension and most others will develop it during the course of the disease. Cyst-induced ischemia appears to cause activation of the renin-angiotensin system; thus, ACE inhibitors or ARBs are first-line therapy. Intensive blood pressure control (goal ≤ 110/75 mm Hg) is recommended in adults younger than 50 years of age with eGFR > 60 mL/min/1.73 m^2; for all other affected individuals, goal blood pressure is ≤ 130/85 mm Hg.

F. Cerebral Aneurysms

About 10–15% of patients have arterial aneurysms in the circle of Willis. Screening arteriography is controversial with some experts recommending screening for all (CT or MR angiography) and some reserving screening for those with a family history of aneurysms, those employed in a high-risk profession (eg, airline pilot), or those undergoing elective surgery with a high risk of developing moderate to severe perioperative hypertension.

G. Other Complications

Individuals with ADPKD are more likely to have mitral valve prolapse (up to 25%), aortic aneurysms, aortic valve abnormalities, and colonic diverticulae. Rates of renal cell carcinoma are 2-fold higher.

Prognosis

Kidney size, reported as total kidney volume, is the best predictor of kidney function decline in patients with autosomal dominant polycystic kidney disease, and can be measured via CT or MRI using the Mayo Classification system (www.mayo.edu/research/documents/pkd-center-adkpkd-classification/doc-20094754). Those at high risk according to this classification system may benefit from treatments that delay cyst growth. Vasopressin receptor antagonists decrease the rate of change in total kidney volume and eGFR decline, and one such medication (tolvaptan) is FDA-approved for the treatment of autosomal dominant polycystic kidney disease. Liberal ingestion of water will have the same physiologic effect on vasopressin, and patients should be encouraged to drink at least 2 L of water daily. Avoidance of caffeine may prevent cyst formation due to effects on G-coupled proteins.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney is a disease involving the distal nephron that affects < 1% of the general population. Although present at birth, it is not usually diagnosed until the third or fourth decade. It is thought to occur due to disruption of the ureteric bud-metanephric mesenchyme interface, often resulting from autosomal dominant mutations in genes responsible for urogenital development. Kidneys have marked, irregular enlargement of the medullary and papillary collecting ducts. This is associated with diffuse medullary cysts, giving a "Swiss cheese" appearance in these regions.

Clinical Findings

Nephrolithiasis is the most common clinical presentation and complication of medullary sponge kidney, affecting up to 70% of patients. Hematuria (either gross or microscopic), recurrent UTIs, or both may also occur. Other findings may include decreased urinary concentrating ability, nephrocalcinosis, and, less commonly, type 1 (distal) renal tubular acidosis. The diagnosis is established clinically through laboratory data and imaging characteristics. CT imaging shows cystic dilatation of the distal collecting tubules with a striated appearance, and calcifications in the renal collecting system. Similar findings on ultrasound may also support the diagnosis.

Treatment

Treatment for medullary sponge kidney is supportive and primarily centered on mitigating risk for stone formation and nephrocalcinosis. Oral alkali therapy (preferably citrate salts); a low salt/low animal protein diet; and at least 3 L of fluid intake daily are recommended, along with oral alkali therapy (preferably citrate salts) and, in some patients, thiazides to lower urinary calcium excretion.

Prognosis

Medullary sponge kidney is generally considered a benign condition unless there are complications from recurrent UTIs, nephrolithiasis, or uncontrolled acidosis.

MULTISYSTEM DISEASES WITH VARIABLE KIDNEY INVOLVEMENT

PLASMA CELL MYELOMA

Plasma cell myeloma is a malignancy of plasma cells (see Chapter 15) that can cause a variety of kidney disorders. Injury is due to the toxic effects of monoclonal immunoglobulins or light chain components produced by plasma cells. Cast nephropathy (also called "myeloma kidney") is the most common kidney disease in plasma cell myeloma and occurs when immunoglobulin light chains (Bence Jones protein) overwhelm the reabsorptive capacity of the tubules, leading to precipitation in the distal nephron and tubular obstruction. Plasma cell myeloma may also cause Fanconi syndrome (generalized dysfunction of the proximal tubule), with signs including type 2 renal tubular acidosis and euglycemic glycosuria. Proteinuria in cast nephropathy is exclusively due to tubular overflow of light chains which will not be detected by urine dipstick (see section on Proteinuria). Hypercalcemia due to bone lysis may be seen. Plasma cell myeloma can also cause renal amyloidosis with nephrotic syndrome; in these patients, urine dipstick will reveal heavy albuminuria due to glomerular damage. Other conditions resulting in kidney disease include plasma cell infiltration of the renal parenchyma and hyperviscosity syndrome compromising renal blood flow. Therapy for AKI (see Acute Kidney Injury, above) attributed to plasma cell myeloma includes correction of hypercalcemia; volume repletion; and chemotherapy for the underlying malignancy, typically with bortezomib-based agents. Plasmapheresis and hemodialysis are sometimes considered to reduce the burden of circulating free light chains, but results have been equivocal and their use is controversial.

Leung N et al. Multiple myeloma with acute light chain cast nephropathy. Blood Cancer J. 2023;13:46. [PMID: 36990996]

SICKLE CELL DISEASE

Kidney damage is common with sickle cell disease. Sickling of RBCs in the relatively hypoxic renal medulla results in congestion and stasis, which leads to hemorrhage, interstitial inflammation, papillary infarcts, and necrosis. Hematuria is common; proteinuria can occur and portends a poorer prognosis. Isosthenuria (urine osmolality equal to that of serum) signals damage to renal capillaries with impaired urinary concentrating ability and excess renal water losses; patients can easily become dehydrated. Sickle cell glomerulopathy is less common but inexorably progresses to ESKD. Treatment of the kidney disease centers on control of sickle cell disease and ensuring adequate fluid intake; ACE inhibitors or ARBs should be considered for albuminuric patients; hydroxyurea may also be renoprotective. Sickle cell trait can also result in kidney disease, though at lower rates than are seen in sickle cell disease. For those who progress to ESKD, renal transplantation should be considered.

Zahr RS et al. Sickle cell disease and CKD: an update. Am J Nephrol. 2024;55:56. [PMID: 37899028]

TUBERCULOSIS

Renal tuberculosis usually results from hematogenous spread and is underdiagnosed. Up to 20% of patients with tuberculosis have extrapulmonary disease, and up to 5% of patients with extrapulmonary tuberculosis have genitourinary involvement. Its classic manifestation is the presence of microscopic pyuria without bacterial growth on urine culture—or “sterile pyuria.” More often, other bacteria are also present, and microscopic hematuria may coexist. Urine cultures are no longer the gold standard for diagnosis, as urine nucleic acid testing has increased sensitivity. Characteristic findings on imaging include papillary necrosis and cavitation of the renal parenchyma. Ureteral strictures or calcifications may also be present. Kidney biopsy demonstrates granulomatous inflammation and tubulointerstitial nephritis; however, the diagnosis is often presumed without biopsy confirmation. Prompt initiation of antituberculosis treatment is indicated, without which chronic inflammation and obstruction will lead to ESKD.

Bausch K et al. Genitourinary tuberculosis: a brief manual for urologists on diagnosis and treatment from the European Association of Urology Urological Infections Panel. Eur Urol Focus. 2024;10:77. [PMID: 37541917]

GOUT & THE KIDNEY

The kidney is the primary organ for uric acid excretion. Patients with proximal tubular dysfunction have decreased excretion of uric acid and are prone to gouty arthritis attacks. Depending on the pH and uric acid concentration, deposition can occur in the tubules, the interstitium, or the urinary tract. The more alkaline pH of the interstitium causes urate salt deposition, whereas the acidic environment of the tubules and urinary tract causes uric acid crystal deposition at high concentrations.

Three disorders of renal uric acid overload can develop: (1) uric acid nephrolithiasis may result in ureteral obstructive uropathy, (2) acute uric acid nephropathy occurs when uric acid crystals precipitate in the distal tubule with tubular obstruction and tubulointerstitial toxicity (usually seen in tumor lysis syndrome), and (3) chronic urate nephropathy with deposition of urate crystals in the alkaline medium of the interstitium, leading to fibrosis and atrophy.

These three disorders are seen in both “overproducers” and “underexcretors” of uric acid. The latter situation may seem counterintuitive; however, these patients have acidic urine, which enables precipitation of relatively insoluble uric acid crystals. Those with hyperuricemia should avoid food and drugs causing hyperuricemia (see Chapter 23), ensure adequate fluid intake, and should be considered for urate-lowering therapy (eg, allopurinol or febuxostat). Treatment of uric acid nephrolithiasis also includes fluid intake that should exceed 3 L/day, and consideration of a urinary alkalinizing agent. Patients with hyperuricemia but no history of gout or uric acid nephrolithiasis have not been shown to benefit from urate-lowering therapy.

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis (NSF) is a rare but devastating multisystem disorder due to exposure to early formulations of gadolinium that occurred exclusively in patients with advanced CKD (stage 4 and ESKD), AKI, or kidney transplant.

NSF was first recognized in hemodialysis patients in 1997, in whom the incidence following exposure to "group I" gadolinium agents (linear, and relatively unstable structure) was approximately 1–4% in the ESKD population and lower in patients with less severe kidney disease. This incidence has decreased over time due to limiting use of gadolinium in patients with CKD and AKI, and the development of safer gadolinium preparations ("group II and group III" agents) with more stable molecular structures that have not been associated with NSF. There is an FDA warning regarding avoidance of group I gadolinium agents for patients with an eGFR < 30 mL/min/1.73 m^2.

Clinical Findings

Nephrogenic systemic fibrosis affects several organ systems, including the skin, muscles, lungs, and cardiovascular system. The most common manifestation is a debilitating fibrosing skin disorder that can range from skin-colored to erythematous papules, which coalesce to brawny patches. The skin can be thick and woody in areas and is painful out of proportion to findings on examination.

Treatment

No treatment has proven definitively effective; a preventive approach of avoiding group I gadolinium exposure in patients at a high risk for renal damage is paramount. Case reports and series describe potential benefit of corticosteroids, photopheresis, plasmapheresis, and sodium thiosulfate, but their true efficacy is unknown. If gadolinium absolutely must be used in patients on dialysis, practice guidelines recommend using a group II or III agent at no more than the standard dose. Hemodialysis immediately after exposure to gadolinium is not considered necessary for group II and III agents.

Brian Jordan, MD

HEMATURIA

ESSENTIALS OF DIAGNOSIS

- Gross hematuria requires evaluation: the upper urinary tract should be imaged, and the lower tract evaluated by cystoscopy.
- In microscopic hematuria, the workup should be risk stratified.

General Considerations

An *upper tract source* (kidneys and ureters) can be identified in 10% of patients with gross or microscopic hematuria. For upper tract sources, stone disease accounts for 40%, medical kidney disease (medullary sponge kidney, glomerulonephritis, papillary necrosis) for 20%, renal cell carcinoma for 10%, and urothelial cell carcinoma of the ureter or renal pelvis for 5%. Medication ingestion and associated medical problems may provide diagnostic clues. Analgesic use (papillary necrosis), cyclophosphamide (chemical cystitis), antibiotics (interstitial nephritis), diabetes mellitus, sickle cell trait or disease (papillary necrosis), a history of stone disease, or malignancy should all be investigated. The *lower tract source* of gross hematuria (in the absence of infection) is most commonly from bleeding prostatic varices or urothelial carcinoma of the bladder. Microscopic hematuria in the male is most commonly from BPH (13%), kidney stones (6%), or urethral stricture (1.4%). *The presence of hematuria in patients receiving antiplatelet or anticoagulation therapy cannot be presumed to be due to the medication; a complete evaluation consisting of upper tract imaging, cystoscopy, and urine cytology is warranted.* (See Chapter 44 for Bladder Cancer, Cancers of the Ureter & Renal Pelvis, Renal Cell Carcinoma, and Other Primary Tumors of the Kidney.)

Clinical Findings

A. Symptoms and Signs

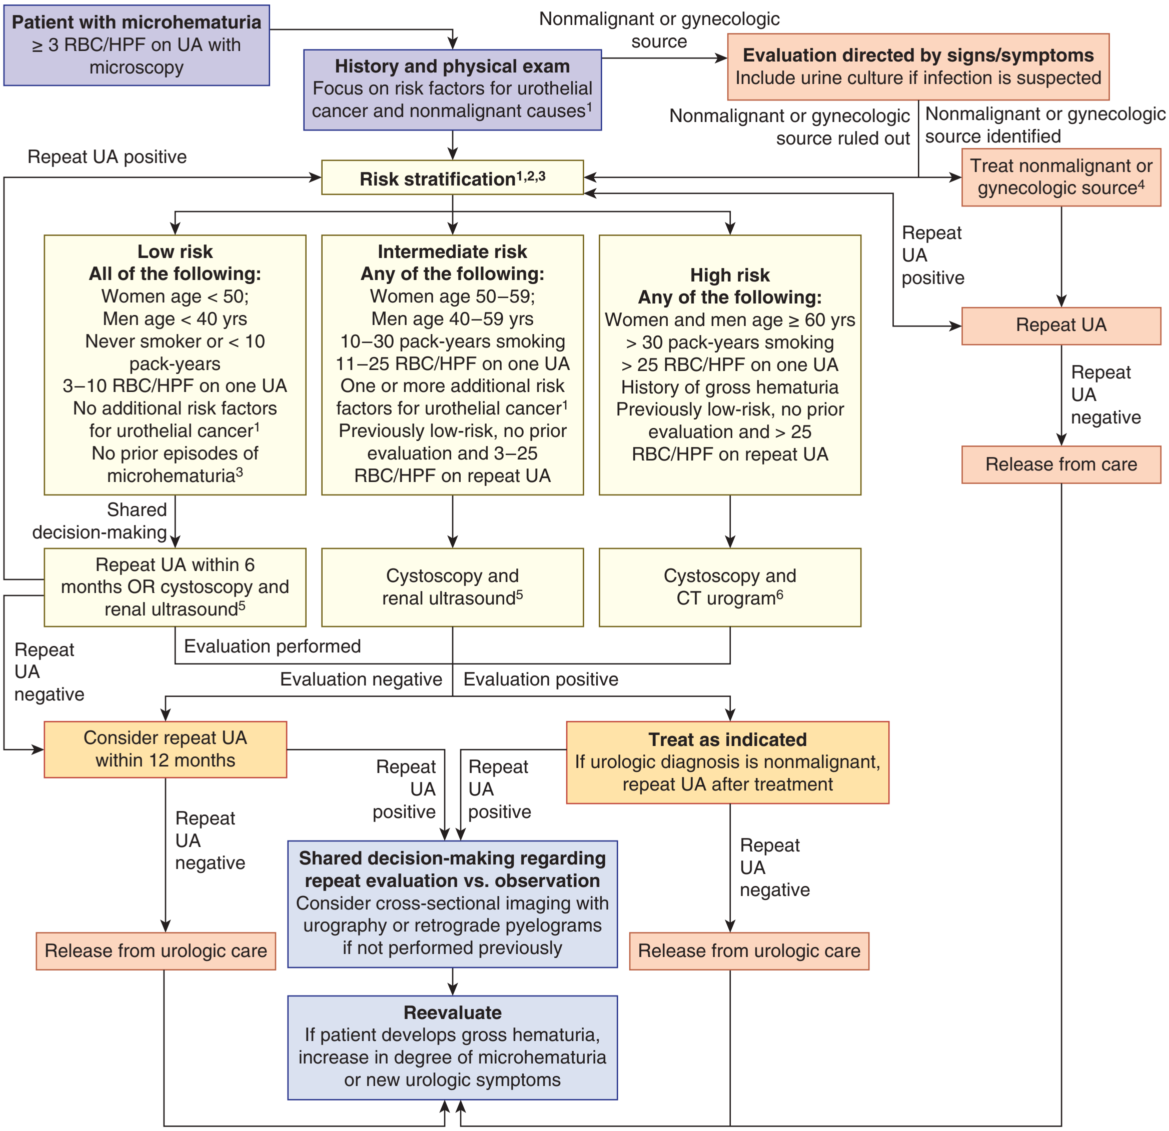
If gross hematuria occurs, a description of the timing (initial, terminal, total) may provide a clue to the localization of disease. Associated symptoms (ie, renal colic, irritative voiding symptoms, or constitutional symptoms) should be investigated. *The history should be focused on risk factors for urothelial cancer* (age, male sex, smoking history, history of gross hematuria, irritative lower urinary tract voiding symptoms, history of cyclophosphamide or ifosfamide chemotherapy, family history of urothelial carcinoma or Lynch syndrome, occupational exposure to benzene chemicals or aromatic amines, history of chronic indwelling foreign body in the urinary tract such as a Foley or suprapubic catheter) and on nonmalignant causes. The physical examination should look for signs of systemic disease (fever, rash, lymphadenopathy, abdominal or pelvic masses) as well as signs of medical kidney disease (hypertension, volume overload). The urologic evaluation may demonstrate an enlarged prostate, flank mass, or urethral disease. The evaluation of patients with hematuria and their risk stratification should *not* be influenced by whether they are taking any antiplatelet or anticoagulant agents.

B. Laboratory Findings

Initial laboratory investigations include a UA and urine culture. **Microhematuria** is defined as three or more RBCs per high-power field on a microscopic evaluation of the urine. The degree of microscopic hematuria is important in risk stratification according to the 2020 American Urological Association hematuria guidelines (Figure 26–1). A positive dipstick reading for heme merits microscopic examination to confirm or refute the diagnosis of hematuria but is not enough to warrant workup on its own. If UA and culture are suggestive of a UTI, follow-up UA after treatment of the infection is important to ensure resolution of the hematuria. An estimate of kidney function should be obtained, since renal insufficiency may influence the methods of upper tract imaging (eg, ability to obtain a contrast CT or MRI imaging) of patients with hematuria. *Urine cytology and other urinary-based markers are* not *routinely recommended in the evaluation of asymptomatic microscopic hematuria.*

C. Risk Stratification

Following initial evaluation, clinicians should categorize patients with microscopic hematuria as low, intermediate, or high risk for a urothelial malignancy (Figure 26–1).



Patient with microhematuria
≥ 3 RBC/HPF on UA with microscopy
History and physical exam
Focus on risk factors for urothelial cancer and nonmalignant causes¹
Nonmalignant or gynecologic source
Evaluation directed by signs/symptoms
Include urine culture if infection is suspected
Nonmalignant or gynecologic source ruled out
Nonmalignant or gynecologic source identified
Repeat UA positive
Risk stratification¹,²,³
Treat nonmalignant or gynecologic source⁴
Repeat UA positive
Low risk
All of the following:
Women age < 50;
Men age < 40 yrs
Never smoker or < 10 pack-years
3–10 RBC/HPF on one UA
No additional risk factors for urothelial cancer¹
No prior episodes of microhematuria³
Intermediate risk
Any of the following:
Women age 50–59;
Men age 40–59 yrs
10–30 pack-years smoking
11–25 RBC/HPF on one UA
One or more additional risk factors for urothelial cancer¹
Previously low-risk, no prior evaluation and 3–25 RBC/HPF on repeat UA
High risk
Any of the following:
Women and men age ≥ 60 yrs
> 30 pack-years smoking
> 25 RBC/HPF on one UA
History of gross hematuria
Previously low-risk, no prior evaluation and > 25 RBC/HPF on repeat UA
Repeat UA
Repeat UA negative
Release from care
Shared decision-making
Repeat UA within 6 months OR cystoscopy and renal ultrasound⁵
Cystoscopy and renal ultrasound⁵
Cystoscopy and CT urogram⁶
Repeat UA negative
Evaluation performed
Evaluation negative
Evaluation positive
Consider repeat UA within 12 months
Treat as indicated
If urologic diagnosis is nonmalignant, repeat UA after treatment
Repeat UA positive
Repeat UA positive
Repeat UA negative

Shared decision-making regarding repeat evaluation vs. observation
Consider cross-sectional imaging with urography or retrograde pyelograms if not performed previously
Release from urologic care
Release from urologic care
Reevaluate
If patient develops gross hematuria, increase in degree of microhematuria or new urologic symptoms

---

[1] Main risk factors for urothelial cancer are those in the AUA risk stratification system (age, male sex, smoking, degree of microhematuria and history of gross hematuria). Additional risk factors for urothelial carcinoma include but are not limited to irritative lower urinary tract voiding symptoms, history of cyclophosphamide or ifosfamide chemotherapy, family history of urothelial carcinoma or Lynch syndrome, occupational exposures to benzene chemicals or aromatic amines, history of chronic indwelling foreign body in the urinary tract.

[2] If medical kidney disease is suspected, consider nephrologic evaluation, but pursue concurrent risk-based urological evaluation.

[3] Patients may be low-risk at first presentation with microhematuria, but may be considered intermediate- or high-risk if found to have persistent microhematuria.

[4] There are nonmalignant and gynecologic sources of hematuria that do not require treatment and/or may confound the diagnosis of microhematuria. Clinicians can consider catheterized urine specimen in women with vaginal atrophy or pelvic organ prolapse. Clinicians must use careful judgment and patient engagement to decide whether to pursue microhematuria evaluation in the setting of chronic conditions that do not require treatment, such as the aforementioned gynecologic conditions, nonobstructing stones or BPH.

[5] Clinician may perform cross-sectional imaging with urography or retrograde pyelograms if hematuria persists after negative renal ultrasound.

[6] If contraindications to CT urogram, MR urogram or noncontrast imaging plus retrograde pyelograms.

▲ **Figure 26–1.** Microscopic hematuria: algorithmic approach to risk stratification of patients as low risk, intermediate risk, and high risk for urothelial malignancy. HPF, high-powered field. (Reproduced with permission from Barocas DA, Boorjian SA, Alvarez RD, et al. Microhematuria: AUA/SUFU Guideline. J Urol. 2020;204(4):778-786.)

D. Evaluation

Patients with **gross hematuria** should have both complete evaluation of the upper tract by a **CT-intravenous pyelogram (CT-IVP)** or a **magnetic resonance urogram (MR-urogram)** with and without contrast with delayed phases. *No imaging study adequately evaluates the bladder, and visual inspection of the bladder by cystoscopy is required.*

Low-risk patients with microscopic hematuria should undertake a shared decision-making approach with their clinician to decide between repeat urinalyses over the next 6 months or proceeding immediately with cystoscopy and **renal ultrasound**. If microscopic hematuria persists on a repeat UA, then patients who did not initially undergo cystoscopy should be reclassified as intermediate- or high-risk and undergo both upper tract imaging according to their risk group, and lower tract evaluation by cystoscopy.

Intermediate-risk patients should undergo both upper tract imaging with renal ultrasound and lower tract evaluation by cystoscopy.

High-risk patients should undergo upper tract evaluation with CT-IVP (preferred), MR-urogram (if CT-IVP contraindicated), and cystoscopic evaluation of the bladder. If there are contraindications to CT-IVP and MR-urogram, clinicians may perform noncontrast axial imaging along with retrograde pyelography at the time of cystoscopy.

Follow-Up

In patients with negative hematuria evaluations, it is typically recommended that a UA with microscopy be repeated at 6–12 months. Patients with a negative follow-up UA require no further evaluation. If microscopic hematuria persists or recurs on follow-up urinalyses, then providers should engage patients with shared decision-making regarding repeat evaluation. However, patients who develop gross hematuria or increased severity of microscopic hematuria should be referred for repeat upper and lower tract evaluation.

When to Refer

In the absence of a clear benign etiology (such as an infection, menstruation, vigorous exercise, acute stone event, medical renal disease, viral illness, trauma, or recent urologic procedure), hematuria (either gross or microscopic) requires evaluation.

GENITOURINARY TRACT INFECTIONS

Urinary tract infections are among the most common entities encountered in medical practice. In acute infections, a single pathogen is usually found, whereas two or more pathogens are often seen in chronic infections. Coliform bacteria are responsible for most non-nosocomial, uncomplicated UTIs, with *Escherichia coli* being the most common. Such infections typically are sensitive to a wide variety of orally administered antibiotics and respond quickly. Nosocomial infections often are due to more resistant pathogens and may require parenteral antibiotics. Renal infections are of particular concern because if they are inadequately treated, loss of kidney function may result. A urine culture is recommended for patients with suspected UTI and ideally should be obtained prior to the initiation of antibiotic therapy. Previously, a colony count > 10^5/mL was considered the criterion for UTI, though up to 50% of women with symptomatic infections may have lower counts. In addition, *the presence of pyuria correlates poorly with the diagnosis of UTI, and thus UA alone is not adequate for diagnosis*. With respect to treatment, *tissue infections* (pyelonephritis, prostatitis) require therapy for 1–2 weeks, while *mucosal infections* (cystitis) require only 1–3 days of therapy.

1. Acute Cystitis

ESSENTIALS OF DIAGNOSIS

- Irritative voiding symptoms.
- Patient usually afebrile.
- Positive urine culture; blood cultures may also be positive.

General Considerations

Acute cystitis is an infection of the bladder, most commonly due to the coliform bacteria (especially *E coli*) and occasionally gram-positive bacteria (enterococci). The route of infection is typically ascending from the urethra. Viral cystitis due to adenovirus is sometimes seen in children but is rare in immunocompetent adults. *Uncomplicated cystitis in men is rare and implies a pathologic process such as infected stones, prostatitis, or chronic urinary retention requiring further investigation.*

Clinical Findings

A. Symptoms and Signs

Irritative voiding symptoms (frequency, urgency, dysuria) and suprapubic discomfort are common. Women may experience gross hematuria, and symptoms may often appear following sexual intercourse. Physical examination may elicit suprapubic tenderness, but examination is often unremarkable. Systemic toxicity is absent.

B. Laboratory Findings

UA should be without squamous cells, indicating a clean collection, and typically shows pyuria, bacteriuria, and varying degrees of hematuria. The degree of pyuria and bacteriuria does not necessarily correlate with the severity of symptoms. Urine culture is positive for the offending organism, but *colony counts exceeding* 10^5*/mL are not required for the diagnosis. Patients with asymptomatic bacteriuria or colonization are expected to have positive urine cultures but do not require treatment except in pregnant women.* Patients with long-term urinary catheters (indwelling urinary [Foley] or suprapubic catheter) or urostomy urinary diversions are expected to be colonized with bacteria, and thus, UA and urine culture are most helpful in directing therapy rather than determining whether symptomatic infection exists.

C. Imaging

Because uncomplicated cystitis is rare in men, appropriate investigation is necessary to elucidate the underlying problem and may include abdominal ultrasonography, postvoid residual testing, and cystoscopy. Follow-up imaging using CT scanning is warranted if pyelonephritis, recurrent infections, or anatomic abnormalities are suspected.

Differential Diagnosis

In women, infectious processes such as vulvovaginitis and pelvic inflammatory disease can usually be distinguished by pelvic examination and UA. In men, urethritis and prostatitis may be distinguished by physical examination (urethral discharge or prostatic tenderness). Bacteriuria on urine culture, in the absence of symptoms, generally should not be treated.

Noninfectious causes of cystitis-like symptoms include pelvic irradiation, chemotherapy (cyclophosphamide), bladder carcinoma, interstitial cystitis, voiding dysfunction disorders, bladder irritants, distal ureteral stone, and psychosomatic disorders.

Prevention

The risk of developing a UTI can be reduced by drinking plenty of fluid and completely emptying the bladder frequently. Women in whom UTIs tend to develop after intercourse should be advised to void before, and especially after intercourse, and may benefit from a single dose of postcoital antibiotic. Postmenopausal women with recurrent UTIs (three or more episodes per year) treated with vaginal estrogen either as a cream or ring have a significant reduction in infections. Daily cranberry tablets may reduce the risk of cystitis, though the data are conflicting. Prophylactic antibiotics are generally discouraged. Prior to institution of antibiotic prophylaxis, a thorough urologic evaluation is warranted to exclude any anatomic abnormality (eg, stones, reflux, fistula, prolapse, urethral diverticula). An initial course of 6–12 months of prophylactic antibiotics can be offered, though the benefits of prophylactic antibiotics should be weighed against the risks associated with expected bacterial resistance.

The risk of acquiring a catheter-associated UTI in hospitalized patients can be minimized by using indwelling catheters only when necessary, implementing systems to ensure removal of catheters when no longer needed, using antimicrobial catheters in high-risk patients, maintaining proper insertion techniques, identifying significant elevated postvoid residuals, and utilizing alternatives such as intermittent catheterization and external collection devices (condom catheters) in appropriately selected men.

Treatment

Uncomplicated cystitis in women can be treated with short-term antimicrobial therapy, which consists of a single dose or 1–7 days of therapy. Fosfomycin, nitrofurantoin, and trimethoprim-sulfamethoxazole are the medications of choice for uncomplicated cystitis (Table 26–1). The US Food and Drug Administration (FDA) advises restricting fluoroquinolone use for uncomplicated infections. Due to emergence of resistant organisms, local patterns of bacterial resistance should be consulted to identify best treatment options. Literature review has proposed that *acute uncomplicated cystitis in women can be diagnosed without office evaluation or urine culture*, and that appropriate first-line therapies include trimethoprim-sulfamethoxazole (160/800 mg twice daily for 3 days), nitrofurantoin (100 mg twice daily for 5–7 days), or fosfomycin trometamol (3 g single dose). In men, uncomplicated UTI is rare; thus, the duration of antibiotic therapy depends on the underlying etiology. Hot sitz baths or urinary analgesics (phenazopyridine, 200 mg orally three times daily) may provide additional symptomatic relief. Postmenopausal women with recurrent cystitis can be treated with vaginal estrogen cream 0.5 g nightly for 2 weeks and then twice weekly thereafter.

Prognosis

Infections typically respond rapidly to therapy, and failure to respond suggests resistance to the selected medication or anatomic abnormalities requiring further investigation.

When to Refer

- Suspicion or radiographic evidence of anatomic abnormality.
- Evidence of urolithiasis.
- Recurrent cystitis due to bacterial persistence.

Table 26–1. Empiric therapy for UTIs.

Diagnosis	Antibiotic	Route	Duration
Acute cystitis[a]			
	First-line:		
	Trimethoprim-sulfamethoxazole, 160/800 mg, (one DS tablet) every 12 hours[1]	Oral	3 days
	Nitrofurantoin (macrocrystals), 100 mg every 12 hours	Oral	5 days
	Fosfomycin, 3 g packet once	Oral	1 day
	Second-line:		
	Ciprofloxacin, 250 mg every 12 hours[2]	Oral	3 days
	Levofloxacin, 250–500 mg daily[2]	Oral	3 days
	Alternative agents:		
	Cephalexin, 500 mg every 6–12 hours	Oral	7 days
	Amoxicillin/clavulanate, 500/125 mg every 12 hours	Oral	3 days
	Cefpodoxime, 100 mg every 12 hours	Oral	3 days
Acute pyelonephritis[a]			
	Hospitalized:		
	Ampicillin, 1 g every 6 hours, plus gentamicin, 1 mg/kg every 8 hours	Intravenous	14 days
	Ceftriaxone, 1 g daily	Intravenous	14 days
	Ciprofloxacin, 400 mg every 12 hours[2]	Intravenous	14 days
	Cefepime/enmetazobactam, 2.5 g every 8 hours[3]	Intravenous	7–14 days
	Non-hospitalized:		
	Initial intravenous dose[4]:		
	Ceftriaxone, 1 g	Intravenous	Once
	Ciprofloxacin, 400 mg[2]	Intravenous	Once
	Gentamicin, 5 mg/kg	Intravenous	Once
	Followed by one of these oral regimens:		
	Ciprofloxacin, 500 mg every 12 hours[2]	Oral	7 days
	Levofloxacin, 750 mg daily[2]	Oral	5 days
	Trimethoprim-sulfamethoxazole, 160/800 mg (one DS tablet) every 12 hours[1]	Oral	14 days
Acute bacterial prostatitis[b]			
	Hospitalized:		
	Ampicillin, 2 g every 6 hours, plus gentamicin, 1.5 mg/kg every 8 hours	Intravenous	Until afebrile
	Followed by one of these outpatient oral regimens:		
	Trimethoprim-sulfamethoxazole, 160/800 mg (one DS tablet) every 12 hours[1]	Oral	3 weeks
	Ciprofloxacin, 250–500 mg every 12 hours[2]	Oral	3 weeks
Chronic bacterial prostatitis[b]			
	First-line:		
	Ciprofloxacin, 500 mg every 12 hours[2]	Oral	1–3 months
	Levofloxacin, 750 mg daily[2]	Oral	28 days
	Second-line:		
	Doxycycline, 100 mg twice daily	Oral	4–12 weeks
	Azithromycin, 500 mg daily	Oral	4–12 weeks
	Clarithromycin, 500 mg daily	Oral	4–12 weeks

(*continued*)

Table 26–1. Empiric therapy for UTIs. (continued)

Diagnosis	Antibiotic	Route	Duration
Acute epididymitis[c]			
Sexually transmitted (under age 35)	Ceftriaxone, 500 mg as single dose, **plus** Doxycycline, 100 mg every 12 hours	Intramuscular Oral	Once 10 days
Sexually transmitted in men who practice insertive anal sex	Ceftriaxone, 500 mg as single dose, **plus** Levofloxacin, 500 mg daily[2]	Intramuscular Oral	Once 10 days
Non–sexually transmitted, usually enteric organisms (age > 35)	Levofloxacin, 500 mg daily[2]	Oral	10 days

[1] Increasing resistance noted (up to 20%).

[2] FDA advises restricting fluoroquinolone use for some uncomplicated infections, including uncomplicated UTIs, because of mental health side effects including disturbances in attention, disorientation, agitation, nervousness, memory impairment, and delirium; musculoskeletal side effect risks of tendinitis and tendon rupture; neuromuscular side effect of peripheral neuropathy and worsening of myasthenia gravis; and endocrine side effect of coma from hypoglycemia.

[3] Indications: adults with complicated UTI, including pyelonephritis, especially those due to extended-spectrum β-lactamase (ESBL) infections caused by *Escherichia coli, Klebsiella, Pseudomonas, Proteus,* and *Enterobacter.*

[4] Infectious Diseases Society of America (IDSA) recommends an initial 24-hour intravenous dose of antibiotic when local resistance of the selected oral regimen exceeds 10%. Please refer to local antibiograms.

2. Acute Pyelonephritis

ESSENTIALS OF DIAGNOSIS

- Fever.
- Flank pain.
- Irritative voiding symptoms.
- Positive urine culture.

General Considerations

Acute pyelonephritis is an infectious inflammatory disease involving the kidney parenchyma and renal pelvis. Gram-negative bacteria are the most common causative agents including *E coli*, *Proteus*, *Klebsiella*, *Enterobacter*, and *Pseudomonas*. Gram-positive bacteria are less commonly seen but include *Enterococcus faecalis* and *Staphylococcus aureus*. The infection usually ascends from the lower urinary tract—with the exception of *S aureus*, which usually is spread by a hematogenous route.

Clinical Findings

A. Symptoms and Signs

Symptoms include fever, flank pain, shaking chills, and irritative voiding symptoms (urgency, frequency, dysuria). Associated nausea and vomiting and diarrhea are common. Signs include fever and tachycardia. *Costovertebral angle tenderness is usually pronounced.*

B. Laboratory Findings

Complete blood cell count shows leukocytosis and a left shift. UA shows pyuria, bacteriuria, and varying degrees of hematuria. White cell casts may be seen. Urine culture demonstrates growth of the offending organism, and blood culture may also be positive.

C. Imaging

In complicated pyelonephritis, renal ultrasound may show hydronephrosis from a stone or other source of obstruction. CT scan may demonstrate decreased perfusion of the kidney or focal areas within the kidney and nonspecific perinephric fat stranding.

Differential Diagnosis

The differential diagnosis includes acute cystitis or a lower urinary source. Acute intra-abdominal disease such as appendicitis, cholecystitis, pancreatitis, or diverticulitis must be distinguished from pyelonephritis. A normal UA is usually seen in gastrointestinal disorders; however, on occasion, inflammation from adjacent bowel (appendicitis or diverticulitis) may result in hematuria or sterile pyuria. Abnormal liver biochemical tests or elevated amylase levels may assist in the differentiation. Lower-lobe pneumonia is distinguishable by abnormal CXR.

In males, the main differential diagnosis for acute pyelonephritis also includes acute epididymitis and acute prostatitis. Physical examination and the location of the pain should permit this distinction.

Complications

Sepsis with shock can occur with acute pyelonephritis. In diabetic patients, emphysematous pyelonephritis resulting from gas-producing organisms may be life-threatening if not adequately treated. **Obstructive pyelonephritis, for example due to a stone, is a surgical emergency and requires urgent attention.** Healthy adults usually recover complete kidney function, yet if coexistent kidney disease is present, scarring or chronic pyelonephritis may result. Inadequate therapy could result in abscess formation.

Treatment

Urine and blood cultures are obtained to identify the causative agent and to determine antimicrobial sensitivity. In the inpatient setting, broad-spectrum intravenous antibiotics (ampicillin and an aminoglycoside) should be initiated until organism sensitivities are available (Table 26–1), with antibiotics adjusted according to sensitivities. Intravenous antibiotics are typically continued for 24 hours after fever resolution, and oral antibiotics to complete a 14-day course of therapy. In the outpatient setting, empiric therapy may be initiated (Table 26–1). *If local antibiograms demonstrate local resistance rates for the oral regimen exceed 10%, an initial 24-hour intravenous dose of antibiotic is required.* Fevers may persist for up to 72 hours even with appropriate antibiotics; failure to respond within 48 hours warrants imaging (CT or ultrasound) to exclude complicating factors that may require intervention (such as a perinephric abscess or an obstructing stone). Catheter drainage may be necessary in the face of urinary retention and nephrostomy drainage if there is ureteral obstruction.

Prognosis

With prompt diagnosis and appropriate treatment, acute pyelonephritis carries a good prognosis. Complicating factors, underlying kidney disease, and increasing patient age may lead to a less favorable outcome.

When to Refer

- Evidence of complicating factors (urolithiasis, obstruction).
- Failure of clinical improvement in 48 hours.

When to Admit

- Severe infections or complicating factors, evidence of sepsis, or need for parenteral antibiotics.
- Need for radiographic imaging or drainage of urinary tract obstruction.

Kurotschka PK et al. Acute uncomplicated UTIs in adults: rapid evidence review. Am Fam Physician. 2024;109:167. [PMID: 38393801]

3. Acute Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- Fever.
- Irritative voiding symptoms.
- Perineal or suprapubic pain; exquisite tenderness common on rectal examination.
- Positive urine culture.

General Considerations

Acute bacterial prostatitis is usually caused by gram-negative rods, especially *E coli* and *Pseudomonas* species, and less commonly by gram-positive organisms (eg, enterococci). The most likely routes of infection include ascent up the urethra and reflux of infected urine into the prostatic ducts. Lymphatic and hematogenous routes are probably rare.

Clinical Findings

A. Symptoms and Signs

Symptoms may follow chronic dysfunctional voiding, urinary retention, and pushing to urinate. Perineal, sacral, or suprapubic pain, fever, and irritative voiding complaints are common. Varying degrees of obstructive symptoms may occur as the acutely inflamed prostate swells, which may lead to urinary retention. High fevers and a warm and often exquisitely tender prostate are detected on examination. Care should be taken to perform a gentle rectal examination, since vigorous manipulations may result in septicemia. *Prostatic massage is contraindicated.*

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. UA shows pyuria, bacteriuria, and varying degrees of hematuria. Urine or expressed prostatic secretions cultures will demonstrate the offending pathogen (Table 26–2).

C. Imaging

Acute prostatitis can progress to prostatic abscess, and a pelvic CT or transrectal ultrasound is indicated in patients who do not respond to antibiotics in 24–48 hours.

Differential Diagnosis

Acute pyelonephritis or acute epididymitis should be distinguishable by the location of pain and physical examination. Acute diverticulitis is occasionally confused with acute prostatitis; however, the history and UA should permit clear distinction. Urinary retention from prostatic

Table 26–2. Clinical characteristics of prostatitis and chronic pelvic pain syndrome.

Findings	Acute Bacterial Prostatitis	Chronic Bacterial Prostatitis	Chronic Nonbacterial Prostatitis	Chronic Pelvic Pain Syndrome
Fever	+	–	–	–
Urinalysis	+	–	–	–
Expressed prostate secretions	Contraindicated	+ WBC + Culture	+ WBC – Culture	– WBC – Culture
Post–prostatic massage urine specimen	Contraindicated	+ Culture	– Culture	– Culture

enlargement is distinguishable by initial or follow-up rectal examination and postvoid residual bladder scan.

Treatment

Hospitalization may be required, and intravenous antibiotics (ampicillin and aminoglycoside) should be initiated until organism sensitivities are available (Table 26–1). After the patient is afebrile for 24–48 hours, oral antibiotics (eg, quinolones if organism is sensitive) are used to complete 4–6 weeks of therapy. If urinary retention develops, an in-and-out catheterization to relieve the initial obstruction or short-term (12 hours) indwelling urinary catheter is appropriate.

Prognosis

Acute bacterial prostatitis is relatively simple to treat, since bacteria are eradicated with appropriate antibiotic therapy. Progression to chronic bacterial prostatitis is rare.

When to Refer

- Evidence of urinary retention.
- Evidence of chronic prostatitis.

When to Admit

- Signs of sepsis.
- Need for surgical drainage of bladder or prostatic abscess.

Lam JC et al. Acute and chronic prostatitis. Am Fam Physician. 2024;110:45. [PMID: 39028781]

4. Chronic Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- Irritative voiding symptoms.
- Perineal or suprapubic discomfort, often dull and poorly localized.
- Abnormal expressed prostatic secretions and positive culture.

General Considerations

Although chronic bacterial prostatitis may evolve from acute bacterial prostatitis or recurrent UTI, *over half of affected men have no history of acute infection*. Gram-negative rods are the most common etiologic agents, but only one gram-positive organism (*Enterococcus*) is associated with chronic infection. Routes of infection are the same as discussed for acute infection.

Clinical Findings

A. Symptoms and Signs

Clinical manifestations are variable. Most patients have varying degrees of irritative voiding symptoms, urethral pain, and obstructive urinary symptoms. Low back and perineal pain are common. Many patients (25–43%) report a history of UTIs. Physical examination is often unremarkable, although the prostate may feel normal, boggy, or indurated. *A postvoid residual urine volume should be measured to evaluate for urinary retention.*

B. Laboratory Findings

UA is normal unless a secondary cystitis is present. *Expressed prostatic secretions* or a *post–prostatic massage voided urine* or both demonstrate increased numbers of leukocytes (> 5–10 per high-power field) and bacterial growth when cultured (Table 26–2). *Culture of the secretions and the post–prostatic massage urine specimen is necessary to make the diagnosis.* Leukocyte and bacterial counts from expressed prostatic secretions do not correlate with severity of symptoms. If no organisms are identified on culture, then nonbacterial prostatitis, chronic pelvic pain, or interstitial cystitis should be suspected.

C. Imaging

Imaging tests are typically not necessary.

Differential Diagnosis

Chronic urethritis may mimic chronic prostatitis, though cultures of the fractionated urine may localize the source of infection to the initial specimen, which comes from the urethra. Cystitis may be secondary to prostatitis, but urine samples after prostatic massage may localize the infection to the prostate. Other chronic prostatic conditions, such as nonbacterial prostatitis, chronic pelvic pain, or interstitial cystitis, are distinguished from chronic bacterial prostatitis by examination and culture of prostatic secretions and post–prostatic massage urine sample. Anal disease may share some of the symptoms of prostatitis, but physical examination should distinguish between the two.

Treatment

As in acute prostatitis, if patients are febrile or systemically ill, they may require admission and initial intravenous therapy with broad-spectrum antibiotics, such as ampicillin plus gentamicin, a third-generation cephalosporin, or a fluoroquinolone (Table 26–1). Therapy would then continue with oral trimethoprim-sulfamethoxazole, fluoroquinolone, or extended-spectrum β-lactamase antibiotic based on culture and sensitivities of expressed prostatic secretion or post–prostatic massage urine. The optimal duration of therapy remains controversial, ranging from 4 to 6 weeks. Symptomatic relief may be provided by anti-inflammatory agents (indomethacin, ibuprofen), hot sitz baths, and α-blockers (tamsulosin, alfuzosin, silodosin).

Prognosis

Chronic bacterial prostatitis may be recurrent, can be difficult to cure, and often requires repeated courses of therapeutic antibiotics.

When to Refer

- Persistent symptoms.
- Consideration of enrollment in clinical trials.

Lam JC et al. Acute and chronic prostatitis. Am Fam Physician. 2024;110:45. [PMID: 39028781]

5. Nonbacterial Chronic Prostatitis/Chronic Pelvic Pain Syndrome

ESSENTIALS OF DIAGNOSIS

- Irritative voiding symptoms.
- Perineal or suprapubic discomfort, similar to that of chronic bacterial prostatitis.
- Presence of WBCs in expressed prostatic secretions but negative culture.

General Considerations

Nonbacterial chronic prostatitis and chronic pelvic pain syndromes are incompletely understood with symptoms due to interrelated cascade of inflammatory, immunologic, endocrine, muscular, neuropathic, and psychological mechanisms. There are a variety of subtypes based on the most pronounced symptoms. Chronic perineal, suprapubic, or pelvic pain is the most common presenting symptom, though men may complain of pain in the testes, groin, and low back. Pain during or after ejaculation is one of the most prominent and bothersome symptoms in many patients. Psychosocial factors (depression, anxiety, catastrophizing, poor social support, stress) also likely play an important role in the exacerbation of chronic pelvic pain symptoms Because the cause of nonbacterial prostatitis remains unknown, the diagnosis is usually one of exclusion, and treatment may require multimodal therapy. Quality of life is greatly decreased for many patients with chronic nonbacterial prostatitis and chronic pelvic pain syndrome.

Clinical Findings

A. Symptoms and Signs

The clinical presentation is identical to that of chronic bacterial prostatitis; however, no history of UTIs is typically present. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) (https://www.med.unc.edu/menshealth/calculator-international-prostatism-symptom-score-ipss) has been validated to quantify symptoms of chronic nonbacterial prostatitis or chronic pelvic pain syndrome.

B. Laboratory Findings

Increased numbers of leukocytes are typically seen in expressed prostatic secretions, but cultures of both expressed prostatic secretions and post–prostatic urine specimens are negative.

Differential Diagnosis

The major distinction is from chronic bacterial prostatitis. *The absence of positive cultures makes the distinction* (Table 26–2). In older men with irritative voiding symptoms and negative cultures, bladder cancer must be excluded with urinary cytologic examination and cystoscopy.

Treatment

Multimodal therapy is recommended according to the various modes of patient presentation. Patients with voiding symptoms are treated with α-blockers (tamsulosin, alfuzosin, silodosin). Antibiotics are used to treat newly diagnosed, antimicrobial-naive patients. Psychosocial disorders are treated with cognitive behavioral therapy, antidepressants, anxiolytics, and, if necessary, referral to mental health specialists. Neuropathic pain is treated with gabapentinoids, amitriptyline, neuromodulation, acupuncture, and if necessary, referral to a pain management specialist (see Chapter 5). Pelvic floor muscle dysfunction may respond to diazepam, biofeedback, physical therapy (Kegel exercises), pelvic shock wave lithotripsy, and heat therapy. Sexual dysfunction with pain is treated with sexual therapy and phosphodiesterase-5 inhibitors (avanafil, sildenafil, tadalafil, vardenafil). Surgery is not recommended for chronic prostatitis.

Prognosis

Annoying, recurrent symptoms are common, but serious sequelae have not been identified.

6. Acute Epididymitis

ESSENTIALS OF DIAGNOSIS

- Fever.
- Irritative voiding symptoms.
- Painful enlargement of epididymis.

General Considerations

Most cases of acute epididymitis are infectious and can be divided into one of two categories that have different age distributions and etiologic agents. *Sexually transmitted forms* typically occur in men under age 35 years, are associated with urethritis, and result from *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. Men who practice insertive anal intercourse may have acute epididymitis from sexually transmitted and enteric organisms. *Non–sexually transmitted forms* typically occur in men age 35 years and older, are associated with UTIs and prostatitis, and are caused by enteric gram-negative rods. The route of infection is typically via the urethra to the ejaculatory duct and then down the vas deferens to the epididymis. Amiodarone has been associated with self-limited epididymitis in a dose-dependent phenomenon.

Clinical Findings

A. Symptoms and Signs

Symptoms may follow chronic dysfunctional voiding, urinary retention, urethral catheter placement, sexual activity, or trauma. Associated symptoms of urethritis (pain at the tip of the penis and urethral discharge) or cystitis (irritative voiding symptoms) may occur. Pain develops in the scrotum and may radiate along the spermatic cord or to the flank. Scrotal swelling and tenderness are usually apparent. Severe cases may develop systemic symptoms such as fever. Early in the course, the epididymis may be distinguishable from the testis; however, later the two may appear as one enlarged, tender mass. A reactive hydrocele may develop. The prostate may be tender on rectal examination.

B. Laboratory Findings

A CBC shows leukocytosis and a left shift. In the sexually transmitted variety, Gram staining of a smear of urethral discharge may be diagnostic of gram-negative intracellular diplococci (*N gonorrhoeae*). White cells without visible organisms on urethral smear signify nongonococcal urethritis, and *C trachomatis* is the most likely responsible pathogen. In the non–sexually transmitted variety, UA shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

C. Imaging

Scrotal ultrasound may aid in the diagnosis if examination is difficult of if there is uncertainty in the diagnosis.

Differential Diagnosis

Scrotal ultrasound is helpful to define the pathology. Tumors generally cause painless enlargement of the testis. UA is negative, and examination reveals a normal epididymis with a palpable testis mass. Testicular torsion usually occurs in prepubertal males but is occasionally seen in young adults. Acute onset of symptoms and a negative UA favor testicular torsion or torsion of one of the testicular or epididymal appendages. **Prehn sign** (elevation of the scrotum improves pain from epididymitis) may be suggestive but is not reliable in its diagnosis. A distal ureteral stone often presents with referred pain into the ipsilateral groin and scrotum, but the scrotum is not tender to palpation and a scrotal ultrasound is normal.

Treatment

Bed rest, ice, and scrotal elevation are important in the acute phase. Treatment is directed toward the identified pathogen (Table 26–3). The sexually transmitted variety in patients under age 35 is treated with a single intramuscular

Table 26–3. Recommended treatment regimens for epididymitis.

Condition	Treatment Regimen
For acute epididymitis most likely caused by chlamydia or gonorrhea	Ceftriaxone 500 mg[1] intramuscularly in single dose **plus** Doxycycline 100 mg orally twice daily for 10 days
For acute epididymitis most likely caused by chlamydia, gonorrhea, or enteric organisms (seen in men who practice insertive anal sex)	Ceftriaxone 500 mg[1] intramuscularly in single dose **plus** Levofloxacin 500 mg orally once daily for 10 days
For acute epididymitis most likely caused by enteric organisms only	Levofloxacin 500 mg orally once daily for 10 days

[1] For persons weighing ≥ 150 kg, 1 g of ceftriaxone should be administered.

Modified from "Recommended Regimens for Epididymitis," in the section on "Epididymitis" from the Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, https://www.cdc.gov/std/treatment-guidelines/epididymitis.htm.

injection of ceftriaxone 500 mg plus 10 days of oral doxycycline 100 mg twice daily; in addition, *any sexual partners from the preceding 60 days must be evaluated and treated as indicated*. Men who practice insertive anal intercourse receive a single intramuscular injection of ceftriaxone 500 mg and 10 days of oral levofloxacin 500 mg daily to cover sexually transmitted and enteric organisms. Non–sexually transmitted forms are treated for 10 days with oral levofloxacin 500 mg daily. Symptoms and signs of epididymitis that do not improve within 3 days require reevaluation of the diagnosis and therapy.

Prognosis

Prompt treatment usually results in a favorable outcome. If a reactive hydrocele or significant scrotal swelling occurs, it may take > 4 weeks to resolve. Delayed or inadequate treatment may result in epididymoorchitis, decreased fertility, or abscess formation.

When to Refer

- Persistent symptoms and infection despite antibiotic therapy.
- Signs of sepsis or abscess formation.

Centers for Disease Control and Prevention (CDC). 2021 Sexually Transmitted Disease Treatment Guidelines: Epididymitis. 2021. https://www.cdc.gov/std/treatment-guidelines/epididymitis.htm, accessed February 14, 2025.

INTERSTITIAL CYSTITIS

ESSENTIALS OF DIAGNOSIS

- Pain with bladder filling; urinary urgency and frequency.
- Submucosal petechiae or ulcers on cystoscopic examination.
- Diagnosis of exclusion.

General Considerations

Interstitial cystitis (painful bladder syndrome) is characterized by pain with bladder filling that is relieved by emptying and is often associated with urgency and frequency with a dramatic exaggeration of normal sensations. This is a diagnosis of exclusion, and patients must have a negative urine culture and cytology and no other obvious cause such as radiation cystitis, chemical cystitis (cyclophosphamide), vaginitis, urethral diverticulum, or genital herpes. Up to 40% of patients referred to urologists for interstitial cystitis may actually be found to have a different diagnosis after careful evaluation. *What was once considered a bladder disorder is now considered a chronic pain syndrome.*

Population-based studies have demonstrated a prevalence between 18 and 40 per 100,000 people. Both sexes are involved, but most patients are women, with a mean age of 40 years at onset. Patients with interstitial cystitis are more likely to report bladder problems in childhood, especially women. Up to 50% of patients may experience spontaneous remission of symptoms, with a mean duration of 8 months without treatment.

The etiology of interstitial cystitis is unknown, and it is most likely not a single disease but rather several diseases with similar symptoms. Associated diagnoses include severe allergies, irritable bowel syndrome, and inflammatory bowel disease. Theories regarding the cause of interstitial cystitis include increased epithelial permeability, neurogenic causes (sensory nervous system abnormalities), and autoimmunity.

Clinical Findings

A. Symptoms and Signs

Pain, pressure, or discomfort with bladder filling that is relieved with urination, and urgency, frequency, and nocturia are the most common symptoms. Patients should be asked about exposure to pelvic radiation or treatment with cyclophosphamide. Examination should exclude genital herpes, vaginitis, or a urethral diverticulum.

B. Laboratory Findings

UA, urine culture, and urinary cytology are obtained to examine for infectious causes and bladder malignancy; in interstitial cystitis, they are all normal. Urodynamic testing can be done to assess bladder sensation and compliance and to exclude detrusor instability.

C. Cystoscopy

Cystoscopy may reveal glomerulations (submucosal hemorrhage) with hydrodistention of the bladder. Total bladder capacity should be determined. Biopsy of any suspicious lesions should be performed to exclude other causes such as carcinoma, eosinophilic cystitis, and tuberculous cystitis. The presence of submucosal mast cells is *not* needed to make the diagnosis of interstitial cystitis.

Differential Diagnosis

Exposures to radiation or cyclophosphamide are discovered by the history. Bacterial cystitis, genital herpes, or vaginitis can be excluded by UA, culture, and physical examination. A urethral diverticulum may be suspected if palpation of the urethra demonstrates an indurated mass that results in the expression of pus from the urethral meatus. Urethral carcinoma presents as a firm mass on palpation.

Treatment

There is no cure for interstitial cystitis, but most patients achieve symptomatic relief from one of several approaches. *Hydrodistention* is a procedure where the bladder is filled with fluid and allowed to stretch under anesthesia;

approximately 20–30% of patients will notice symptomatic improvement that lasts 3–6 months. Amitriptyline (10–75 mg/day orally) is often used as first-line medical therapy in patients with interstitial cystitis. Both central and peripheral mechanisms may contribute to its activity. Nifedipine (30–60 mg/day orally) and other calcium channel blockers have also demonstrated some activity in patients with interstitial cystitis. Pentosan polysulfate sodium (Elmiron) is an oral synthetic sulfated polysaccharide that helps restore integrity to the epithelium of the bladder in a subset of patients, and it has been evaluated in a placebo-controlled trial. Other options include intravesical instillation of dimethyl sulfoxide (DMSO) and heparin. Intravesical bacillus Calmette-Guérin (BCG) is not beneficial. Patients with very small bladder capacities (< 200 mL) are unlikely to respond to medical therapy.

Further treatment modalities include transcutaneous electric nerve stimulation (TENS), acupuncture, stress reduction, exercise, biofeedback, massage, and pelvic floor relaxation. Surgical therapy for interstitial cystitis should be considered only as a last resort and may require cystourethrectomy with urinary diversion.

When to Refer

Persistent and bothersome symptoms in the absence of identifiable cause.

URINARY STONE DISEASE

ESSENTIALS OF DIAGNOSIS

- Severe flank pain.
- Nausea and vomiting.
- Identification on noncontrast CT or ultrasonography.

General Considerations

Urinary stone disease is exceeded in frequency as a urinary tract disorder only by infections and prostatic disease. It affects approximately 1 in 10 Americans per year, representing an approximately threefold relative increase over the prior three decades. Historically men have been much more frequently affected by urolithiasis than women; however, more recently, the prevalence in women has increased 45% (from 6.5% up to 9.4%) while the prevalence in men has remained slightly higher but stable (11.9%). This persistent increase in prevalence in women has been attributed to increasing obesity and metabolic syndrome rates. Initial presentation usually occurs in the third through fifth decades, and > 50% of patients will become recurrent stone formers.

Stone formation requires saturated urine that is dependent on solute concentration, ionic strength, pH, and complexation. There are five major types of urinary stones: **calcium oxalate**, **calcium phosphate**, **struvite (magnesium ammonium phosphate)**, **uric acid**, and **cystine.** The most common types are those composed of calcium oxalate or phosphate (85%), and for that reason most urinary stones are radiopaque on plain abdominal radiographs. Uric acid stones may be radiolucent if pure or partially radiopaque if mixed with calcium. Cystine and struvite stones are faintly visible on radiographs.

Geographic factors contribute to the development of stones. *High humidity and elevated temperatures are contributing factors*, and the incidence of symptomatic ureteral stones is greatest in such areas during hot summer months. Climate change is projected to further increase the burden of disease for individuals and society. Higher incidence of stones has also been associated with sedentary lifestyle, obesity, hypertension, insulin resistance and poor glycemic control, carotid calcification, and cardiovascular disease.

Many commonly prescribed medications increase the risk of formation of kidney stones, including carbonic anhydrase inhibitors (topiramate, zonisamide, acetazolamide), systemic corticosteroids (prednisone), antiretroviral protease inhibitors (indinavir and others), gout medications (probenecid), diuretics (furosemide, bumetanide, torsemide, triamterene), decongestants (guaifenesin, ephedrine), and laxatives (if abused for weight loss). The risk of stones from calcium supplementation is controversial. Thus, if calcium supplementation is medically necessary, it is recommended that the calcium supplement be taken with meals, and that total calcium intake (diet plus supplementation) not exceed 2000 mg daily. Dietary calcium intake should not be restricted unless excessive (> 2000 mg daily). Several large recent studies of the novel antidiabetic SGLT-2 inhibitors and GLP-1 agonists have demonstrated their safety in patients with kidney stones, with convincing evidence SGLT-2 inhibitors reduce the risk of stones by nearly 40%.

Inadequate hydration is another very important dietary factor in the development of urinary stones for essentially all stone formers. Excess animal protein and salt intake (> 3500 mg daily) and restricted dietary calcium intake also increase the risk of stones.

Genetic factors may contribute to urinary stone formation. While approximately 50% of calcium-based stones are thought to have a heritable component, other stone types are better characterized genetically. **Cystinuria** is an autosomal recessive disorder where homozygous individuals have markedly increased excretion of cystine and frequently have numerous recurrent episodes of urinary stones. Distal renal tubular acidosis may be transmitted as a hereditary trait, and urolithiasis occurs in up to 75% of affected patients.

Clinical Findings

A. Symptoms and Signs

Obstructing urinary stones usually present with acute, unremitting, and severe colic. Pain most often occurs suddenly and may awaken patients from sleep. It is typically localized to the flank and may be associated with nausea and vomiting. In sharp contrast to patients with an acute abdomen, *patients with kidney stones are constantly moving*, trying to find a comfortable position. The pain may occur episodically and may radiate anteriorly over the abdomen. As the stone progresses down the ureter, the pain may be referred into the ipsilateral groin, and when the stone reaches the distal ureter near the bladder, patients may complain of marked urinary urgency, frequency, and dysuria. In men, pain may radiate to the tip of the penis; this can be confused as a symptom of a UTI. After the stone passes into the bladder, there is immediate relief of symptoms, then *the stone passes harmlessly through the urethra*. Stone size does not correlate with the severity of the symptoms but does impact the duration and likelihood of successfully passing. If the stone fails to pass and obstruction persists, patients may note a deceptive improvement in symptoms. As many as 25% of patients with resolution of pain will have a persistent stone, and thus, it is recommended patients strain their urine as *follow-up imaging is recommended in all patients if the stone has not been witnessed to pass.*

B. Laboratory Findings

Regardless of symptom severity, UA usually reveals microscopic or gross hematuria (~90%). However, the absence of microhematuria does not exclude urinary stones. Caution should be taken in interpreting a single spot urine pH since it fluctuates significantly through the day, although a persistent urinary pH < 5.5 may suggest a uric acid stone, while a persistent urinary pH > 7.2 may suggest a struvite (infection-related) or calcium phosphate stone. Patients with an obstructing stone should be evaluated with serum white blood count, electrolytes, renal function, and UA to assess for obstruction with infection, renal insufficiency, or renal failure with electrolyte abnormalities since fever or other signs of infection are an indication for urgent intervention with a drainage procedure (ureteral stent or nephrostomy tube) to relieve the obstruction.

C. Metabolic Evaluation

Stone analysis can facilitate counseling for prevention of recurrence. Patients with uncomplicated first-time stones should undergo dietary counseling as outlined below and can be offered an optional complete metabolic evaluation.

General dietary counseling includes encouraging patients to augment their fluid intake to increase their urine volume (goal urinary output of > 2500 mL/day). This typically requires a fluid intake of 3000 mL/day or more. Stone formers should reduce their sodium intake (goal < 3500 mg/day), and reduce their animal protein intake (eggs, fish, chicken, pork, and beef). Stone formers should be encouraged to increase their fruit and vegetable intake but *not* to restrict dietary calcium. Detailed medical and dietary history, serum chemistries, and UA should be obtained for all patients with newly diagnosed nephrolithiasis. A serum parathyroid hormone level should be checked when hyperparathyroidism is suspected as the cause of calcium oxalate or calcium phosphate stones, and a serum uric acid should be obtained to exclude severe hyperuricemia, which can lead to uric acid stones as well as crystal deposition in the kidneys or heart. A 24-hour urine collection to determine urinary volume, creatinine, pH, calcium, uric acid, oxalate, phosphate, sodium, and citrate excretion is recommended for interested patients with their first stone, for all patients who have recurrent stones, and for patients at high risk for recurrence. Results are used to personalize medical management to individual patient risk factors.

D. Imaging

Noncontrast CT is the most accurate imaging modality for evaluating flank pain given its superior sensitivity and specificity over other tests; however, ultrasonography (which does not use ionizing radiation) is a safe and effective alternative for initial evaluation of renal colic and one that can be used in the emergency department with good accuracy. CT scans should be obtained in the prone position to help differentiate distal ureterovesicular stones from those that have already passed into the urinary bladder. A "low-dose" imaging protocol should be used when available and repeated CT scans should be minimized due to the substantial cumulative radiation exposure that patients with recurrent stones can face. Stone density can be estimated with Hounsfield units (HU) on CT scans to help determine stone type. All stones, whether radiopaque or radiolucent on plain abdominal radiographs, will be visible on noncontrast CT except the rare calculus caused by a protease inhibitor, or crystalized medication (guaifenesin, triamterene, ciprofloxacin). A plain abdominal radiograph (kidney, ureter, and bladder [KUB]) and renal ultrasound examination will diagnose up to 80% of stones. Since > 60% of patients with acute renal colic will have a stone in the distal 4 cm of the ureter, attention should be directed to that region when examining radiographs and ultrasonographic studies. Pain from a kidney stone is due to the dilatation of the ureter and kidney from the obstruction, and thus small nonobstructing kidney stones are typically not associated with pain.

Medical Treatment & Prevention

To reduce the recurrence rate of urinary stones, dietary modification is key. Metabolic evaluation often identifies a modifiable risk factor that can further reduce stone recurrence rates. If no medical treatment is provided, stones will generally recur in 50% of patients within 5 years. Some stone types (eg, uric acid, cystine, brushite, struvite) are prone to rapid recurrence. Consistent increased fluid intake to dilute the urine and prevent dehydration is the most important dietary risk factor to reduce stone recurrence and may diminish the risk by 50%. Increasing fluid intake to ensure a voided volume of 2.5 L/day is recommended (normal average voided volume is 1.6 L/day). Urine should be clear or light yellow at each void. Medical therapy should be tailored to the patient's metabolic workup and the activity of their stone disease. Routine follow-up every 6–8 months and annual imaging (preferably with ultrasonography) will help encourage medical compliance, assess for interval stone formation or growth, and permit adjustments in medical therapy based on repeat metabolic studies.

A. General Dietary Recommendations

A 24-hour urinary sodium level of > 150 mmol/day indicates excessive sodium intake. Sodium intake should be limited to < 3500 mg daily. Excessive sodium intake will increase renal sodium and calcium excretion, increase urinary monosodium urates (that can act as a nidus for stone growth), increase the relative saturation of calcium phosphate, and decrease urinary citrate excretion. All of these factors encourage stone growth.

A urinary sulfate level of > 20 mEq/day indicates excessive animal protein intake. Animal protein intake is best limited to 1 g/kg/day. Excess intake leads to acidic urine, increases urinary calcium, oxalate, and uric acid excretion, and decreases urinary citrate excretion. *Patients should be reminded that animal protein includes animal flesh such as eggs and fish in addition to traditional "red meat."*

Dietary calcium intake should not be restricted in an effort to decrease stone formation because it may paradoxically lead to increased stone formation due to increased oxalate absorption and consequent hyperoxaluria.

Patients should be encouraged to increase dietary fruit, vegetable, and fiber intake as this may increase urinary citrate, provides dietary alkali, and likely replaces consumption of higher-risk foods like animal protein.

B. Calcium Nephrolithiasis

1. Hypercalciuria—Elevated urinary calcium levels (> 4 mg/kg/day or > 250 mg/day for males and > 200 mg/day for females) lead to hypercalciuric calcium nephrolithiasis. After primary hyperparathyroidism has been excluded based on serum calcium and PTH testing, thiazide diuretics should be prescribed since they decrease renal calcium excretion in patients with high urinary calcium and recurrent calcium stones. Chlorthalidone and indapamide are first-line agents since they can be administered once a day, while hydrochlorothiazide for hypercalciuria should be administered twice a day. Despite some evidence questioning the efficacy of thiazides, they remain a mainstay of kidney stone prevention. All patients respond to thiazide diuretics with decreases in urinary calcium unless they have primary hyperparathyroidism or are nonadherent with taking the medication. Clinicians should periodically test patients taking thiazide diuretics for hypokalemia. Patients should be encouraged to increase their dietary potassium intake by focusing on greater fruit and vegetable intake, and if insufficient, some patients may require potassium supplementation. Patients with hypercalciuria are at risk of bone mineral density problems due to the excessive calcium losses in the urine, though treatment with thiazide diuretics can halt and increase bone density 1% per year while receiving therapy.

2. Hyperuricosuria—Hyperuricosuric calcium nephrolithiasis is defined by elevated urinary uric acid levels (> 800 mg/day for males and > 750 mg/day for females). It is usually secondary to dietary purine excess or endogenous uric acid metabolic defects. Excess uric acid in the urine can lead to uric acid stones if the urine pH is low, or to calcium stones if a crystal forms and then calcifies. Dietary purine restriction can reduce hyperuricosuria in 85% of cases. Patients with hyperuricosuria, normocalciuria, and recurrent calcium oxalate stones can be successfully treated with allopurinol. *However, allopurinol is not first-line treatment of uric acid stones; urinary alkalinization is first-line therapy (see below).*

3. Hyperoxaluria—Hyperoxaluric calcium nephrolithiasis (> 40 mg/day of urinary oxalate) is usually due to either an intestinal malabsorption disorder or a mismatch in dietary calcium and oxalate intake. Patients with a history of chronic diarrhea, inflammatory bowel disease, malabsorption, or gastric bypass surgery are at risk for hyperoxaluria. In these disorders, increased intestinal fat or bile (or both) combine with calcium to form a soap-like product. Calcium is therefore unavailable to bind to oxalate, leading to free oxalate absorption. Even a small increase in free oxalate absorption significantly increases risk of stone formation. If the process cannot be effectively curtailed, oral calcium should be increased with meals, either by diet or by taking low-dose calcium carbonate supplements (250 mg). When dietary calcium and oxalate intake are consumed concurrently, they are unable to be absorbed systemically since they bind together in the intestinal tract. But if dietary calcium is restricted, or if dietary oxalate is excessive, free oxalate is rapidly absorbed and excreted in the urine, leading to hyperoxaluric calcium nephrolithiasis. Treatment includes adhering to a diet containing moderate calcium intake (1000–1200 mg daily). Treatment also involves avoiding high-oxalate-containing foods including potatoes, cocoa powder and chocolate, beets, spinach, rhubarb, Swiss chard, nuts of all types, and soy products. Patients with excess urinary oxalate levels should be reminded to avoid soy milk and nut-based products (peanut butter, almond milk). Patients with lactose intolerance may select rice milk, oat milk, and hemp milk. NOTE: High-dose ascorbic acid (> 2000 mg/day) will substantially increase urinary oxalate levels.

4. Hypocitraturia—Urinary citrate is the most important inhibitor of stone formation. Urinary citrate binds to calcium, decreasing available calcium for precipitation and subsequent stone formation. Low urine citrate levels (< 450 mg/day) increase the risk of stones. **Hypocitraturic calcium nephrolithiasis** is usually idiopathic. Hypocitraturia occurs secondary to any metabolic acidemia (chronic diarrhea, distal renal tubular acidosis), or with low serum potassium levels (long-term treatment with thiazide or loop diuretics). Usually, effective treatment in these situations is potassium citrate supplementation: a typical dose is 40–60 mEq total daily intake, divided into two or three daily doses. Alternatively, there are over-the-counter drinks such as lemonade and orange juice that have been shown to modestly increase urinary citrate. However, they must be consumed in fairly large quantities and can contain tremendous calories if not consumed as a diet variety. Several supplements have been rigorously tested and are available as an alternative to prescription potassium citrate (Moonstone powder, LithoLyte powder, Kidney COP, KSP tabs, LithoBalance, NOW potassium citrate capsules, TheraLith XR) with varying levels of citrate, alkali, and cost.

C. Uric Acid Calculi

Urinary pH is the most important contributor to uric acid stone formation, and thus first-line efforts to prevent uric acid stones should focus on alkalinizing the urine with oral potassium citrate or sodium bicarbonate. Efforts to decrease urinary uric acid (with allopurinol 300 mg/day orally) should be reserved for patients continuing to form stones *despite* adequate urinary alkalinization and hydration. In patients who form pure uric acid stones, urine pH is consistently < 5.5. Increasing the urinary pH dramatically increases uric acid solubility, leading to prevention of stone formation (with urine pH > 6.0) and to stone dissolution (with urine pH > 6.5). *Nitrazine pH test strips* (which turn blue with alkaline urine pH > 6.0) are often useful to some patients in reinforcing adherence to urinary alkalinization efforts. Less common contributors to uric acid stone formation include hyperuricemia, myeloproliferative disorders, chemotherapy for malignancies with rapid cell turnover or cell death, abrupt and dramatic weight loss, and uricosuric medications (probenecid).

D. Struvite Calculi

Struvite stones are composed of magnesium-ammonium-phosphate and are faintly visible on plain radiographs. They are most common in women with recurrent UTIs and patients with chronic bladder catheters and are due to urease-producing organisms, including *Proteus*, *Pseudomonas*, *Providencia*, and, less commonly, *Klebsiella*, *Staphylococcus*, and *Mycoplasma* (but not *E coli*). Clinically, they rarely present with colic from a ureteral stone. Instead, a struvite stone is discovered as a large staghorn calculus forming a cast of the renal collecting system and is often associated with recurrent UTIs with the same organism. Urinary pH is high, routinely above 7.2. Struvite stones are relatively soft and amenable to percutaneous removal. Appropriate perioperative antibiotics are required. They can recur rapidly, and efforts should be taken to remove all of the stone and then to prevent further UTIs and reduce bacterial colonization levels. Some patients who develop recurrent struvite stones benefit from methenamine 1 g twice daily plus vitamin C 500 mg twice daily to suppress bacterial growth. Cases that recur despite methenamine and vitamin C may require a daily prophylactic antibiotic or acetohydroxamic acid, which is typically reserved for refractory cases that have not responded to other treatments as the medication is often poorly tolerated and has a significant side-effect profile.

E. Cystine Calculi

Cystine stones are caused by a genetic metabolic defect resulting in abnormal excretion of cystine. These stones are exceptionally challenging to manage medically. Prevention involves markedly increasing fluid intake during the day and night to achieve a urinary volume of 3–4 L/day, decreasing sodium and dietary cystine intake, and increasing urinary alkalinization (typically with high-dose potassium citrate) with a goal urinary pH > 7.0. Refractory stone formers may be treated with disulfide inhibitors such as tiopronin (α-mercaptoproprionylglycine) or penicillamine. There are no known inhibitors of cystine calculi.

Medical Expulsion & Surgical Treatment

Signs of infection, including associated fever, tachycardia, hypotension, and elevated WBC count, may indicate a UTI behind the obstructing stone. **Any obstructing stone with associated infection is a medical emergency requiring urology consultation and prompt drainage of the kidney with a ureteral stent or a percutaneous nephrostomy tube.** Antibiotics alone are inadequate and only used as an adjunct to drainage of the infected urine behind the obstruction.

In the acute setting, forcing intravenous fluids will not push stones down the ureter. Forced diuresis is counterproductive and exacerbates pain and can lead to fluid overload; instead, a euvolemic state should be achieved.

A. Ureteral Stones

Ureteral stones are usually discovered at three sites: the ureteropelvic junction, the crossing of the ureter over the iliac artery, or the ureterovesicular junction. Stones smaller than 5–6 mm in diameter usually pass spontaneously. **Medical expulsive therapy** with α-blockers (eg, tamsulosin 0.4 mg orally once daily) in combination with an anti-inflammatory agent (eg, ibuprofen 600 mg orally three times per day), with or without a short course of a low-dose oral corticosteroid (eg, prednisone 10 mg orally daily for 5–10 days), may increase the rate of spontaneous stone passage and appears to be most effective for distal stones > 5 mm. Patients should be advised that this use of α-blockers is common but off-label. *Attempted medical expulsive therapy with effective pain medications and imaging follow-up are appropriate for a few weeks. If the stone fails to pass within 4 weeks, the patient has fever, intolerable pain, or persistent nausea or vomiting, or the patient must return to work or anticipates travel, then surgical intervention is indicated.*

Stones in the mid and distal ureter that require surgical removal are best managed with ureteroscopy. Ureteroscopic stone treatment is an outpatient procedure typically performed under general anesthesia involving placement of a small endoscope through the urethra and bladder and into the ureter. Under direct vision, basket extraction or laser fragmentation is performed. Recent evidence supports concurrent treatment of additional kidney stones at the time of ureteral stone treatment, as it dramatically reduces the risk of relapse. A ureteral stent is often placed temporarily to allow drainage of the kidney while the swelling and inflammation from the stone and procedure resolve.

Extracorporeal shock wave lithotripsy (SWL) can be offered as second-line therapy. SWL utilizes an external energy source focused on the stone with the aid of fluoroscopy or ultrasonography. SWL is typically performed under anesthesia or sedation as an outpatient procedure with the goal of stone fragmentation. Most stone fragments then pass uneventfully within 2 weeks. Occasionally, the stone fails to fragment well and fragments obstruct the ureter. Conservative management usually results in spontaneous resolution of the obstruction with eventual passage of the stone fragments. Fragments that have not passed within 6 weeks are unlikely to do so without intervention. SWL is strictly contraindicated in patients who are pregnant, have untreated UTI, have uncorrected coagulopathy, or must continue receiving anticoagulant or antiplatelet therapy. A ureteral stent is typically not necessary with SWL.

Proximal ureteral stones can be treated with SWL or ureteroscopy. SWL is less successful with larger stones and those that are very dense. In cases of SWL failure, ureteroscopic treatment is required.

B. Renal Calculi

Patients with small, asymptomatic, nonobstructing renal calculi, without UTI or obstruction, may not warrant surgical treatment. If surveillance is undertaken, the patient should be monitored with serial abdominal radiographs or renal ultrasonographic examinations every 3–12 months. If the calculi grow or become symptomatic, intervention is indicated. SWL is most effective for stones < 1 cm in the lower pole of the kidney or < 2 cm elsewhere in the kidney. SWL is less effective for stones that are very hard (cystine, brushite, calcium oxalate stones > 1000–1200 Hounsfield units on CT scan) and for obese patients (skin-to-stone distance > 10–12 cm). SWL is discouraged in staghorn and infectious stones. Ureteroscopy and **laser lithotripsy** are effective for multiple stones and larger stones, although very large stones may require multiple treatment sessions. As laser lithotripsy is performed with direct vision, stones tend to be more completely fragmented. Stones larger than 15–20 mm and staghorn calculi (large, branched stones occupying at least two renal calices) are best treated via **percutaneous nephrolithotomy**. Percutaneous nephrolithotomy is performed by inserting a needle into the appropriate renal calyx and dilating a tract large enough to allow a nephroscope to pass directly into the kidney. Larger and more complex renal stones can be identified, fragmented, and removed. In unusual cases, laparoscopic, robotic-assisted, or open stone removal may be considered.

When to Refer

- Evidence of urinary obstruction.
- Urinary stone with associated flank pain.
- Anatomic abnormalities, solitary kidney, or CKD.
- Larger stones (approximately 6 mm or larger) including staghorn stones.
- Concomitant pyelonephritis or recurrent UTI.

When to Admit

- Intractable nausea and vomiting or pain.
- Obstructing stone with fever or other signs of infection.

MALE SEXUAL DYSFUNCTION & ERECTILE DYSFUNCTION

ESSENTIALS OF DIAGNOSIS

- Erectile dysfunction is an exceedingly common condition that negatively impacts quality of life when left untreated.
- Most erectile dysfunction is related to underlying medical issues, may be an early sign of cardiovascular disease, and requires evaluation.
- Peyronie disease is a common disorder caused by scar formation within the erectile bodies of the penis resulting in pain, penile deformity, and sexual dysfunction.
- Peyronie disease is treatable by intralesional medication, surgery, or a combination of both.

General Considerations

Male sexual dysfunction is manifested in a variety of ways, and patient history is critical to proper classification and treatment. **Erectile dysfunction** is the consistent inability to attain or maintain a sufficiently rigid penile erection for sexual intercourse. *More than half of men aged 40–70 years have erectile dysfunction, and its incidence increases with age.* Loss of erections may result from neurogenic, arterial, venous, hormonal, or psychological causes. Concurrent medical problems may damage one or more of the mechanisms. Normal male erection relies on intact autonomic and somatic nerves to the penis, arterial blood flow supplied by the paired cavernosal arteries, and smooth and striated musculature of the corpora cavernosa and pelvic floor. Erection is initiated by nerve impulses in the pelvic plexus leading to an increase in arterial flow, active relaxation of the smooth muscle within the sinusoids of the corpora cavernosa, and an increase in venous resistance. Contraction of the ischiocavernosus muscle causes further rigidity of the penis with intracavernosal pressures exceeding systolic blood pressure. Nitric oxide is the key neurotransmitter that initiates and sustains erections.

The most common cause of erectile dysfunction is a decrease in arterial flow resultant from progressive vascular disease. Endothelial dysfunction results from the decreased bioavailability of nitric oxide with subsequent impairment of arterial vasodilation. *Erectile dysfunction may be an early manifestation of systemic endothelial dysfunction, which precedes more severe atherosclerotic cardiovascular disease.* Many medications, especially antihypertensive, antidepressant, and opioid agents, are associated with erectile dysfunction.

Anejaculation is the loss of seminal emission and may result from androgen deficiency by decreasing prostate and seminal vesicle secretions, or by sympathetic denervation as a result of spinal cord injury, diabetes mellitus or pelvic or retroperitoneal surgery or radiation. **Retrograde ejaculation** may occur as a result of mechanical disruption of the bladder neck due to congenital abnormalities, transurethral prostate surgery, pelvic radiation, sympathetic denervation, or treatment with α-blockers. **Premature ejaculation** refers to ejaculation with minimal stimulation and before a person desires, which may cause significant distress. Primary premature ejaculation may be treated with behavioral modification, sexual health counseling, local anesthetic agents, and systemic medications used alone or in combination. Secondary premature ejaculation is due to erectile dysfunction and responds to treatment of the underlying disorder. **Peyronie disease** is a fibrotic disorder of the tunica albuginea of the penis resulting in varying degrees of penile pain, curvature, or deformity. Peyronie disease affects up to 10% of men and, similar to erectile dysfunction, is more common with increased age. While 10% of men improve spontaneously, 50% will stabilize and the remainder will progress if left untreated. Penile deformity can impair normal sexual function and impact self-esteem.

Priapism is prolonged painful penile erection in the absence of sexual stimulation that results in ischemic injury of the corpora cavernosa from venous congestion, blood coagulation within the cavernous sinuses, and complete cessation of arterial inflow (low flow or "ischemic" priapism). **Ischemic priapism is a medical emergency requiring immediate medical or surgical intervention to avoid irreversible penile damage.** Ischemic priapism may be caused by RBC dyscrasias, drug use, and any of the treatments for erectile dysfunction.

Clinical Findings

A. Symptoms and Signs

Erectile dysfunction should be distinguished from problems with libido, orgasm, ejaculation, and penile deformity. The severity, intermittency, timing, and associated symptoms of erectile dysfunction should be noted. The history should include inquiries about dyslipidemia, hypertension, depression, neurologic disease, diabetes mellitus, kidney disease, endocrine disorders, and cardiac or peripheral vascular disease. Pelvic trauma, surgery, or irradiation increases a man's likelihood of erectile dysfunction. Histories of prostate cancer treatment or Peyronie disease should be queried. In the absence of other medical history, the onset of erectile dysfunction may be the first sign of endothelial dysfunction and further cardiovascular risk stratification should be considered. Medication use should be reviewed, with special attention given to the use of nitrate-containing medications. Alcohol, tobacco, marijuana, and other recreational drug use are associated with an increased risk of sexual dysfunction. Validated instruments, such as the Sexual Health Inventory for Men (SHIM) or Erectile Hardness Score (EHS), can be used for screening and diagnosing erectile dysfunction as well as monitoring therapeutic response.

During the physical examination, vital signs, body habitus (obesity), and secondary sexual characteristics should be assessed. Basic cardiovascular and neurologic examinations should be performed. The genitalia should be examined, noting the stretched length of the penis, fibrosis of the penile shaft, and any abnormalities in size or consistency of either testicle.

B. Laboratory Findings

Laboratory evaluation should be performed in select cases based on patient history and physical examination findings. Possible testing includes serum lipid profile, glucose, and testosterone. Patients with an abnormal testosterone should have measurement of free testosterone and LH to distinguish hypothalamic-pituitary dysfunction from primary testicular failure.

Treatment

Treatment of men suffering from sexual dysfunction should be patient-centered and goal-oriented. Lifestyle modification and reduction of cardiovascular risk factors are important components of treatment and should include smoking cessation; reduction of alcohol intake; diet; exercise; and treatment of diabetes, dyslipidemia, and hypertension. Men who have a psychogenic component to their erectile dysfunction or who are experiencing emotional distress will benefit from sexual health therapy or psychological counseling.

A. Hormonal Replacement

In men with hypogonadism who have undergone complete endocrinologic evaluation, restoration of normal testosterone levels may improve sexual function (see Male Hypogonadism in Chapter 31).

B. Vasoactive Therapy

1. Oral agents—Sildenafil, vardenafil, tadalafil, and avanafil inhibit phosphodiesterase type 5 (PDE-5), preventing the degradation of cGMP and increasing blood flow into the penis. These medications are similar but have variable effectiveness in different patients. The medications have variable durations of onset, activity, and side effects. Each medication should be initiated at the lowest dose and titrated to achieve the desired effect. These medications are *contraindicated in patients taking nitroglycerin or nitrates*, since there may be exaggerated cardiac preload reduction causing hypotension and syncope.

The combination of PDE-5 inhibitors and α-receptor blockers (prescribed for lower urinary tract symptoms) may cause a larger reduction in systemic blood pressure than when PDE-5 inhibitors are used alone. However, these two classes of medication may be safely used in combination if they are initiated and titrated in a stepwise fashion.

2. Injectable or suppository medications—Injection of prostaglandin E_1 into the corpora cavernosa is an acceptable form of treatment for erectile dysfunction. Injections are performed using a tuberculin-type syringe or a metered-dose injection device. The base and lateral aspect of the penis is used as the injection site to avoid injury to the superficial blood and nerve supply located dorsally. Complications include priapism, penile pain, bruising, fibrosis, and infection. Prostaglandin E_1 is often compounded with papaverine, phentolamine, or atropine to increase effectiveness and reduce side effects, most notably penile discomfort. Patients using such compounded agents should be cautioned about the risk of priapism and variability of drug effect due to differences in compounding. Prostaglandin E_1 can also be delivered via an intraurethral suppository, but this is not widely available.

C. Vacuum Erection Device

The vacuum erection device creates negative pressure around the penis, drawing blood into the corpora cavernosa. Once tumescence is achieved, an elastic constriction band is placed around the penile base to prevent loss of erection. Such devices are effective but may cause penile discomfort and numbness leading to a high rate of disuse. Serious complications are rare.

D. Penile Prosthetic Surgery

Penile prostheses are surgically implanted into the paired corpora cavernosa and may be semi-rigid (malleable) or inflatable. Inflatable prostheses are self-contained hydraulic devices that result in relatively natural appearance and function. Inflatable prosthetics are used most commonly because they emulate the tumescence and detumescence of the normal erection. This therapy is appropriate for patients who have not achieved a satisfactory response to other therapies.

E. Medical and Surgical Therapy for Peyronie Disease

Oral medications have been found to have little benefit for reduction of penile curvature associated with Peyronie disease and should not be recommended. Injectable collagenase *Clostridium histolyticum* is approved by the FDA for the treatment of Peyronie disease. Collagenase enzymatically severs disordered collagen fibers after injection into the penile plaque, causing improvement in penile curvature. Surgical treatment is an alternative for men with compromised sexual function due to severe curvature, with lesions causing penile instability, or with inadequate results from collagenase. The choice of corrective procedure should be tailored to each patient after a detailed evaluation of disease severity and sexual function.

When to Refer

- Patients with erectile dysfunction who have an unsatisfactory response to oral medications.
- Patients with Peyronie disease or other penile deformity.
- Patients with sexual dysfunction and a history of pelvic or perineal trauma, surgery, or radiation.
- Patients with priapism to the emergency department for immediate intervention to allow restoration of penile perfusion.

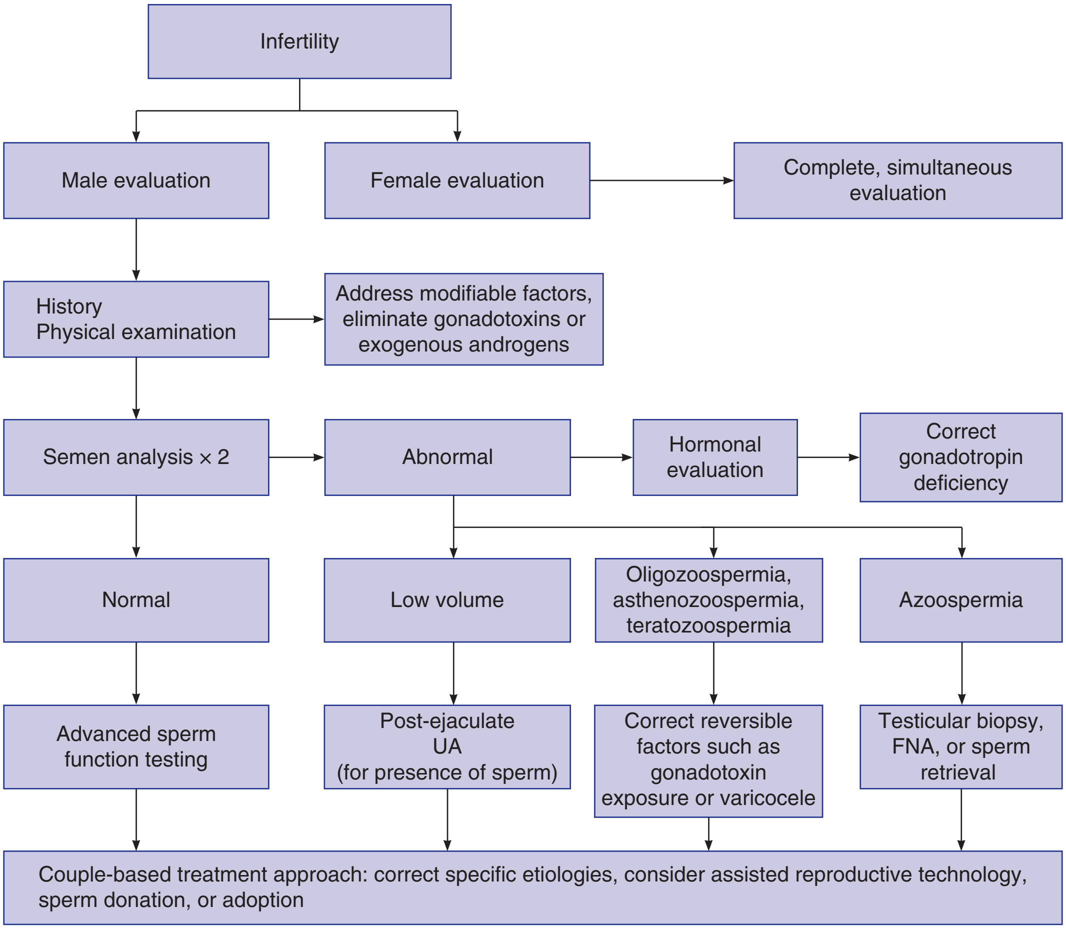
MALE INFERTILITY

ESSENTIALS OF DIAGNOSIS

- Infertility is common, and male factors contribute to up to 50% of cases.
- Causes include decreased or absent sperm production or function, or obstruction of the male genital tract.
- Abnormal semen quality is a risk factor for infertility and may indicate poor health or increased risk of certain health conditions.

General Considerations

Infertility is the inability of a couple to conceive a child after 1 year of sexual intercourse without contraceptive use. It affects 15–20% of couples in the United States, and *male factors contribute to up to half of cases*. The evaluation of both partners is critical for optimizing treatment. Following a detailed history and physical examination, a semen analysis should be performed at least twice, on two separate occasions (Figure 26–2). Because spermatogenesis requires approximately 75 days, it is important to review health events and gonadotoxic exposures from the preceding 3 months. Male infertility is associated with a higher risk of testicular germ cell cancer and with a higher rate of medical comorbidity. These men should be



Infertility
Male evaluation
Female evaluation
Complete, simultaneous evaluation
History
Physical examination
Address modifiable factors, eliminate gonadotoxins or exogenous androgens
Semen analysis × 2
Abnormal
Hormonal evaluation
Correct gonadotropin deficiency
Normal
Low volume
Oligozoospermia, asthenozoospermia, teratozoospermia
Azoospermia
Advanced sperm function testing
Post-ejaculate UA (for presence of sperm)
Correct reversible factors such as gonadotoxin exposure or varicocele
Testicular biopsy, FNA, or sperm retrieval
Couple-based treatment approach: correct specific etiologies, consider assisted reproductive technology, sperm donation, or adoption

▲ **Figure 26–2.** Couple-based approach to evaluation and treatment of male factor infertility. FNA, fine-needle aspiration.

counseled and screened appropriately and taught testicular self-examination.

Clinical Findings

A. Symptoms and Signs

The history should include prior testicular insults (torsion, cryptorchidism, trauma), infections (mumps orchitis, epididymitis, sexually transmitted infections, COVID-19), environmental factors (excessive heat, radiation, chemotherapy, prolonged pesticide exposure), medications (testosterone, finasteride, cimetidine, selective serotonin reuptake inhibitors, and spironolactone may affect spermatogenesis; phenytoin may lower FSH; sulfasalazine and nitrofurantoin affect sperm motility; tamsulosin causes retrograde ejaculation), and other drugs (alcohol, tobacco, marijuana). Sexual function, frequency and timing of intercourse, use of lubricants, and each partner's previous fertility are important. Past medical and surgical history should be surveyed for chronic disease, including obesity, cardiovascular, thyroid, or liver disease (decreased spermatogenesis); diabetes mellitus (decreased spermatogenesis, retrograde or anejaculation); or radical pelvic or retroperitoneal surgery (absent seminal emission secondary to sympathetic nerve injury).

Physical examination should assess features of hypogonadism: underdeveloped sexual characteristics, diminished male pattern hair distribution (axillary, body, facial, pubic), body habitus, gynecomastia, and obesity. Testicular size should be noted (normal size approximately 4.5 × 2.5 cm, volume 18 mL). **Varicoceles** are abnormally dilated, refluxing veins of the pampiniform plexus that can be identified in the standing position by gentle palpation of the spermatic cord and, on occasion, may only be appreciated with the Valsalva maneuver. The vasa deferentia and epididymides should be palpated (absence of all or part of one or both of the vasa deferentia may indicate the presence of a cystic fibrosis variant, congenital bilateral or unilateral absence of the vasa deferentia).

B. Laboratory Findings

Semen analysis should be performed after 2–5 days of ejaculatory abstinence. The specimen should be analyzed within 1 hour after collection. Abnormal sperm concentrations are < 15 million/mL (**oligozoospermia** is the presence of < 15 million sperm/mL in the ejaculate; **azoospermia** is the complete absence of sperm). Normal semen volume should be equal to or > 1.5 mL (lesser volumes may be due to retrograde ejaculation, ejaculatory duct obstruction, congenital bilateral absence of the vasa deferentia, or hypogonadism). Normal sperm motility and morphology demonstrate > 39% motile cells and > 3% normal morphology. Abnormal motility (asthenozoospermia) may result from varicocele, antisperm antibodies, infection, abnormalities of the sperm flagella, or ejaculatory duct obstruction. Abnormal morphology may result from a varicocele, infection, or exposure to gonadotoxins (eg, tobacco, marijuana).

Endocrine evaluation is warranted if sperm concentration is below 10 million sperm/mL or if the history and physical examination suggest an endocrinologic origin. Initial testing should include serum total testosterone and FSH. Specific abnormalities in these hormones should prompt additional testing, including serum LH, free testosterone, prolactin, and estradiol. Elevated FSH and LH levels and low testosterone levels (**hypergonadotropic** or **primary hypogonadism**) are associated with primary testicular failure. Low FSH and LH associated with low testosterone (**hypogonadotropic** or **secondary hypogonadism**) may be of hypothalamic or pituitary origin. Elevation of serum prolactin may indicate the presence of prolactinoma. Elevation of estradiol may indicate abnormal peripheral conversion of testosterone to estrogen by aromatase.

C. Genetic Testing

Men with sperm concentrations < 1 million/mL should consider testing for Y chromosome microdeletions and karyotypic abnormalities. Gene deletions from the long arm of the Y chromosome may cause azoospermia or oligozoospermia with age-related decline in spermatogenesis that is transmissible to male offspring. When small (5 mL), firm testes are identified, karyotyping should be performed to identify Klinefelter syndrome. Partial or complete absence of the vasa deferentia should prompt testing for gene pathogenic variants associated with cystic fibrosis.

D. Imaging

Scrotal ultrasound aids in characterizing the testes and may detect a testicular mass or varicocele. Men with low ejaculate volume and no evidence of retrograde ejaculation may undergo transrectal ultrasound to evaluate the prostate and seminal vesicles. MRI of the sella turcica should be performed in men with elevated prolactin or hypogonadotropic hypogonadism to evaluate the anterior pituitary gland. MRI of the pelvis and scrotum should be considered for men in whom the testes cannot be identified in the scrotum by physical examination or ultrasound. Men with unilateral absence of the vas deferens should have abdominal ultrasound or CT to exclude absence of the ipsilateral kidney.

Treatment

A. General Measures

Education about intercourse timing in relation to the woman's ovulatory cycle as well as the avoidance of spermicidal lubricants should be discussed. In cases of gonadotoxic exposure or medication-related factors, the offending agent should be removed whenever feasible. Patients with active genitourinary tract infections should be treated with appropriate antibiotics. Healthy lifestyle habits, including diet, exercise, and avoidance of gonadotoxins (tobacco, excessive alcohol, and marijuana), should be reinforced.

B. Varicocele

Varicocelectomy is performed to prevent retrograde blood flow in abnormal spermatic cord veins. Surgical ligation, which is accomplished via a subinguinal incision with the aid of a surgical microscope and Doppler ultrasound, is the gold standard approach given its high efficacy and low complication rates. Percutaneous venographic embolization of varicoceles is another approach but incurs both radiation and intravenous contrast exposure. Embolization may be the best approach for recurrence of varicocele after surgery.

C. Endocrine Therapy

Hypogonadotropic hypogonadism may be treated with human chorionic gonadotropin (2000 IU intramuscularly three times a week) once primary pituitary disease has been excluded or treated. If sperm concentration fails to rise after 12 months, recombinant FSH therapy should be initiated (150 IU subcutaneously three times a week). Clomiphene citrate is a selective estrogen receptor modulator (SERM) that stimulates a functioning pituitary gland to increase gonadotropin production. Anastrozole inhibits aromatization of testosterone to estradiol, thereby enhancing gonadotropin production. While studied extensively in men, neither clomiphene nor anastrozole is approved by the US FDA for treatment of male infertility. Therefore, men should be counseled appropriately before using either medication.

D. Ejaculatory Dysfunction Therapy

Patients with retrograde ejaculation may benefit from α-adrenergic agonists (pseudoephedrine, 60 mg orally three times a day) or imipramine (25 mg orally three times a day). Medical failures may require the collection of post-ejaculation urine for intrauterine insemination. Anejaculation can be treated with vibratory stimulation or electroejaculation in select cases, or may warrant surgical sperm retrieval for use with in vitro fertilization (IVF).

E. Ductal Obstruction

Obstruction of the vas deferens after vasectomy may be treated by microsurgical vasectomy reversal or by surgical sperm retrieval in combination with IVF. While dependent on the duration of vasectomy, overall, microsurgical vasectomy reversal is highly successful in returning sperm to the ejaculate.

F. Assisted Reproductive Techniques

Intrauterine insemination and in vitro fertilization (with or without intracytoplasmic sperm injection) are alternatives for patients in whom other means of treating reduced sperm concentration, motility, or functionality have failed. Intrauterine insemination should be performed only when adequate numbers of motile sperm are noted in an ejaculate sample. With the use of intracytoplasmic sperm injection, some men with azoospermia may still initiate a pregnancy by surgical retrieval of sperm from the testicle, epididymis, or vas deferens.

When to Refer

- Couples with infertility or who are concerned about their fertility potential.
- Men with known genital insults, genetic diagnoses, or syndromes that preclude natural fertility.
- Reproductive-aged men with newly diagnosed cancer or other disease that may require cytotoxic therapies with interest in fertility preservation.

BENIGN PROSTATIC HYPERPLASIA

ESSENTIALS OF DIAGNOSIS

- History and physical examination including digital rectal examination.
- International prostate symptom score and UA.
- In-office testing to assess prostate size and shape, assessment of postvoid residual and urinary flow rate.
- Characterize obstructive or irritative voiding symptoms.
- Absence of UTI, neurologic disorder, stricture disease, prostatic or bladder malignancy.

General Considerations

Benign prostatic hyperplasia is extremely common, and its incidence rises with increasing age. Autopsy studies have shown histologically proven *BPH in 60% of men aged 60 and 80% of men aged 80. Bothersome urinary symptoms related to BPH also increase with age, although it is important to note that these symptoms can occur without significant enlargement on exam*. Obstructive voiding symptoms are reported by approximately 25% of men aged 55 and 50% of men aged 75. *It is critical for the clinician to discriminate between "obstructive" and "irritative" symptoms to target the root cause of that patient's bother.* This may be related to prostatic enlargement, high smooth muscle tone at the bladder neck or prostatic urethra, or underlying detrusor overactivity, which all require specific treatments.

Risk factors for the development of BPH are poorly understood. Some studies have suggested a genetic predisposition and some have noted racial differences. Approximately 50% of men under age 60 years who undergo surgery for BPH may have a heritable form of the disease. This form is most likely an autosomal dominant trait, and first-degree male relatives of such patients carry an increased relative risk of approximately fourfold.

Lower urinary tract symptoms result from the complex interplay of a dynamic system and are often multifactorial.

Clinical Findings

A. Symptoms

The symptoms of BPH can be divided into obstructive and irritative complaints. *Obstructive symptoms* include hesitancy, decreased force and caliber of the stream, sensation of incomplete bladder emptying, double voiding (urinating a second time within minutes), straining to urinate, and postvoid dribbling. *Irritative symptoms* include urgency, dysuria, frequency, and nocturia.

The American Urological Association (AUA) symptom index (Table 26–4) is an important tool used in the evaluation of patients with this disorder and should be calculated for all patients before starting therapy. The answers to seven questions quantitate the severity of obstructive or irritative complaints on a scale of 0–5. Thus, the score can range from 0 to 35 with increasing severity of symptoms. An estimation of *postvoid residual* can provide important information on bladder emptying and the need for more urgent intervention.

A detailed history focusing on the urinary tract should be obtained to exclude other possible causes of symptoms such as prostate cancer, UTI, neurogenic bladder, or urethral stricture. A focused medical history may also reveal other comorbidities that can directly affect urinary symptoms such as metabolic syndrome, HF, Parkinson disease, and obstructive sleep apnea.

B. Signs

A physical examination, digital rectal examination (DRE), and a focused neurologic examination should be performed on all patients. The size and consistency of the prostate should be noted. While prostate size does not correlate perfectly with the severity of symptoms or the degree of

Table 26–4. American Urological Association symptom index for benign prostatic hyperplasia.[1]

Questions to Be Answered	Not at All	Less Than One Time in Five	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finish urinating?	0	1	2	3	4	5
2. Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5
3. Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5

[1] Sum of seven circled numbers equals the symptom score. See text for explanation.

Reproduced, with permission, from Barry MJ et al; Measurement Committee of the American Urological Association. The American Urological Association symptom index for benign prostatic hyperplasia. J Urol. 2017;197(2S):S189-97.

obstruction, it can inform treatment decisions. BPH usually results in a smooth, firm, elastic enlargement of the prostate. Induration, if detected, must alert the clinician to the possibility of cancer, and further evaluation is needed (ie, PSA testing, transrectal ultrasound, and biopsy). Examination of the lower abdomen may reveal a distended bladder.

C. Laboratory Findings

UA should be performed to exclude infection or hematuria. Clinicians should consider obtaining a serum PSA test in patients within the screening age range.

D. Imaging

Urologists are advised to consider prostate volume assessment prior to surgical intervention to determine the most appropriate approach (eg, water vapor therapy for smaller glands vs simple prostatectomy for a very large gland). This assessment can be done with cystoscopy; transrectal ultrasound; or cross-sectional imaging of the pelvis.

E. Cystoscopy

Cystoscopy is not required to determine the need for treatment but may assist in determining the best approach in patients opting for surgical therapy.

F. Additional Tests

Uroflowmetry and postvoid residual should be assessed prior to surgical treatment of the prostate and can be useful in tracking response to treatments. Cystometrograms and urodynamic profiles should be reserved for patients with unclear etiology of symptoms, suspected neurologic disease, or those who have not responded to previous prostate surgery.

Differential Diagnosis

A history of prior urethral instrumentation, urethritis, sexually transmitted infections, or trauma should be elucidated to exclude urethral stricture or bladder neck contracture. Hematuria and pain are commonly associated with bladder stones. Carcinoma of the prostate may be detected by abnormalities on DRE or an elevated PSA (see Chapter 44). A UTI can mimic the irritative symptoms of BPH and can be readily identified by UA and culture; however, a UTI can also be a complication of BPH. Carcinoma of the bladder, especially carcinoma in situ, may also present with irritative voiding complaints; however, UA usually shows evidence of hematuria (see Chapter 44). Patients with a neurogenic bladder may also have many of the same symptoms and signs as those with BPH; however, a history of neurologic disease, stroke, diabetes mellitus, or back injury may be obtained, and diminished perineal or lower extremity sensation or alterations in rectal sphincter tone or in the bulbocavernosus reflex might be observed on examination. Simultaneous alterations in bowel function (constipation) might also suggest the possibility of a neurologic disorder. Urodynamics studies can distinguish between neurogenic etiologies and obstructive etiologies for poor bladder emptying.

Treatment

Clinical practice guidelines exist for the evaluation and treatment of patients with BPH. Following the evaluation as outlined above, patients may be offered various forms of therapy for BPH. Patients are advised to consult with their primary care clinicians or urologists to make an educated decision on the basis of the relative efficacy and side effects of the treatment options.

Patients with mild symptoms (AUA scores 0–7) and relatively low bother scores may be managed by watchful waiting only. *Medical therapy is appropriate for those with significant bother attributed to their symptoms.* Surgery should be considered for those who have moderate to severe symptoms and have failed medical therapy. This is defined as a lack of efficacy, progressive symptoms despite medical treatment, or medication side effects or adverse reactions. More serious sequelae of BPH—recurrent UTI, recurrent gross hematuria attributed to the prostate, bladder stones, refractory urinary retention (failing at least one attempt at catheter removal), or obstructive nephropathy—are classic indications for surgery, but patients should generally be trialed on medical management prior to proceeding to surgery.

A. Watchful Waiting

The risk of progression or complications is uncertain. Not all symptoms require treatment, and intervention should be tailored to the degree of bother and impact on quality of life for most men. While men with progressive symptoms and large prostates do have a higher chance of developing urinary retention or requiring surgical intervention in the future, this risk is thought to be relatively low overall.

A large randomized study from 1998 compared finasteride with placebo in men with moderate to severely symptomatic disease and enlarged prostates on DRE. Patients in the placebo arm demonstrated a 7% risk of developing urinary retention over 4 years. Behavioral and lifestyle modifications may be offered prior to medical or surgical therapy.

B. Medical Therapy

1. α-Blockers—α-adrenergic receptors are ubiquitous, but the prostate and bladder neck have high levels of α_{1A}-receptors. Activation of these receptors results in increased prostatic smooth muscle tone, urethral constriction, and impaired urine flow. Blocking these receptors leads to smooth muscle relaxation and reduced resistance at the bladder outlet. α-blockade has been shown to result in both objective and subjective degrees of improvement in the symptoms and signs of BPH. α-blockers can be classified according to their receptor selectivity (Table 26–5) as well as their half-life.

Several nonselective α-blockers previously utilized in the treatment of BPH have fallen out of favor for more selective medications. Terazosin and doxazosin can still be offered but require dose titration and have higher rates of orthostatic hypotension and dizziness; prazosin and phenoxybenzamine are not used in BPH treatment.

Table 26–5. α-blockade agent treatment for benign prostatic hyperplasia (listed in alphabetical order).

Agent	Action	Oral Dose
Alfuzosin	α_{1A}-blockade	10 mg daily
Doxazosin	α_1-blockade	1–8 mg daily
Silodosin	α_{1A}-blockade	4 or 8 mg daily
Tadalafil	Phosphodiesterase type 5 inhibitor	5 mg daily
Tamsulosin	α_{1A}-blockade	0.4 or 0.8 mg daily
Terazosin	α_1-blockade	1–10 mg daily

Long-acting, nonselective α-blockers allow for once-a-day dosing, but dose titration is necessary. Terazosin improves symptoms, and in numerous studies, it is superior to placebo or finasteride. Terazosin is started at a dosage of 1 mg orally daily for 3 days, increased to 2 mg orally daily for 11 days, then 5 mg orally daily. Additional dose escalation to 10 mg orally daily can be performed if necessary. Doxazosin is started at a dosage of 1 mg orally daily for 7 days, increased to 2 mg orally daily for 7 days, then 4 mg orally daily. Additional dose escalation to 8 mg orally daily can be performed if necessary.

α_{1A}-receptors are localized to the prostate and bladder neck. Selective blockade of these receptors results in fewer systemic side effects than nonselective α-blocker therapy thus obviating the need for dose titration. The typical dose of tamsulosin is 0.4 mg orally daily taken 30 minutes after a meal. Alfuzosin is a long-acting α_{1A}-blocker; its dose is 10 mg orally once daily with food, and it does not require titration. Several randomized, double-blind, placebo-controlled trials have been performed comparing terazosin, doxazosin, tamsulosin, and alfuzosin with placebo. All agents have demonstrated safety and efficacy. **Floppy iris syndrome**, a complication of cataract surgery, can occur in patients taking both nonselective α-blockers and α_{1A}-blockers well after cessation of therapy.

2. 5-α-Reductase inhibitors—Finasteride and dutasteride block the conversion of testosterone to dihydrotestosterone, resulting in reduction in size of the gland and improvement in symptoms. *Six months of therapy are required for maximum effects on prostate size* (20–30% reduction) and symptomatic improvement.

Several randomized, double-blind, placebo-controlled trials have been performed comparing finasteride with placebo. Efficacy, safety, and durability are well established. However, symptomatic improvement is seen only in men with enlarged prostates (> 40 mL by ultrasonographic examination). Side effects include decreased libido, decrease in volume of ejaculate, and erectile dysfunction. *Serum PSA is reduced by approximately 50% in patients receiving finasteride therapy, but the % free PSA is unchanged.* Therefore, in order to compare with pre-finasteride PSA levels, the serum PSA of a patient taking finasteride should be doubled.

Studies have shown that finasteride therapy decreases the incidence of urinary retention and the need for operative treatment in men with enlarged prostates and moderate to severe symptoms. The larger the prostate over 40 mL, the greater the relative-risk reduction. Dutasteride is a nonselective 5-α-reductase inhibitor (5ARI) that appears to be similar to finasteride in its effectiveness; it is dosed at 0.5 mg orally daily.

Both 5ARIs have been shown to be effective chemopreventive agents for prostate cancer in large RCTs. A 25% risk reduction was observed in men with both low and high risk for prostate cancer. However, despite the strength of the evidence for 5ARIs in reducing the risk of prostate cancer, an FDA advisory committee recommended against labeling these agents for prostate cancer chemoprevention, citing the *potential increased risk of high-grade cancers* in these studies (1.8% vs 1.0% for finasteride and 1% vs 0.5% for dutasteride), isolated risk reduction in low-grade cancers, and inability to apply the findings to the general population. Moreover, the FDA has included the increased risk of being diagnosed with high-grade prostate cancer in the labels of all 5ARIs.

3. Phosphodiesterase-5 inhibitor—Tadalafil is approved by the FDA to treat the symptoms and signs of BPH (Table 26–5); it is also approved for first-line use in men with both urinary symptoms and erectile dysfunction. The data from two randomized, double-blind, placebo-controlled trials demonstrated significant improvements in standardized measurements of urinary function between 2 and 4 weeks after initiating treatment at 5 mg once daily, with minimal adverse effects.

4. Combination therapy—The Medical Therapy of Prostatic Symptoms (MTOPS) trial (2003) was a large, randomized, placebo-controlled trial comparing finasteride, doxazosin, the combination of the two, and placebo in 3047 men observed for a mean of 4.5 years. Long-term combination therapy with doxazosin and finasteride was safe and reduced the risk of overall clinical progression of BPH significantly more than did treatment with either medication alone. Combination therapy and finasteride alone reduced the long-term risk of acute urinary retention and the need for invasive therapy.

C. Surgical Therapy

Most cases of BPH requiring surgery can be managed with transurethral or minimally invasive techniques. This remains an area of active research and innovation with several new technologies available. An overview of all the surgical options and decision making was published by the American Urological Association (Figure 26–3).

1. Transurethral resection of the prostate (TURP)—Over 95% of prostate surgeries can be performed endoscopically (through the urethra). TURP is the gold standard treatment for surgical treatment of BPH, and it often requires a 1- to 2-day hospital stay. Most head-to-head surgical studies comparing TURP to minimally invasive therapies show that symptom scores and flow rate improvements are superior following TURP compared with other minimally invasive therapies. It is one of the most durable treatments available, with patients remaining symptom-free for an average of 5–10 years. The risks of TURP include retrograde ejaculation (75%), erectile dysfunction (5–10%), and urinary incontinence (< 1%). Potential complications include (1) bleeding; (2) urethral stricture or bladder neck contracture; (3) perforation of the prostate capsule with extravasation; and (4) **transurethral resection syndrome**, a hypervolemic, hyponatremic state resulting from absorption of the hypotonic irrigating solution. This is rarely seen currently, as bipolar electrocautery and isotonic saline irrigation have largely replaced monopolar electrocautery for TURP.

2. Transurethral incision of the prostate (TUIP)—Men with moderate to severe symptoms and small prostates (< 30 g) often have posterior commissure hyperplasia or an “elevated bladder neck.” These patients will often benefit from incision of the prostate. The procedure is more rapid and less morbid than TURP. Outcomes in well-selected patients are comparable, though a lower rate of retrograde ejaculation has been reported (25%).

3. Photoselective vaporization of the prostate (PVP)—Various laser technologies exist and vary by wavelength and energy produced. The original KTP greenlight laser uses a 532-nm wavelength that is selectively absorbed by hemoglobin, leading to improved hemostasis. Advantages include combined vaporization and coagulation with significant reduction in tissue volume, making this an *ideal choice for anticoagulated patients*. Outcomes are similar to those seen with TURP. Disadvantages include limitations on prostate volume that can be efficiently treated (< 80 cc) and difficulty controlling bleeding from larger venous channels, the lack of tissue for pathologic examination, variable effectiveness, and more frequent irritative voiding during recovery.

4. Aquablation—This ultrasound-guided, robot-executed waterjet ablation of the prostate is designed to relieve prostatic obstruction with limited bleeding, shorter operative time, and preservation of sexual function. It is one of the few size-agnostic transurethral surgical options for BPH and has been shown to effectively treat glands ranging in size from 30 mL to 150 mL. Urinary outcomes have been shown to be comparable to the gold standard TURP with lower risk of stricture, incontinence, and sexual dysfunction. Pretreatment transrectal ultrasound is used to map out the obstructive adenoma to be ablated, while excluding the ejaculatory ducts. Real-time transrectal ultrasound is then used to monitor tissue resection during the procedure. The resection is performed under general or spinal anesthesia using a heat-free water jet from a transurethrally placed robotic handpiece with simultaneous suction of ablation tissue through the device. Following the resection, electrocautery or traction from a three-way catheter is used to obtain hemostasis. A 5-year multicenter clinical trial (2022) showed significant and sustained improvements in urinary flow rate, postvoid residual volume, and quality of life.

5. Laser enucleation—Holmium laser enucleation of the prostate (**HoLEP**) is a technique of enucleating the

• TUIP4
• TURP
• TUVP
MEDICALLY COMPLICATED PATIENTS

Patients concerned with preservation of erectile and ejaculatory function may be offered PUL or WVTT as data indicate that both therapies provide a greater likelihood of preservation of sexual function.

In patients who are at higher risk of bleeding, such as those on anticoagulation drugs, therapies with a lower need for blood transfusion, such as HoLEP, PVP, and ThuLEP, should be considered. For additional information on the use of anticoagulation and antiplatelet therapy in surgical patients, refer to the ICUD/AUA review on Anticoagulation and Antiplatelet Therapy in Urologic Practice.

Based on the evidence reports of the current guidelines, the following criteria are recommended when utilizing these approaches:

[1] RWT: prostate volume 30–80 cc.

[2] PUL: absence of obstructing midline prostate tissue and prostate volume 30–80 cc.

[3] WVTT: prostate volume 30–80 cc.

[4] TUIP: prostate volume ≤30 cc.

[5] TIPD: prostate volume 25–75 cc and absence of obstructive middle lobe.

▲ **Figure 26–3.** **Surgical management of lower urinary tract symptoms attributed to BPH. adenomatous lobes intact and morcellating the tissue within the bladder. Advantages of HoLEP compared with other methods include ability to treat all prostate sizes, low re-treatment rates, few complications, and shorter duration of bladder catheterization. There is a higher rate of transient stress incontinence, but this typically resolves within 3 months. This technique is an attractive alternative to the simple prostatectomy for very large glands (> 100 cc) with comparable outcomes. However, due to the steep learning curve for operators, it is not as widely available as other techniques. It may also be performed via **thulium laser enucleation of the prostate (ThuLEP)** depending upon surgeon experience and preference.

D. Minimally Invasive Therapies

1. Prostatic urethral lift (UroLift)—The UroLift system uses permanent nitinol and stainless steel implants placed under cystoscopic guidance to retract the lateral lobes of the prostate and mechanically open the prostatic urethra. The procedure can be performed under local anesthesia in the outpatient setting, and holding anticoagulation medication is not necessary. The ideal candidate has primarily lateral lobe hyperplasia and a prostate volume under 80 cc. Short-term data show improved symptoms and voiding flow rates with no de novo erectile dysfunction or incontinence. Re-treatment rates within 5 years have been reported to be as high as 13.6%.

2. Water vapor thermal therapy (Rezūm)—This minimally invasive technique uses a modified cystoscope to deliver water vapor into the prostatic tissue. As the steam condenses back into water, it releases large amounts of stored thermal energy leading to tissue necrosis and resorption of tissue within about 3 months. This procedure is done in the clinic or ambulatory surgery setting; it requires 3–7 days of bladder catheterization. In contrast to the UroLift procedure, there is a significant reduction in prostate volume over time, about 30% by 6 months, which relieves lower urinary tract symptoms as a result. A 5-year RCT reported significant objective improvement in lower urinary tract symptoms as early as 2 weeks post-procedure, improvement that remained durable throughout the 5-year period. Recommended prostate volume for Rezūm treatment is 30–80 cc. Advantages include the minimally invasive, outpatient nature of the procedure with no significant bleeding risk even for anticoagulated patients, ability to treat the median lobe, and no reports of de novo erectile dysfunction or urinary incontinence. Disadvantages include slower recovery and longer bladder catheterization times compared to TURP and laser procedures. Surgical re-treatment rate at 5 years was reported to be 4.4%, a rate far lower than other minimally invasive options.

3. Optilume balloon dilation—The Optilume BPH catheter system is the first minimally invasive device with a dual mechanical and pharmacological mechanism of action that builds on the device's original use in treating recurrent urethral strictures. The BPH balloon creates an anterior commissurotomy with simultaneous paclitaxel delivery to prevent regrowth or refusion of the anterior prostatic lateral lobes. A double-blind, randomized, sham-controlled study showed improvement in flow rate, post-void residual (PVR), and patient satisfaction scores that were sustained at 1 year. Treatment was limited to prostates ranging in size from 20 to 80 mL, and long-term benefit has yet to be proven.

4. Temporary implantable nitinol device (iTIND)—This procedure involves placing a device with three expanding nitinol struts into the prostatic urethra and bladder neck. It is left in place for 5–7 days and then removed. The resulting ischemic necrosis from the struts leaves grooves or channels, similar to a TUIP. Early data shows benefit in smaller prostates, but more study is needed to determine optimal patient selection and durability.

E. Simple Prostatectomy

When the prostate is very large, a simple prostatectomy by an open or robotic enucleation approach may be considered. Glands > 100 cc are usually considered for enucleation. In addition to size, other relative indications for simple prostatectomy include when there is a concomitant bladder diverticulum or stone, and when dorsal lithotomy positioning of the patient is not possible. The robotic approach has improved recovery, lower blood loss, and shortened hospital stays.

F. Prostate Artery Embolization

Initially described in the 1970s to control bleeding, angioembolization of the bilateral prostatic arteries has been shown to reduce prostate volume, and recent data show some relief of urinary symptoms. Selective embolization using 100- to 500-mcm microspheres results in a low risk of nontarget ischemia. Due to its minimally invasive nature it can be considered in select patients, particularly those with larger glands who are not candidates for other available treatments.

When to Refer

- Obstructive uropathy.
- Patient dissatisfaction with medical therapy.
- Patient interest in surgical treatments.
- Need for further evaluation (cystoscopy) or surgical intervention.

Nervous System Disorders

Vanja C. Douglas, MD
Michael J. Aminoff, MD, DSc, FRCP

HEADACHE

Headache is such a common complaint and can occur for so many different reasons that its proper evaluation may be difficult. New, severe, or acute headaches are more likely than chronic headaches to relate to an intracranial disorder; the approach to such headaches is discussed in Chapter 2. **Chronic headaches** may be primary or secondary to another disorder. Common **primary** headache syndromes include migraine, tension-type headache, and cluster headache. Important **secondary** causes to consider include intracranial lesions, head injury, cervical spondylosis, dental or ocular disease, temporomandibular joint dysfunction, sinusitis, hypertension, depression, and a wide variety of general medical disorders. Although underlying structural lesions are *not* present in most patients presenting with headache, it is nevertheless important to bear this possibility in mind. About one-third of patients with brain tumors, for example, present with a primary complaint of headache.

1. Migraine

ESSENTIALS OF DIAGNOSIS

- Headache, usually pulsatile, lasting 4–72 hours.
- Pain is typically, but not always, unilateral.
- Nausea, vomiting, photophobia, and phonophobia are common accompaniments.
- Pain is aggravated with routine physical activity.
- An aura of transient neurologic symptoms (commonly visual) may precede head pain in one quarter of patients.

General Considerations

The pathophysiology of migraine probably relates to neuronal dysfunction in the trigeminal system resulting in release of vasoactive neuropeptides such as calcitonin gene–related peptide leading to neurogenic inflammation, sensitization, and headache. Migraine aura is hypothesized to result from cortical spreading depression, a wave of neuronal and glial depolarization that moves slowly across the cerebral cortex corresponding to the clinical symptoms (ie, occipital cortex and visual aura). Migraine often exhibits a complex, polygenic pattern of inheritance. Sometimes, an autosomal dominant inheritance pattern is apparent, as in **familial hemiplegic migraine**, in which attacks of lateralized weakness represent the aura.

Clinical Findings

Typical migrainous headache is a lateralized throbbing headache that occurs episodically following its onset in adolescence or early adult life. In many cases, the headaches do not conform to this pattern, although their associated features and response to antimigrainous medications nevertheless suggest a similar basis. In this broader sense, migrainous headaches may be lateralized or generalized, may be dull or throbbing, and are sometimes associated with anorexia, nausea, vomiting, photophobia, phonophobia, osmophobia, cognitive impairment, and blurring of vision. They usually build up gradually and last several hours or longer. Headaches are often preceded by a 24–48 hour prodrome of mood or autonomic symptoms. Focal disturbances of neurologic function (**migraine aura**) may precede or accompany the headaches. Visual disturbances occur commonly and may consist of field defects (**scotoma**); of luminous visual hallucinations such as stars, sparks, unformed light flashes (**photopsia**), geometric patterns, or zigzags of light; or of some combination of field defects and luminous hallucinations (**scintillating scotomas**). Other focal disturbances such as aphasia or numbness, paresthesias, clumsiness, dysarthria, dysequilibrium, or weakness in a circumscribed distribution may also occur.

In rare instances, the neurologic or somatic disturbance accompanying typical migrainous headaches becomes the sole manifestation of an attack ("**migraine aura without headache**"). Rarely, the patient may be left with a permanent neurologic deficit following a migrainous attack, and migraine with aura is a risk factor for stroke.

Patients often give a family history of migraine. Attacks may be triggered by emotional or physical stress, lack or excess of sleep, missed meals, odors, alcoholic beverages, bright lights, loud noise, menstruation, or use of oral contraceptives.

An uncommon variant is **migraine with brainstem aura**, in which blindness or visual disturbances throughout both visual fields are accompanied or followed by dysarthria, dysequilibrium, tinnitus, and perioral and distal paresthesias and are sometimes followed by transient loss or impairment of consciousness or by a confusional state. This, in turn, is followed by a throbbing (usually occipital) headache, often with nausea and vomiting.

In **recurrent painful ophthalmoplegic neuropathy** (previously termed "ophthalmoplegic migraine"), lateralized pain—often about the eye—is accompanied by nausea, vomiting, and diplopia due to transient external ophthalmoplegia. The ophthalmoplegia is due to third nerve palsy, sometimes with accompanying sixth nerve involvement, and may outlast the orbital pain by several days or even weeks. The ophthalmic division of the fifth nerve has also been affected in some patients. The condition is rare and a diagnosis of exclusion; more common causes of a painful ophthalmoplegia are internal carotid artery aneurysms and diabetes.

Treatment

Management of migraine consists of avoidance of any precipitating factors, together with prophylactic or symptomatic pharmacologic treatment if necessary.

A. Symptomatic Therapy

During acute attacks, rest in a quiet, darkened room may be helpful until symptoms subside. A simple analgesic (eg, aspirin, acetaminophen, ibuprofen, or naproxen) taken immediately often provides relief, but prescription medication is sometimes necessary. *To prevent medication overuse, use of simple analgesics should be limited to 15 days or less per month, and, in general, other medications should be limited to no more than 10 days per month.*

1. Ergotamines—Cafergot, a combination of ergotamine tartrate (1 mg) and caffeine (100 mg), is often helpful; one or two tablets are taken at the onset of headache or warning symptoms, followed by one tablet every 30 minutes, if necessary, up to six tablets per attack and no more than 10 days per month. Cafergot given rectally (one-half to one suppository containing 2 mg of ergotamine) or dihydroergotamine mesylate intravenously (0.5–1 mg) or subcutaneously or intramuscularly (1–2 mg), or intranasally (0.5 mg in each nostril) may be useful when vomiting precludes use of oral medications. Ergotamine-containing preparations should be *avoided* during pregnancy, in patients with CVD or its risk factors, and in patients taking potent CYP 3A4 inhibitors.

2. Serotonin agonists—Triptans are 5-HT$_{1b/1d}$ receptor agonists that inhibit release of vasoactive neuropeptides. Sumatriptan is a rapidly effective agent for aborting attacks when given subcutaneously by an autoinjection device (4–6 mg once subcutaneously, may repeat once after 2 hours if needed; maximum dose 12 mg/24 hours). Nasal and oral preparations are available but may be less effective due to slower absorption. Zolmitriptan is available in oral and nasal formulations. The dose is 5 mg orally or in one nostril once; this may be repeated once after 2 hours. The maximum dose for both formulations is 10 mg/24 hours. Other triptans are available, including rizatriptan (5–10 mg orally at onset, may repeat every 2 hours twice [maximum dose 30 mg/24 hours]); naratriptan (1–2.5 mg orally at onset, may repeat once after 4 hours [maximum dose 5 mg/24 hours]); almotriptan (6.25–12.5 mg orally at onset, may repeat once after 2 hours [maximum dose 25 mg/24 hours]); frovatriptan (2.5 mg orally at onset, may repeat once after 2 hours [maximum dose 7.5 mg/24 hours]); and eletriptan (20–40 mg orally at onset; may repeat once after 2 hours [maximum dose 80 mg/24 hours]). Eletriptan is useful for immediate therapy, and frovatriptan, which has a longer half-life, may be worthwhile for patients with prolonged attacks or attacks provoked by menstrual periods. Patients often experience greater benefit when the triptan is combined with naproxen (500 mg orally).

Triptans may cause nausea and vomiting. They are best avoided in persons who are pregnant, and in patients with hemiplegic or basilar migraine, a history of stroke or transient ischemic attack, or uncontrolled hypertension. In patients whose hypertension is controlled, triptans are commonly used safely, although caution is advised. *Triptans are contraindicated in patients with coronary or peripheral vascular disease and Prinzmetal angina.*

Lasmiditan (50–200 mg taken once at headache onset; no more than one dose in 24 hours) is a 5-HT$_{1F}$ receptor agonist that lacks the vasoconstrictive properties of triptans and can be given safely to patients with cardiovascular risk factors. Dizziness and somnolence are common side effects, and patients should not drive within 8 hours of administration.

3. Calcitonin gene–related peptide antagonists—Rimegepant sulfate (75 mg orally dissolved tablet taken once at headache onset; maximum dose 75 mg/24 hours), ubrogepant (50 or 100 mg orally at headache onset, may repeat once after 2 hours; maximum dose 200 mg/24 hours), and zavegepant (10 mg intranasally once in one nostril at headache onset, 10 mg/spray; maximum dose 10 mg/24 hours) achieve pain freedom in 20% and pain relief in 60% of patients within 2 hours. Hypersensitivity reactions may occur immediately or several days after administration with rimegepant.

4. Other agents—Prochlorperazine is effective and may be administered rectally (25 mg suppository), intravenously or intramuscularly (5–10 mg), or orally (5–10 mg). Intravenous metoclopramide (10–20 mg) is also useful in the emergency department setting. Various butalbital-containing combination oral analgesics risk overuse and dependence and should only be used as a last resort. Opioid analgesics should be *avoided* because of high rates of rebound headache and the tendency to develop **medication overuse headache**.

5. Neuromodulation—Sham-controlled trials show that single-pulse transcranial magnetic stimulation aborts migraine with aura, and noninvasive vagus nerve stimulation, transcutaneous trigeminal nerve stimulation, and remote electrical stimulation applied to the upper arm abort migraine with or without aura. Transcranial magnetic stimulation is contraindicated in patients with epilepsy.

B. Preventive Therapy

Preventive treatment may be necessary if migraine headaches occur more frequently than two or three times a month or significant disability is associated with attacks. Avoidance of triggers and maintenance of homeostasis with regular sleep, meals, and hydration should not be neglected; a headache diary may be useful to identify triggers. Some more common agents used for prophylaxis are listed in Table 27–1. The medication chosen first will vary with the individual patient, depending on factors such as comorbid obesity, depression, anxiety, hypertension, and patient preference. Several medications may have to be tried in turn before headaches are brought under control. Once a medication has been found to help, it should be continued for several months. If the patient remains headache-free, the dose may be tapered and the medication eventually withdrawn. Acupuncture reduces headache frequency and intensity in migraine, with and without aura, and is as effective and safer than prophylactic pharmacologic treatment in migraine without aura and **chronic migraine** (at least 15 days per month with headaches lasting 4 hours per day or longer). Botulinum toxin type A injected into selected head and neck muscles reduces headache frequency in chronic migraine. Transcutaneous supraorbital neurostimulation, single-pulse transcranial magnetic stimulation, and non-invasive vagus nerve stimulation reduced headache frequency as reflected in a meta-analysis of RCTs and are approved in the United States. A meta-analysis of placebo-controlled trials showed biofeedback therapy to be highly effective for prevention of migraine.

Chen Y et al. Non-invasive brain stimulation treatments for migraine prophylaxis: a network meta-analysis of randomized controlled trials. Acta Neurol Belg. 2023;123:1481. [PMID: 37184609]

Whealy M et al. The 5-HT1B and 5-HT1D agonists in acute migraine therapy: ergotamine, dihydroergotamine, and the triptans. Handb Clin Neurol. 2024;199:17. [PMID: 38307644]

2. Tension-Type Headache

This is the most common type of primary headache disorder. Patients frequently report pericranial tenderness, poor concentration, and other nonspecific symptoms, in addition to headaches that are often vise-like or tight in quality but not pulsatile. Headaches may be exacerbated by emotional stress, fatigue, noise, or glare. The headaches are usually generalized, may be most intense about the neck or back of the head, and are not associated with focal neurologic symptoms. There is diagnostic overlap with migraine.

Abortive therapy with simple analgesics is usually effective. Anti-migraine preparations are *not* recommended unless the patient has comorbid migraine headaches. Tricyclic antidepressants, such as amitriptyline, are supported for headache prophylaxis by randomized trial evidence and often are tried first. Treatment of comorbid anxiety or depression is important. Behavioral therapies that may be effective include physical therapy, biofeedback therapy, and relaxation training.

Florczyk S et al. Headache treatment options. J Am Board Fam Med. 2024;37:737. [PMID: 39455276]

3. Cluster Headache

Cluster headache affects predominantly middle-aged men. The pathophysiology is unclear but may relate to activation of cells in the ipsilateral hypothalamus, triggering the trigeminal autonomic vascular system. There is often no family history of headache or migraine. Episodes of severe unilateral periorbital pain occur daily for several weeks and are often accompanied by one or more of the following: ipsilateral nasal congestion, rhinorrhea, lacrimation, redness of the eye, and Horner syndrome (ptosis, pupillary meiosis, and facial anhidrosis or hypohidrosis). During attacks, patients are often restless and agitated. Episodes typically occur at night, awaken the patient, and last between 15 minutes and 3 hours. Spontaneous remission then occurs, and the patient remains well for weeks or months before another bout of closely spaced attacks. *Bouts may last for 4 to 8 weeks and may occur up to several times per year.* During a bout, many patients report alcohol triggers an attack; others report that stress, glare, or ingestion of specific foods occasionally precipitates attacks. In occasional patients, remission does not occur. This variant has been referred to as **chronic cluster headache**. In longstanding cases, Horner syndrome may persist between attacks.

Cluster headache is one of the **trigeminal autonomic cephalgias**, which include hemicrania continua, paroxysmal hemicrania, and short-lasting neuralgiform headache attacks. Similar to cluster headache, the other trigeminal autonomic cephalgias consist of unilateral periorbital pain associated with ipsilateral autonomic symptoms such as conjunctival injection and tearing; they are distinguished from cluster headache by different attack duration and frequency and, in some cases, their exquisite responsiveness to indomethacin.

Treatment of an individual attack with oral medications is generally unsatisfactory, but subcutaneous (6–12 mg) or intranasal (20 mg/spray) sumatriptan or inhalation of 100% oxygen (12–15 L/min for 15 minutes via a nonrebreather mask) are effective. Zolmitriptan (5–10 mg nasal spray) is also effective. Dihydroergotamine (0.5–1 mg intramuscularly or intravenously) or viscous lidocaine (1 mg of 4–6% solution intranasally) is sometimes effective.

Various prophylactic agents include oral medications such as verapamil (start at 240 mg daily, increase by 80 mg every 2 weeks to 960 mg daily, with routine ECG to monitor the PR interval), lithium carbonate (start at 300 mg daily, titrating according to serum levels and treatment response up to a typical total daily dose of 900–1200 mg, divided three or four times), topiramate (100–400 mg daily), and galcanezumab (300 mg subcutaneously monthly until end of cluster period). As there is often a delay before these medications are effective, transitional therapy is often used. Prednisone (60–100 mg daily for 5 days followed by gradual withdrawal over 7–10 days) is effective in 70–80% of patients, and suboccipital corticosteroid injection about the greater occipital nerve is effective in 75%. Ergotamine tartrate can be given as rectal suppositories (0.5–1 mg at

Table 27–1. Pharmacologic prophylaxis of migraine (listed in alphabetical order within classes).

Medication	Usual Adult Oral Daily Dose	Selected Side Effects and Comments
Antiepileptic[1]		
Topiramate[2]	100 mg (divided twice daily)	Somnolence, nausea, dyspepsia, irritability, dizziness, ataxia, nystagmus, diplopia, glaucoma, renal calculi, weight loss, hypohidrosis, hyperthermia.
Valproic acid[2]	500–1000 mg (divided twice daily)	Nausea, vomiting, diarrhea, drowsiness, alopecia, weight gain, hepatotoxicity, thrombocytopenia, tremor, pancreatitis.
Cardiovascular		
Candesartan[2,3]	8–32 mg once daily	Dizziness, cough, diarrhea, fatigue.
Guanfacine[3]	1 mg once daily	Dry mouth, somnolence, dizziness, constipation, erectile dysfunction.
Propranolol[2,4]	80–240 mg (divided twice to four times daily)	Fatigue, dizziness, hypotension, bradycardia, depression, insomnia, nausea, vomiting, constipation.
Verapamil[3,5]	120–240 mg (divided three times daily)	Headache, hypotension, flushing, edema, constipation. May aggravate atrioventricular nodal heart block and HF.
Antidepressant[6]		
Amitriptyline[3,7]	10–150 mg at bedtime	Sedation, dry mouth, constipation, weight gain, blurred vision, edema, hypotension, urinary retention.
Venlafaxine[3]	37.5–150 mg extended-release once daily	Nausea, somnolence, dry mouth, dizziness, diaphoresis, sexual dysfunction, anxiety, weight loss.
Monoclonal Antibodies Against Calcitonin Gene–Related Peptide		
Eptinezumab	100 mg intravenously every 3 months	Hypersensitivity reaction during infusion, nasopharyngitis.
Erenumab	70–140 mg subcutaneously once monthly	Injection site reactions, constipation, muscle cramps, antibody development.
Fremanezumab	225 mg subcutaneously once monthly	Injection site reactions, antibody development.
Galcanezumab	120 mg subcutaneously daily × 2 doses, followed by 120 mg monthly	Injection site reactions, antibody development.
Calcitonin Gene–related Peptide Receptor Antagonists		
Atogepant	10–30 mg once daily	Nausea, constipation, fatigue.
Rimegepant	75 mg once every other day	Hypersensitivity, nausea.
Other		
Acupuncture		More rapid pain relief and fewer side effects than pharmacologic treatment.
Botulinum toxin A	Intramuscular injection	Injection site reaction, hypersensitivity, muscle weakness.
Coenzyme Q10	300 mg once daily	
Magnesium citrate	200–300 mg twice daily	Diarrhea, nausea.
Memantine[3]	5 mg once daily to 10 mg twice daily	Somnolence, sedation, nausea.
Riboflavin	400 mg once daily	Yellow-orange discoloration of urine.
Transcutaneous supraorbital neurostimulation	20 minutes daily	Transient paresthesia at site of stimulation.
Transcranial magnetic stimulation	Up to 4 pulses twice daily	Transient light-headedness, paresthesias, tinnitus. Contraindicated in patients with implanted medical devices in head or neck, excluding dental work.
Noninvasive vagus nerve stimulation	Two 2-minute treatments twice daily	Contraindicated in patients with implanted medical devices.

[1] Gabapentin and possibly other antiepileptics have also been used successfully.
[2] Caution or avoid during pregnancy.
[3] Not FDA-approved for this indication.
[4] Other β-adrenergic antagonists such as atenolol, metoprolol, nadolol, and timolol are similarly effective.
[5] Other calcium channel antagonists (eg, nimodipine, nicardipine, and diltiazem) may also help.
[6] Depression is commonly comorbid with migraine disorder and may warrant separate treatment.
[7] Other tricyclic antidepressants (eg, nortriptyline and imipramine) may help similarly.

night or twice daily), by mouth (2 mg daily), or by subcutaneous injection (0.25 mg three times daily for 5 days per week). Noninvasive electrical stimulation of the vagus nerve at headache onset successfully aborts pain in 30–50% of attacks; this treatment is approved in the United States.

May A et al. European Academy of Neurology guidelines on the treatment of cluster headache. Eur J Neurol. 2023;30:2955. [PMID: 37515405]

4. Posttraumatic Headache

A variety of nonspecific symptoms may follow closed head injury, regardless of whether consciousness is lost (see Head Injury). Headache is often a conspicuous feature. It usually appears within a day or so following injury, may worsen over the ensuing weeks, and then gradually subsides. It is usually a constant dull ache, with superimposed throbbing that may be localized, lateralized, or generalized. Headaches are sometimes accompanied by nausea, vomiting, or scintillating scotomas and often respond to simple analgesics; severe headaches may necessitate preventive treatment as outlined for migraine.

Teli P et al. Headache management in traumatic brain injury. J Neurol Sci. 2024;463:123002. [PMID: 39047510]

5. Primary Cough Headache

Severe head pain may be produced by coughing (and by straining, sneezing, and laughing) but, fortunately, usually lasts for a few minutes or less. Intracranial lesions, usually in the posterior fossa (eg, Arnold-Chiari malformation), are present in about 10% of cases, and brain tumors or other space-occupying lesions may present in this way. Accordingly, *CT scanning or MRI should be undertaken in all patients.*

The disorder is usually self-limited, although it may persist for several years. For unknown reasons, symptoms sometimes clear completely after lumbar puncture. Indomethacin (75–150 mg daily orally) may provide relief. Similar activity-triggered headache syndromes include primary exertional headache and primary headache associated with sexual activity.

Nandyala A et al. Primary cough headache. Curr Pain Headache Rep. 2023;27:679. [PMID: 377477622]

6. Headache Due to Giant Cell (Temporal or Cranial) Arteritis

This topic is discussed in Chapter 23.

7. Headache Due to Intracranial Mass Lesion

Intracranial mass lesions of all types may cause headache owing to displacement of vascular structures and other pain-sensitive tissues. While pain and location are nonspecific, headache may be worse upon lying down, awaken the patient at night, or peak in the morning after overnight recumbency. *The key feature prompting brain imaging is a new or worsening headache in middle or later life.* Other features suggesting an intracranial lesion include signs or symptoms of infection or malignancy such as fever, night sweats, and weight loss; immunocompromise; or history of malignancy. Signs of focal or diffuse cerebral dysfunction or of increased intracranial pressure (eg, papilledema) also necessitate investigation.

Friedman SA et al. Secondary headache disorders: approach, workup, and special considerations in select populations. Semin Neurol. 2022;42:418. [PMID: 36220127]

8. Medication Overuse (Analgesic Rebound) Headache

In many patients with **chronic daily headaches**, medication overuse is responsible. Patients have chronic pain or severe headache unresponsive to medication (typically defined as no effect after having been used regularly for more than 3 months). Ergotamines, triptans, medications containing butalbital, and opioids cause medication overuse headache when taken on more than 10 days per month; acetaminophen, acetylsalicylic acid, and NSAIDs may also be offenders if taken on more than 15 days per month. Medications such as lasmiditan and the calcitonin gene–related peptide antagonists have not been associated with overuse headaches; nevertheless, their use is also generally restricted to 10 days per month. Dopamine antagonists are unlikely to cause overuse headache, but their use should also be limited to prevent drug-induced parkinsonism or dyskinesia. Early initiation of a migraine preventive therapy, especially with antibodies to calcitonin gene related peptide, permits withdrawal of analgesics and eventual relief of headache.

Koonalintip P et al. Medication-overuse headache: update on management. Life (Basel). 2024;14:1146. [PMID: 39337929]

9. Headache Due to Other Neurologic Causes

Cerebrovascular disease may be associated with headache, but the mechanism is unclear. Headache may occur with internal carotid artery occlusion or carotid dissection and after carotid endarterectomy. Acute severe headache (**"thunderclap"**) accompanies subarachnoid hemorrhage, carotid or vertebral artery dissection, cerebral venous thrombosis, ischemic or hemorrhagic stroke, reversible cerebral vasoconstriction syndrome, hypertensive crisis, posterior reversible leukoencephalopathy syndrome, pituitary apoplexy, spontaneous intracranial hypotension, vasculitis, and meningeal infections; accompanying focal neurologic signs, impairment of consciousness, and signs of meningeal irritation indicate the need for further investigations. Headaches are also a feature of idiopathic intracranial hypertension (pseudotumor cerebri).

Dull or throbbing headache is a frequent sequela of lumbar puncture and may last for several days. It is aggravated by the erect posture and alleviated by recumbency. The mechanism is unclear, but the headache is commonly attributed to leakage of CSF through the dural puncture site. Its incidence may be reduced if an atraumatic needle (instead of a beveled, cutting needle) is used for the lumbar puncture.

Friedman SA et al. Secondary headache disorders: approach, workup, and special considerations in select populations. Semin Neurol. 2022;42:418. [PMID: 36220127]

When to Refer

- Thunderclap onset.
- Increasing headache unresponsive to simple measures.
- History of trauma, hypertension, fever, visual changes.
- Presence of neurologic signs or of scalp tenderness.

When to Admit

Suspected subarachnoid hemorrhage or other structural intracranial lesion.

FACIAL PAIN

1. Trigeminal Neuralgia

ESSENTIALS OF DIAGNOSIS

- Brief episodes of stabbing facial pain.
- Pain is in the territory of the second and third division of the trigeminal nerve.
- Pain exacerbated by touch.

General Considerations

Trigeminal neuralgia ("tic douloureux") is most common in middle and later life. It affects women more frequently than men. Pain may be due to an anomalous artery or vein impinging on the trigeminal nerve.

Clinical Findings

Momentary episodes of sudden lancinating facial pain commonly arise near one side of the mouth and shoot toward the ipsilateral ear, eye, or nostril. The pain may be triggered by such factors as touch, movement, drafts, and eating. To lessen the likelihood of triggering further attacks, many patients try to hold their face still while talking. Spontaneous remissions for several months or longer may occur. As the disorder progresses, however, the episodes of pain become more frequent, remissions become shorter and less common, and a dull ache may persist between the episodes of stabbing pain. Symptoms remain confined to the distribution of the trigeminal nerve (usually the second or third division) on one side only.

Differential Diagnosis

The characteristic features of the pain in trigeminal neuralgia usually distinguish it from other causes of facial pain. Neurologic examination shows no abnormality except in a few patients in whom trigeminal neuralgia is symptomatic of some underlying lesion, such as multiple sclerosis or a brainstem neoplasm, in which case the finding will depend on the nature and site of the lesion. High-resolution contrast-enhanced brain MRI should be obtained to rule out secondary causes and evaluate for neurovascular compression. Secondary causes are more likely in patients younger than 40 years and those with bilateral symptoms.

Treatment

The medications most helpful for treatment are oxcarbazepine (although not approved by the FDA for this indication) or carbamazepine, with monitoring by serial blood counts and liver biochemical tests. If these medications are ineffective or cannot be tolerated, phenytoin should be tried. Doses and side effects of these medications are shown in Table 27–3. Topiramate (50 mg orally twice daily), lamotrigine (400 mg orally daily), or baclofen (10–20 mg orally three or four times daily) may also be helpful, either alone or in combination with one of these other agents. Gabapentin (up to 3600 mg orally daily) may also relieve pain, especially in patients with multiple sclerosis.

For neuralgia refractory to medical treatment, several surgical treatment options are available that provide initial pain relief in at least 80% of patients. Microvascular surgical decompression with separation of the anomalous vessel (usually not visible on CT scans, MRI, or arteriograms) from the nerve root produces long-term relief of symptoms in roughly 75% of patients. Three less invasive techniques are based on destruction of nociceptive trigeminal nerve fibers, which causes sensory loss in addition to symptom relief in half of patients: (1) radiofrequency rhizotomy produces long-term pain relief in 60% of patients, (2) percutaneous balloon compression of the trigeminal ganglion in 67%, and (3) stereotactic radiosurgery to the trigeminal nerve root in 45%. In older patients, radiofrequency rhizotomy and stereotactic radiosurgery are sometimes preferred because both can be performed without general anesthesia and have few complications. Surgical exploration is inappropriate in patients with trigeminal neuralgia due to multiple sclerosis, but the less invasive techniques are sometimes helpful.

Pergolizzi JV et al. An update on pharmacotherapy for trigeminal neuralgia. Expert Rev Neurother. 2024;24:773. [PMID: 38870050]

2. Atypical Facial Pain

Facial pain without the typical features of trigeminal neuralgia is generally a constant, burning pain that may have a restricted distribution at its onset but soon spreads to the rest of the face on the affected side and sometimes involves the other side, the neck, or the back of the head as well. The disorder is especially common in middle-aged women, many with depression, but it is not clear whether depression is the cause of or a reaction to the pain. Simple analgesics, tricyclic antidepressants, carbamazepine, oxcarbazepine, and phenytoin should be given a trial; however, the response is often disappointing. Opioid analgesics pose a danger of substance use disorder. Attempts at surgical treatment are *not* indicated.

Cutri RM et al. Neuralgia and atypical facial, ear, and head pain. Otolaryngol Clin North Am. 2022;55:595. [PMID: 35680205]

3. Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is an uncommon disorder in which pain similar in quality to that in trigeminal neuralgia occurs in the throat, about the tonsillar fossa, and sometimes deep in the ear and at the back of the tongue. The pain may be precipitated by swallowing, chewing, talking, or yawning and is sometimes accompanied by syncope. In most instances, no underlying structural abnormality is present; multiple sclerosis is sometimes responsible. Oxcarbazepine and carbamazepine are the treatments of choice and should be tried before surgical procedures are considered. Microvascular decompression is often effective and is generally preferred over destructive surgical procedures such as partial rhizotomy in medically refractory cases.

Cutri RM et al. Neuralgia and atypical facial, ear, and head pain. Otolaryngol Clin North Am. 2022;55:595. [PMID: 35680205]

4. Postherpetic Neuralgia

Postherpetic neuralgia develops in about 15% of patients who have herpes zoster (shingles). This complication is especially likely to occur in older or immunocompromised persons, when the rash is severe, and when the first division of the trigeminal nerve is affected. It also relates to the duration of the rash before treatment is instituted. A history of shingles and the presence of cutaneous scarring resulting from shingles aid in the diagnosis. Severe pain with shingles correlates with the intensity of postherpetic symptoms.

Acyclovir (800 mg five times daily) or valacyclovir (1000 mg three times daily), when *given within 72 hours* of rash onset, reduces the incidence of postherpetic neuralgia by almost half; systemic corticosteroids do *not* help prevent postherpetic neuralgia (see Chapter 6). Management of the established complication is with simple analgesics. If they fail to help, a trial of a tricyclic antidepressant (eg, amitriptyline or nortriptyline, up to 100–150 mg daily orally) is often effective. Other patients respond to gabapentin (up to 3600 mg daily orally) or pregabalin (up to 600 mg/daily orally). Subcutaneous injection of botulinum toxin A into the affected region produced sustained pain relief in 87% of patients in a small placebo-controlled trial. Topical application of capsaicin cream may be helpful, as may topical lidocaine (5%). *The administration of* ***recombinant zoster vaccine*** *to patients over the age of 50 years is important in reducing the likelihood of herpes zoster or reducing the severity of postherpetic neuralgia.*

Valero EG et al. Analgesic treatment approach for postherpetic neuralgia: a narrative review. J Pain Palliat Care Pharmacother. 2023;37:184. [PMID: 36731106]

5. Facial Pain Due to Other Causes

Facial pain may be caused by temporomandibular joint dysfunction in patients with malocclusion, abnormal bite, or faulty dentures. There may be tenderness of the masticatory muscles, and sometimes pain begins at the onset of chewing. This pattern differs from that of jaw (masticatory) claudication, a symptom of giant cell arteritis, in which pain develops progressively with mastication. Treatment of the underlying joint dysfunction relieves symptoms.

A relationship of facial pain to chewing or temperature changes may suggest a dental disturbance. The cause is sometimes not obvious, and diagnosis requires careful dental examination and radiographs. Sinusitis and ear infections causing facial pain are usually recognized by a history of respiratory tract infection, fever, and, in some instances, nasal or aural discharge. There may be localized tenderness. Radiologic evidence of sinus infection or mastoiditis is confirmatory.

Glaucoma is an important ocular cause of facial pain, usually localized to the periorbital region.

On occasion, pain in the jaw may be the principal manifestation of angina pectoris. Precipitation by exertion and radiation to more typical areas suggest a cardiac origin.

Barad M et al. Orofacial pain. Continuum (Minneap Minn). 2024;30:1397. [PMID: 39445947]

▶ When to Refer

- Worsening pain unresponsive to simple measures.
- Continuing pain of uncertain cause.
- For consideration of surgical treatment (trigeminal or glossopharyngeal neuralgia).

EPILEPSY

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent unprovoked seizures.
- ▶ Characteristic electroencephalographic changes accompany seizures.
- ▶ Mental status abnormalities or focal neurologic symptoms may persist for hours postictally.

▶ General Considerations

The term “epilepsy” denotes any disorder characterized by *recurrent unprovoked seizures.* A seizure is a transient disturbance of cerebral function due to an abnormal paroxysmal neuronal discharge in the brain. Epilepsy is relatively common, affecting approximately 0.5% of the population in the United States.

Patients with recurrent seizures provoked by a readily reversible cause, such as withdrawal from alcohol or drugs, hypo- or hyperglycemia, or uremia, are not considered to have epilepsy.

▶ Classification of Epilepsy

According to the International League Against Epilepsy classification system, recurrent seizures should be classified first by seizure type, second by epilepsy type, and third, if possible, by epilepsy syndrome. The etiology of recurrent seizures should be sought at each stage of classification (see Etiology of Epilepsy).

A. Seizure Types

The International League Against Epilepsy distinguishes seizures affecting only part of the brain (focal seizures) from those that are generalized.

1. Focal-onset seizures—The initial clinical and electroencephalographic manifestations of focal (partial) seizures indicate that only a restricted part of one cerebral hemisphere has been activated. The ictal manifestations depend on the area of the brain involved. Focal seizures are classified by motor or nonmotor onset as well as by whether awareness is impaired.

A. MOTOR VERSUS NONMOTOR ONSET—Seizures with motor onset may be **clonic, tonic, atonic, myoclonic**, or **hyperkinetic**, or may manifest as **automatisms** or **epileptic spasms**. The most commonly observed focal motor seizures consist of clonic jerking or automatisms. Nonmotor seizures may be manifested by sensory symptoms (eg, paresthesias or tingling, gustatory, olfactory, visual or auditory sensations), behavior arrest, cognitive symptoms (eg, speech arrest, déjà vu, jamais vu), emotional symptoms (eg, fear), or autonomic symptoms or signs (eg, abnormal epigastric sensations, sweating, flushing, pupillary dilation). Focal sensory and motor seizures may spread (or "march") to different parts of the limb or body depending on their cortical representation and were previously called "simple partial" seizures.

B. AWARE VERSUS IMPAIRED AWARENESS—Awareness is defined as knowledge of self and environment and of events occurring during a seizure. Impaired awareness may be preceded, accompanied, or followed by the various motor and nonmotor symptoms mentioned above. Such seizures were previously called "complex partial" seizures.

C. FOCAL TO BILATERAL TONIC-CLONIC—Focal seizures sometimes involve loss of awareness and evolve to bilateral tonic-clonic seizures, in a process previously called "secondary generalization."

2. Generalized onset seizures—Generalized seizures are thought to originate in or rapidly spread to involve *bilateral cortical networks*. In some cases, the distinction between focal and generalized onset can only be made by electroencephalogram (EEG). Generalized seizures are classified into those with motor or nonmotor features. Awareness is typically lost with generalized seizures but may be retained partially in the briefest absence attacks and some myoclonic seizures.

A. NONMOTOR (ABSENCE) SEIZURES—These are characterized by impairment of consciousness, sometimes with mild clonic, tonic, myoclonic, or atonic components (ie, reduction or loss of postural tone), autonomic components (eg, enuresis), or accompanying automatisms. Onset and termination of attacks are abrupt. If attacks occur during conversation, the patient may miss a few words or may break off in midsentence for a few seconds. The impairment of external awareness is so brief that the patient is unaware of it. **Absence ("petit mal") seizures** almost always begin in childhood and frequently cease by the age of 20 years or are then replaced by other forms of generalized seizure. Electroencephalographically, such attacks are associated with bursts of bilaterally synchronous and symmetric 3-Hz spike-wave activity. A normal background in the electroencephalogram and normal or above-normal intelligence imply a good prognosis for the ultimate cessation of these seizures. **Atypical absence seizures** may demonstrate more marked changes in tone, or attacks may have a more gradual onset and termination than in typical absence seizures. They commonly occur in patients with multiple seizure types, may be accompanied by developmental delay or mental retardation, and are associated with slower spike-wave discharges than those in typical absence attacks.

B. MOTOR SEIZURES—Types of generalized motor seizures include **tonic-clonic, clonic, tonic, myoclonic, myoclonic-tonic-clonic, myoclonic-atonic, atonic**, and **epileptic spasms.** During tonic-clonic seizures there is sudden loss of consciousness, the patient becomes rigid and falls to the ground, and respiration is arrested. This tonic phase, which usually lasts for under 1 minute, is followed by a clonic phase in which there is jerking of the body musculature that may last for 2 or 3 minutes and is then followed by a stage of flaccid coma. During the seizure, the tongue or lips may be bitten, urinary or fecal incontinence may occur, and the patient may be injured. Immediately after the seizure, the patient may recover consciousness, drift into sleep, have a further convulsion without recovery of consciousness between the attacks **(status epilepticus)**, or after recovering consciousness have a further convulsion **(serial seizures).** In other cases, patients may behave in an abnormal fashion in the immediate postictal period, without subsequent awareness or memory of events **(postepileptic automatism)**. Headache, disorientation, confusion, drowsiness, nausea, soreness of the muscles, or some combination of these symptoms commonly occurs postictally. Myoclonic seizures consist of single or multiple myoclonic jerks. Atonic seizures consist of brief (< 2 seconds) loss of muscle tone and often result in falls **(epileptic drop attacks)**. **Epileptic spasms** are sudden flexion or extension of truncal muscles; these seizures usually manifest during infancy.

3. Unknown onset seizures—In some circumstances, seizures cannot be classified because of incomplete information or because they do not fit into any category. Generally, with additional information from the history or from video-EEG telemetry, the seizure onset can be correctly classified.

B. Epilepsy Types

The International League Against Epilepsy classifies epilepsy by the seizure type. Thus, epilepsy may be **focal**, **generalized**, or **combined generalized and focal.** The EEG may be helpful in facilitating classification.

C. Epilepsy Syndromes

Epilepsy syndromes are defined by constellations of seizure types, EEG findings, and imaging features, and often also depend on age at onset and comorbidities. Not every patient with epilepsy can be given a syndromic diagnosis. Several well-known epilepsy syndromes exist but are beyond the scope of this chapter.

Etiology of Epilepsy

In parallel to classifying the seizure type, epilepsy type, and epilepsy syndrome (if applicable), the cause of the patient's seizures should be sought. The International League Against Epilepsy lists six broad etiologic categories; sometimes a patient's seizures have more than one etiology.

A. Structural Etiology

1. Pediatric age groups—Congenital abnormalities and perinatal injuries may result in seizures presenting in infancy or childhood.

2. Mesial temporal sclerosis—Hippocampal sclerosis is a recognized cause of focal and secondarily generalized seizures of uncertain etiology.

3. Trauma—Trauma is an important cause of seizures at any age, but especially in young adults. Posttraumatic epilepsy is more likely to develop if the dura mater was penetrated and generally becomes manifest within 2 years following the injury. Seizures developing in the first week after head injury do not necessarily imply that future attacks will occur. There is *no* evidence that prophylactic anticonvulsant medication treatment reduces the incidence of posttraumatic epilepsy.

4. Tumors and other space-occupying lesions—Neoplasms may lead to seizures at any age, but they are an especially important cause of seizures in middle and later life, when the incidence of neoplastic disease increases. Seizures are commonly the initial symptoms of the tumor and often are focal in character. They are most likely to occur with structural lesions involving the frontal, parietal, or temporal regions. *Tumors must be excluded by imaging studies (MRI preferred over CT) in all patients with onset of seizures after 20 years of age, focal seizures or signs, or a progressive seizure disorder.*

5. Vascular diseases—Stroke and other vascular diseases become increasingly frequent causes of seizures with advancing age and are the most common cause of seizures with onset at age 60 years or older.

6. Degenerative disorders—Alzheimer disease and other degenerative disorders are a cause of seizures in later life.

B. Genetic Etiology

This category encompasses a broad range of disorders, for which the age at onset ranges from the neonatal period to adolescence or even later in life. Monogenic disorders tend to exhibit an autosomal dominant pattern of inheritance, and where the mutation is known, the responsible gene often encodes a neuronal ion channel. A genetic etiology may also underpin certain epilepsies with a metabolic or structural basis.

C. Infectious Etiology

Infectious diseases must be considered in all age groups as potentially reversible causes of seizures. Seizures may occur with an acute infective or inflammatory illness, such as bacterial meningitis or herpes encephalitis, or in patients with more longstanding or chronic disorders, such as neurosyphilis or cerebral cysticercosis. In patients with AIDS, seizures may result from CNS toxoplasmosis, cryptococcal meningitis, secondary viral encephalitis, or other infective complications. Seizures are a common sequela of supratentorial brain abscess, developing most frequently in the first year after treatment.

D. Metabolic Etiology

Inborn errors of metabolism and other inherited conditions may cause epilepsy as one of their manifestations (eg, pyridoxine deficiency, mitochondrial disease); these disorders typically present during childhood.

E. Immune Etiology

Autoimmune diseases such as SLE and autoimmune limbic encephalitis may cause epilepsy; often the epilepsy can be cured with immunotherapy and lifelong antiepileptic medication treatment is not necessary.

F. Unknown Etiology

In many cases, the cause of epilepsy cannot be determined.

Clinical Findings

A. Symptoms and Signs

Nonspecific changes such as headache, mood alterations, lethargy, and myoclonic jerking alert some patients to an impending seizure hours before it occurs. *These prodromal symptoms are distinct from the aura*; the aura that may precede a generalized seizure by a few seconds or minutes is itself a part of the seizure indicating focal onset from a restricted part of the brain.

In most patients, seizures occur unpredictably at any time and without any relationship to posture or ongoing activities. Occasionally, however, they occur at a particular time (eg, during sleep) or in relation to external precipitants such as lack of sleep, missed meals, emotional stress, menstruation, alcohol ingestion (or alcohol withdrawal), or use of certain recreational drugs. Fever and nonspecific infections may also precipitate seizures in patients with epilepsy. In a few patients, seizures are provoked by specific stimuli such as flashing lights or a flickering television set (**photosensitive epilepsy**), music, or reading.

Clinical examination between seizures shows no abnormality in patients with idiopathic epilepsy, but in the immediate postictal period, extensor plantar responses may be seen. The presence of lateralized or focal signs postictally suggests that seizures may have a focal origin. In patients with symptomatic epilepsy, the findings on examination will reflect the underlying cause.

B. Imaging

MRI is indicated for patients with focal neurologic symptoms or signs, focal seizures, or electroencephalographic findings of a focal disturbance. It should also be performed in patients with clinical evidence of a progressive disorder and in those with new onset of seizures after the age of 20 years because of the possibility of an underlying neoplasm. CT is generally less sensitive than MRI in detecting small structural brain abnormalities but may be used when MRI is contraindicated or unavailable.

C. Laboratory Studies

Initial investigations after a first seizure should include CBC, serum glucose, electrolytes, creatinine, calcium, magnesium, and liver biochemical tests to exclude various causes of provoked seizures and to provide a baseline for subsequent monitoring of long-term effects of treatment. Routine laboratory investigations are *not* usually necessary after recurrent seizures in patients with known epilepsy. A lumbar puncture may be necessary when any sign of infection is present or in the evaluation of new-onset seizures in the acute setting.

D. Electroencephalography

Electroencephalography may support the clinical diagnosis of epilepsy (by demonstrating paroxysmal abnormalities containing spikes or sharp waves), provide a guide to prognosis, and help classify the seizure disorder. Classification of the disorder is important for determining the most appropriate anticonvulsant medication with which to start treatment. For example, absence and focal seizures with impaired awareness may be difficult to distinguish clinically, but the electroencephalographic findings and treatment of choice differ in these two conditions. Finally, by localizing the epileptogenic source, the electroencephalographic findings are important in evaluating candidates for surgical treatment.

Differential Diagnosis

The distinction between the various disorders likely to be confused with generalized seizures is usually based on the history. *The importance of obtaining an eyewitness account of the attacks cannot be overemphasized.*

A. Differential Diagnosis of Focal Seizures

1. TIAs—These are distinguished from seizures by their longer duration, lack of spread, and negative (eg, weakness or numbness) rather than positive (eg, convulsive jerking or paresthesias) symptoms. Level of consciousness, which is unaltered, does not distinguish them.

2. Migraine aura—Migraine aura may produce positive or negative symptoms, tends to spread slowly from one part of the body to another (over minutes rather than seconds), and is usually longer in duration (minutes to hours). It is usually, but not always, followed by a typical migraine headache.

3. Transient focal neurologic episodes—Most commonly observed in patients with cerebral amyloid angiopathy, these events resemble migraine aura and are theorized to have a similar pathophysiologic basis in cortical spreading depression triggered by areas of superficial siderosis or convexity subarachnoid hemorrhage.

4. Panic attacks—These may be hard to distinguish from focal seizures unless there is evidence of an anxiety disorder between attacks and the attacks have a clear relationship to external circumstances.

5. Rage attacks—These are situational and lead to goal-directed aggressive behavior.

B. Differential Diagnosis of Generalized Seizures

1. Syncope—Syncopal episodes usually occur in relation to postural change, emotional stress, instrumentation, pain, or straining. They are typically preceded by pallor, sweating, nausea, and malaise and lead to loss of consciousness accompanied by flaccidity; recovery occurs rapidly with recumbency, and there is no postictal headache or confusion. In some instances, however, motor accompaniments and urinary incontinence may simulate a seizure.

2. Cardiac disease—Cerebral hypoperfusion due to a disturbance of cardiac rhythm should be suspected in patients with known cardiac or vascular disease or in older patients who present with episodic loss of consciousness. Prodromal symptoms are typically absent. Cardiac rhythm monitoring may be necessary to establish the diagnosis. A relationship of attacks to physical activity and the finding of a systolic murmur are suggestive of aortic stenosis.

3. Brainstem ischemia—Loss of consciousness is preceded or accompanied by other brainstem signs. Basilar artery migraine and vertebrobasilar vascular disease are discussed elsewhere in this chapter.

4. Psychogenic nonepileptic seizure (PNES)—Simulating an epileptic seizure, a PNES may occur due to a conversion disorder or malingering. Many patients also have epileptic seizures or a family history of epilepsy. A history of childhood physical or sexual abuse is common. Although a PNES tends to occur at times of emotional stress, this may also be the case with epileptic seizures.

Clinically, the attacks superficially resemble tonic-clonic seizures, but there may be obvious preparation before a PNES. Moreover, there is usually no tonic phase; instead, there may be an asynchronous thrashing of the limbs and the attack rarely leads to injury. Eyes are often forcibly closed during PNES, unlike epileptic seizures, in which they are typically open. Consciousness may be normal or “lost,” but in the latter context, the occurrence of goal-directed behavior or of shouting, swearing, etc, indicates that it is feigned. Postictally, there are no changes in behavior or neurologic findings.

Often, clinical observation is insufficient to discriminate epileptic from nonepileptic seizures and **video electroencephalographic monitoring** is required. Elevation of serum lactate above 2.4 mmol/L for up to 3 hours after a convulsion is common after a generalized convulsive epileptic seizure but rare after a PNES or transient loss of consciousness from other causes and may be a helpful adjunct to electroencephalography.

Treatment

A. General Measures

For patients with epilepsy, medication is prescribed with the goal of preventing further attacks and is *usually continued until there have been no seizures for at least 2 years*. Patients should be advised to avoid situations that could be dangerous or life-threatening if further seizures should occur. Legislation may require clinicians to report to the state authorities any patients with seizures or other episodic disturbances of consciousness; *driving cessation for 6 months* or as legislated is appropriate following an unprovoked seizure.

1. Choice of medication—Medication selection depends on seizure type, side effect profile, coexisting medical conditions, route of metabolism, drug interactions, and cost (Tables 27–2 and 27–3). In women of childbearing age, special consideration must be given to potential teratogenicity and interactions with oral contraceptives. *All antiepileptics are potentially teratogenic*, although the teratogenicity of the newer antiseizure medications is less clear. Nevertheless, antiepileptic medication must be given to pregnant persons with epilepsy to prevent seizures, which can pose serious risk to the fetus from trauma, hypoxia, or other factors.

The dose of the selected anticonvulsant is gradually increased until seizures are controlled or until side effects prevent further increases. If seizures continue despite treatment at the maximal tolerated dose, a second medication is added and the dose increased depending on tolerance; the first medication is then gradually withdrawn. In most patients with seizures of a single type, satisfactory control can be achieved with a single anticonvulsant. Treatment with two medications may further reduce seizure frequency or severity but usually only at the cost of greater toxicity. Treatment with more than two medications is almost always unhelpful unless the patient is having seizures of different types.

2. Monitoring—Individual differences in drug metabolism cause a given dose of a medication to produce different blood concentrations in different patients, and this will affect the therapeutic response. In general, *the dose of an antiepileptic agent is increased, depending on tolerance, to achieve the desired clinical response regardless of the serum drug level.* When a dose is reached that either controls seizures or is the maximum tolerated, then a steady-state trough drug level may be obtained for future reference; rechecking this level may be appropriate during pregnancy, if a breakthrough seizure occurs, a dose change occurs, or another (potentially interacting) medication is added to the regimen. A laboratory's therapeutic range for a medication is only a guide; many patients achieve good seizure control with no adverse effect at serum levels that exceed the stipulated range, and in these cases no dose adjustment is needed. The most common cause of a lower concentration of medication than expected for the prescribed dose is suboptimal patient adherence. Adherence can be improved by

Table 27–2. Approved indications for antiseizure medications (listed in alphabetical order within seizure type or epilepsy syndrome).

Seizure Type or Epilepsy Syndrome	Approved as Monotherapy or Adjunctive Therapy	Approved Only as Adjunctive Therapy
Absence seizures	Clonazepam[2], ethosuximide, valproic acid	
Akinetic (atonic) seizures	Clonazepam	
Cyclin-dependent kinase-like 5 deficiency	Ganaxolone[3]	
Dravet syndrome	Cannabidiol	
Focal onset seizures	Brivaracetam, carbamazepine, cenobamate, eslicarbazepine felbamate[1], lacosamide, lamotrigine, levetiracetam, oxcarbazepine, perampanel, phenobarbital, primidone, topiramate, valproic acid	Clorazepate, ezogabine, gabapentin, pregabalin, tiagabine, vigabatrin, zonisamide
Generalized onset seizures	Carbamazepine, phenobarbital, primidone, topiramate	Lacosamide, lamotrigine, levetiracetam, perampanel
Infantile spasms	Vigabatrin	
Lennox-Gastaut syndrome	Cannabidiol, clonazepam	Clobazam, felbamate[1], lamotrigine, rufinamide, topiramate
Multiple seizure types including absence seizures		Valproic acid
Myoclonic seizures	Clonazepam	Levetiracetam
Tuberous sclerosis complex	Cannabidiol	

[1] Not to be used as a first-line medication; when used, blood counts should be performed regularly (every 2–4 weeks). Should be used only in selected patients because of risk of aplastic anemia and hepatic failure. It is advisable to obtain written informed consent before use.

[2] Approved in patients who have failed to respond to succinimides (ethosuximide).

[3] Approved in patients 2 years or older.

Table 27–3. Medication treatment for seizures in adults (listed in alphabetical order).

Medication[1]	Usual Adult Daily Oral Dose	Minimum No. of Daily Doses	Time to Steady-State Medication Levels	Optimal Medication Level and Laboratory Monitoring[1]	Selected Side Effects and Idiosyncratic Reactions
Brivaracetam	50–100 mg	2	1–2 days	CBC, liver biochemical tests	Somnolence, fatigue, ataxia, vertigo, psychosis, leukopenia, hypersensitivity (bronchospasm and angioedema).
Cannabidiol	5–20 mg/kg	2	11–13 days	Liver biochemical tests at baseline, 1, 3, and 6 months	Somnolence, fatigue, anorexia, weight loss, anemia, diarrhea, rash, sleep disorder, infections. Elevation in liver enzymes may occur; reduce dose in hepatic impairment.
Carbamazepine	400–1600 mg (immediate- or extended-release)	2	3–4 days	4–8 mcg/mL CBC, liver biochemical tests, BUN/Cr	Nystagmus, dysarthria, diplopia, ataxia, drowsiness, nausea, blood dyscrasias, hepatotoxicity, hyponatremia, Stevens-Johnson syndrome.[2] May exacerbate myoclonic seizures.
Cenobamate	200–400 mg	1	14 days	Liver biochemical tests, potassium	Multiorgan hypersensitivity, QT shortening, somnolence, dizziness, cognitive dysfunction, blurred vision.
Clobazam	10–40 mg	2	7–10 days		Lethargy and somnolence, ataxia, insomnia, dysarthria, aggression, constipation, fever, Stevens-Johnson syndrome.
Clonazepam	0.04–0.2 mg/kg	2	7–10 days	20–80 ng/mL CBC, liver biochemical tests	Drowsiness, ataxia, irritability, behavioral changes, exacerbation of tonic-clonic seizures.
Clorazepate	22.5–90 mg	2	10 days		Sedation, dizziness, confusion, ataxia, depression, dependency/abuse.
Ethosuximide	500–1500 mg	2	5–10 days	40–100 mcg/mL CBC, liver biochemical tests, UA	Nausea, vomiting, anorexia, headache, lethargy, unsteadiness, blood dyscrasias, SLE, urticaria, pruritus.
Eslicarbazepine	400–1200 mg	1	4 days	Serum sodium and chloride; liver biochemical tests	As for carbamazepine.
Ezogabine	300–1200 mg	3	2–3 days	ECG to assess QT interval	Dizziness, somnolence, confusion, vertigo, nausea, ataxia, psychiatric disturbances, prolonged QT interval, retinal abnormalities.[3]
Felbamate[4]	1200–3600 mg	3	4–5 days	CBC and reticulocytes, liver biochemical tests	Anorexia, nausea, vomiting, headache, insomnia, weight loss, dizziness, hepatotoxicity, fatal aplastic anemia. Reserved for refractory epilepsy.
Gabapentin	900–3600 mg	3	1 day		Sedation, fatigue, ataxia, nystagmus, weight loss.
Ganaxolone	450–1800 mg	3	7 days		Sedation, fever, excessive salivation, seasonal allergy.
Lacosamide	100–400 mg	2	3 days	ECG if known cardiac conduction problems or severe cardiac disease	Vertigo, diplopia, nausea, headache, fatigue, ataxia, tremor, anaphylactoid reactions, PR prolongation, cardiac dysrhythmia, suicidality.
Lamotrigine	100–500 mg	2	4–5 days		Sedation, skin rash, visual disturbances, dyspepsia, ataxia.
Levetiracetam	1000–3000 mg	2	2 days		Somnolence, ataxia, headache, behavioral changes.
Oxcarbazepine	900–1800 mg	2	2–3 days	Serum sodium	As for carbamazepine.

(*continued*)

Table 27–3. Medication treatment for seizures in adults (listed in alphabetical order). (continued)

Medication[1]	Usual Adult Daily Oral Dose	Minimum No. of Daily Doses	Time to Steady-State Medication Levels	Optimal Medication Level and Laboratory Monitoring[1]	Selected Side Effects and Idiosyncratic Reactions
Perampanel	4–12 mg	1	3 weeks		Dizziness, somnolence, irritability, weight gain, falls, ataxia, dysarthria, blurred vision.
Phenobarbital	100–200 mg	1	14–21 days	10–40 mcg/mL CBC, liver biochemical tests, BUN/Cr	Drowsiness, nystagmus, ataxia, skin rashes, learning difficulties, hyperactivity.
Phenytoin	200–400 mg	1	5–10 days	10–20 mcg/mL CBC, liver biochemical tests, folate	Nystagmus, ataxia, dysarthria, sedation, confusion, gingival hyperplasia, hirsutism, megaloblastic anemia, blood dyscrasias, skin rashes, fever, SLE, lymphadenopathy, peripheral neuropathy, dyskinesias. May exacerbate myoclonic seizures.
Pregabalin	150–300 mg	2	2–4 days		Somnolence, dizziness, poor concentration, weight gain, thrombocytopenia, skin rashes, anaphylactoid reactions.
Primidone	750–1500 mg	3	4–7 days	5–12 mcg/mL CBC	Sedation, nystagmus, ataxia, vertigo, nausea, skin rashes, megaloblastic anemia, irritability.
Rufinamide	800–3200 mg	2	2 days		Somnolence, headache, dizziness, suicidality, Stevens-Johnson syndrome, leukopenia, shortened QT interval, nausea, vomiting.
Tiagabine	32–56 mg	2	2 days		Somnolence, anxiety, dizziness, poor concentration, tremor, diarrhea.
Topiramate	200–400 mg	2	4 days	Serum bicarbonate, BUN/Cr in older patients	Somnolence, nausea, dyspepsia, irritability, dizziness, ataxia, nystagmus, diplopia, glaucoma, renal calculi, weight loss, hypohidrosis, hyperthermia.
Valproic acid	1500–2000 mg	2–3	2–4 days	50–100 mcg/mL CBC, liver biochemical tests	Nausea, vomiting, diarrhea, drowsiness, alopecia, weight gain, hepatotoxicity, thrombocytopenia, tremor, pancreatitis. Teratogenic; avoid in women of childbearing age.
Vigabatrin	3000 mg	2	2 days		Somnolence, anorexia, nausea, vomiting, agitation, hostility, confusion, suicidality, neutropenia, Stevens-Johnson syndrome, permanent visual field loss.[2]
Zonisamide	200–600 mg	1	14 days	BUN/Cr, serum bicarbonate	Somnolence, ataxia, anorexia, nausea, vomiting, rash, confusion, renal calculi. Do not use in patients with sulfonamide allergy.

Cr, creatinine. Note that many factors influence optimal dose of these drugs including age, tolerance, and concomitant medication.

[1] Patients starting treatment with any antiepileptic drug should be monitored for new or worsening depression or suicidal thoughts, especially during the first weeks of therapy. Baseline measurement of creatinine clearance is advisable in renally metabolized drugs.

[2] Carriers of the HLA-B*1502 allele are at higher risk for Stevens-Johnson syndrome. Patients of Asian ancestry should be tested for this allele prior to initiation of therapy.

[3] Regular ophthalmologic examination is recommended.

[4] Not to be used as a first-line drug; when used, blood counts should be performed regularly (every 2–4 weeks). Should be used only in selected patients because of risk of aplastic anemia and hepatic failure. It is advisable to obtain written informed consent before use.

limiting to a minimum the number of daily doses. Recurrent seizures or status epilepticus may result if medications are taken erratically, and in some circumstances nonadherent patients may be better off without any medication. All anticonvulsants have side effects, and many require baseline and regular laboratory monitoring (Table 27–3).

3. Discontinuance of medication—*Only when adult patients have been seizure-free for 2 years should withdrawal of medication be considered.* Unfortunately, there is no way of predicting which patients can be managed successfully without treatment, although seizure recurrence is more likely in (1) patients with a longer duration of epilepsy prior to remission, (2) those with a shorter duration of remission, (3) those who initially did not respond to therapy, (4) those with seizures having focal features or of multiple types, (5) those with onset during adulthood, and (6) those with continuing electroencephalographic abnormalities. Dose reduction should be gradual (over weeks or months), and medications should be withdrawn one at a time. If seizures recur, treatment is reinstituted with the previously effective regimen.

4. Surgical treatment—Patients with seizures refractory to two or more medications may be candidates for operative treatment. Surgical resection is most efficacious when there is a single well-defined seizure focus, particularly in the temporal lobe. Among well-chosen patients, up to 70% remain seizure-free after extended follow-up. Additional surgical techniques for medically refractory epilepsy approved in the United States include laser interstitial thermal therapy, deep brain stimulation, responsive cortical stimulation, and vagus nerve stimulation.

B. Special Circumstances

1. Solitary seizures—In patients who have had only one seizure or a flurry of seizures over a brief period of several hours, investigation as outlined earlier should exclude an underlying cause requiring specific treatment. An electroencephalogram should be obtained, preferably within 24 hours after the seizure. Prophylactic anticonvulsant treatment is generally *not* required unless further attacks occur or investigations reveal underlying pathology. The risk of seizure recurrence varies in different series between about 30% and 70%, with higher risk of recurrence in patients with structural brain lesions or abnormalities on electroencephalogram. Epilepsy should *not* be diagnosed based on a solitary seizure. If seizures occur in the context of transient, nonrecurrent systemic disorders such as hyponatremia or hypoglycemia, the diagnosis of epilepsy is inaccurate, and long-term prophylactic anticonvulsant treatment is unnecessary.

2. Alcohol withdrawal seizures—The characteristic alcohol withdrawal seizure pattern is one or more generalized tonic-clonic seizures that may occur within 48 hours or so of withdrawal from alcohol after a period of high or prolonged intake. If the seizures have consistently focal features, the possibility of an associated structural abnormality, often traumatic in origin, must be considered. Treatment with anticonvulsants is generally not required for alcohol withdrawal seizures, since they are self-limited. Benzodiazepines are effective and safe for preventing further seizures. Status epilepticus may complicate alcohol withdrawal and is managed along conventional lines. Further attacks will not occur if the patient abstains from alcohol.

3. Tonic-clonic status epilepticus—Poor adherence to the anticonvulsant regimen is the most common cause; however, any disorder that can cause a single seizure may be responsible. The mortality rate may be as high as 20%, and among survivors the incidence of neurologic and cognitive sequelae is high. The prognosis relates to the underlying cause as well as the length of time between onset of status epilepticus and the start of effective treatment.

Status epilepticus is a medical emergency. Initial management includes maintenance of the airway and 50% dextrose (25–50 mL) intravenously in case hypoglycemia is responsible. If seizures continue, an intravenous bolus of lorazepam, 4 mg, is given at a rate of 2 mg/min and repeated once after 10 minutes if necessary; alternatively, 10 mg of midazolam is given intramuscularly, and again after 10 minutes if necessary. Diazepam can also be given rectally as a gel (0.2 mg/kg). These measures are usually effective in halting seizures for a brief period. Respiratory depression and hypotension may complicate the treatment and are treated as in other circumstances, including intubation and mechanical ventilation and admission to an ICU.

Regardless of the response to lorazepam or midazolam, fosphenytoin or phenytoin should be administered intravenously. Fosphenytoin (18–20 mg phenytoin equivalents [PE]/kg) is rapidly and completely converted to phenytoin following intravenous administration and is preferred because it is less likely to cause reactions at the infusion site, can be given with all common intravenous solutions, and may be administered at a faster rate (150 mg PE/min). When fosphenytoin is not available, phenytoin (18–20 mg/kg) is given intravenously at a rate of 50 mg/min. Phenytoin is best injected directly but can also be given in saline; it precipitates, however, if injected into glucose-containing solutions. Because arrhythmias may develop during rapid administration of fosphenytoin or phenytoin, ECG monitoring is prudent. Hypotension may occur, especially if diazepam has also been given. Alternatively or additionally, intravenous valproate (loading dose 20–40 mg/kg over 15 minutes, maximum dose 3000 mg) or levetiracetam (loading dose 60 mg/kg over 15 minutes, maximum dose 4500 mg) is used for status epilepticus. Although neither is approved by the FDA for this indication, both were equivalent to fosphenytoin in a randomized trial. Due to the teratogenicity of valproate, it should be avoided in persons who may be pregnant.

If seizures continue, phenobarbital is then given in a loading dose of 10–20 mg/kg intravenously by slow or intermittent injection (50 mg/min). Respiratory depression and hypotension are especially common with this therapy.

If these measures fail, general anesthesia with ventilatory assistance may be required; some experts recommend proceeding directly to general anesthesia if convulsions do not cease after the initial 18–20 PE/kg fosphenytoin load. Intravenous midazolam may provide control of refractory status epilepticus; the suggested loading dose is 0.2 mg/kg, followed by 0.05–0.2 mg/kg/hour. Propofol (1–2 mg/kg as an intravenous bolus, followed by infusion at 2–15 mg/kg/hour depending on response) may also be used, as may pentobarbital (5–15 mg/kg intravenously, followed by 0.5–4 mg/kg/hour).

After status epilepticus is controlled, an oral medication program for the long-term management of seizures is started, and investigations into the cause of the disorder are pursued.

4. Nonconvulsive status epilepticus—In some cases, status epilepticus presents not with convulsions, but with a fluctuating abnormal mental status, confusion, impaired responsiveness, and automatism. Electroencephalography establishes the diagnosis. The treatment approach outlined above applies to any type of status epilepticus, although intravenous anesthesia is usually not necessary. The prognosis is a reflection of the underlying cause rather than of continuing seizures.

When to Refer

- Behavioral episodes of uncertain nature.
- Seizures are difficult to control with monotherapy.
- There is a progressive neurologic disorder.

When to Admit

- Status epilepticus.
- Frequent seizures requiring rapid medication titration and electroencephalographic monitoring.
- For inpatient monitoring when PNES is suspected.

DYSAUTONOMIA

ESSENTIALS OF DIAGNOSIS

- Postural hypotension or abnormal heart rate regulation.
- Abnormalities of sweating, intestinal motility, sexual function, or sphincter control.
- Syncope may occur.
- Symptoms occur in isolation or any combination.

General Considerations

Dysautonomia may occur as a result of pathological processes in the central or peripheral nervous system. It is manifested by a variety of symptoms related to abnormalities of blood pressure regulation, thermoregulatory sweating, GI function, sphincter control, sexual function, respiration, and ocular function. The differential diagnosis depends on the time course of autonomic dysfunction and whether dysautonomia is an isolated symptom or associated with central or peripheral neurologic symptoms and signs.

A. Causes in the Central Nervous System

Disease at certain sites, regardless of its nature, may lead to dysautonomic symptoms. Postural hypotension, which is usually the most troublesome and disabling symptom, may result from spinal cord transection and other myelopathies (eg, due to tumor or syringomyelia) above the T6 level or from brainstem lesions such as syringobulbia and posterior fossa tumors. Sphincter or sexual disturbances may result from cord lesions at any level. Certain primary degenerative disorders are responsible for dysautonomia occurring in isolation (**pure autonomic failure**) or in association with more widespread abnormalities (**multisystem atrophy**) that may include parkinsonism, pyramidal symptoms, and cerebellar deficits. Postural hypotension is also a prominent symptom of idiopathic Parkinson disease and dementia with Lewy bodies.

B. Causes in the Peripheral Nervous System

A pure autonomic neuropathy may occur acutely or subacutely after a viral infection or as a paraneoplastic disorder related usually to small cell lung cancer, particularly in association with certain antibodies, such as anti-Hu or those directed at neuronal nicotinic ganglionic acetylcholine receptors. Dysautonomia is often conspicuous in patients with Guillain-Barré syndrome, manifesting with marked hypotension or hypertension or cardiac arrhythmias that may have a fatal outcome. It may also occur with diabetic, uremic, amyloidotic, and various other metabolic or toxic neuropathies; in association with leprosy or Chagas disease; and as a feature of certain hereditary neuropathies with autosomal dominant or recessive inheritance or an X-linked pattern. Autonomic symptoms are prominent in the crises of hepatic porphyria. Small fiber neuropathies may underlie some cases of postural orthostatic tachycardia syndrome (POTS) due to impaired contractility in denervated venules and resulting preload failure (see below). Patients with botulism or the Lambert-Eaton myasthenic syndrome may have constipation, urinary retention, and a sicca syndrome as a result of impaired cholinergic function.

Clinical Findings

A. Symptoms and Signs

Dysautonomic symptoms include syncope, postural hypotension, paroxysmal hypertension, persistent tachycardia without other cause, facial flushing, hypo- or hyperhidrosis, vomiting, constipation, diarrhea, dysphagia, abdominal distention, disturbances of micturition or defecation, erectile dysfunction, apneic episodes, and declining night vision. In syncope, prodromal malaise, nausea, headache, diaphoresis, pallor, visual disturbance, loss of postural tone, and a sense of weakness and impending loss of consciousness are followed by actual loss of consciousness. It is usually accompanied by hypotension and bradycardia and may occur in response to emotional stress, postural hypotension, vigorous exercise in a hot environment, obstructed venous return to the heart, acute pain or its anticipation, fluid loss, and a variety of other circumstances. Although the patient is usually flaccid, some motor activity is not uncommon, and urinary (and rarely fecal) incontinence may also occur, thereby simulating a seizure. Recovery is rapid once the patient becomes recumbent, but headache, nausea, and fatigue commonly persist.

B. Evaluation of the Patient

The extent and severity of autonomic dysfunction should be determined, and the presence of associated neurologic symptoms and signs ascertained. Bedside testing of autonomic function includes examination of pupillary reactivity, examination of the skin for areas of excessive or reduced sweating and of the hands and feet for color or temperature changes, as well as assessment of blood pressure and heart rate in the supine position and 3 minutes after standing. With dysautonomia, *postural hypotension is not accompanied by a compensatory rise in heart rate.* Specialized tests include the cardiovascular response to the Valsalva maneuver and deep respiration, tilt-table testing, the thermoregulatory sweat test, the quantitative sudomotor axon reflex test, and the quantitative direct and indirect axon reflex test. Tests of GI motility and urodynamics may be helpful when symptoms of dysmotility, incontinence, or urinary retention are present.

The neurologic examination should focus on detecting signs of parkinsonism, cerebellar dysfunction, disorders of neuromuscular transmission, and peripheral neuropathy. All patients should be tested for vitamin B_{12} deficiency and diabetes. Patients with acute or subacute isolated dysautonomia should undergo testing for ganglionic acetylcholine receptor, anti-Hu, voltage-gated potassium channel complex, and voltage-gated calcium channel antibodies. For those with evidence of peripheral neuropathy, nerve conduction studies; electromyography; and testing for HIV, amyloidosis, Sjögren syndrome, and Fabry disease are indicated. If there is evidence of central pathology, imaging studies will exclude a treatable structural cause. If the neurologic examination is normal, reversible, non-neurologic causes of symptoms must be considered. Isolated postural hypotension and syncope may relate to a reduced cardiac output, paroxysmal cardiac dysrhythmias, volume depletion, various medications, and endocrine and metabolic disorders such as Addison disease, hypo- or hyperthyroidism, pheochromocytoma, and carcinoid syndrome.

Treatment

The most disabling symptoms are usually postural hypotension and syncope. Abrupt postural change, prolonged recumbency, heavy meals, and other precipitants should be avoided. Medications associated with postural hypotension should be discontinued or reduced in dose. Treatment may include wearing waist-high elastic hosiery, salt supplementation, sleeping in a semierect position (which minimizes the natriuresis and diuresis that occur during recumbency), ingestion of 500 mL water 30 minutes before arising, and fludrocortisone (0.1–0.5 mg orally daily). Vasoconstrictor agents may be helpful and include midodrine (2.5–10 mg orally three times daily), droxidopa (100–600 mg orally three times daily), and ephedrine (15–30 mg orally three times daily). Other agents that have been used occasionally or experimentally are dihydroergotamine, yohimbine, pyridostigmine, atomoxetine, and clonidine; refractory cases may respond to erythropoietin (epoetin alfa) or desmopressin. Patients must be monitored for recumbent hypertension. Postprandial hypotension is helped by caffeine. There is no satisfactory treatment for disturbances of sweating, but an air-conditioned environment is helpful in avoiding extreme swings in body temperature.

When to Refer

- When the diagnosis is uncertain.
- When symptoms persist despite conventional treatment.

Hovaguimian A. Dysautonomia: diagnosis and management. Neurol Clin. 2023;41:193. [PMID: 36400555]

POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME (POTS)

Clinical Findings

In POTS, orthostatic symptoms (tremulousness, lightheadedness, palpitations, visual disturbances, weakness, fatigue, anxiety, hyperventilation, nausea) develop with a significant tachycardia (an increase of 30 beats/min or more or a heart rate of 120 beats/min or more) within 10 minutes of standing, in the absence of postural hypotension or an autonomic neuropathy. POTS is more common in women than men and in patients between 20 and 50 years of age. Other medical problems causing a tachycardia must be excluded.

Its pathophysiology is uncertain but may involve cardiac deconditioning; impaired peripheral vasoconstriction due to peripheral sympathetic denervation, leading to venous pooling in the legs on standing and a compensatory tachycardia (“**neuropathic POTS**”); or an exaggerated sympathetic response to standing, with markedly elevated levels of plasma norepinephrine causing the tachycardia (“**hyperadrenergic POTS**”). Other possible mechanisms include hypovolemia, possibly from impaired function of the renin-angiotensin system (“**volume dysregulation POTS**”) and excessive mast cell activation leading to inappropriate release of histamine during physical activity. Psychological mechanisms have also been invoked. POTS may be associated with joint hypermobility syndrome and mitral valve prolapse, and it may follow pregnancy, surgery, trauma, chemotherapy, vaccinations, or viral infections, including SARS-CoV-2.

Treatment

Management may involve volume repletion, a high salt diet and copious fluids, postural and psychophysiologic training, and a graduated exercise program. Medication treatment may include a β-blocking agent (eg, propranolol

10–40 mg three times daily or metoprolol 12.5–50 mg twice daily), phenobarbital (15 mg in the morning, 60 mg at night), or clonidine (0.2 mg twice daily) for patients with hyperadrenergic POTS; and midodrine, droxidopa, pyridostigmine, or fludrocortisone at the doses described for postural hypotension if a neuropathic basis for symptoms is suspected. The long-term prognosis is unclear but approximately 50% of patients recover within 3 years.

Boris JR et al. Long-term POTS outcomes survey: diagnosis, therapy, and clinical outcomes. J Am Heart Assoc. 2024;13:e033485. [PMID: 38958137]

TRANSIENT ISCHEMIC ATTACKS

ESSENTIALS OF DIAGNOSIS

- Focal neurologic deficit of acute onset.
- Clinical deficit resolves completely within 24 hours.
- Risk factors for vascular disease often present.

General Considerations

Transient ischemic attacks (TIAs) are characterized by *focal ischemic cerebral neurologic deficits that last for < 24 hours* (usually < 1–2 hours). About 30% of patients with stroke have a history of TIAs and 5–10% of patients with TIAs will have a stroke within 90 days. The natural history of attacks is variable. Some patients will have a major stroke after only a few attacks, whereas others may have frequent attacks for weeks or months without having a stroke. *The risk of stroke is high in the first 3 months after an attack, particularly in the first month and especially within the first 48 hours*. The stroke risk is greater in patients older than 60 years, in patients with diabetes, or after TIAs that last longer than 10 minutes and with symptoms or signs of weakness, speech impairment, or gait disturbance. In general, carotid ischemic attacks are more liable than vertebrobasilar ischemic attacks to be followed by stroke.

Urgent intervention in TIA patients reduces rates of subsequent stroke, and *the condition should be treated with a similar sense of urgency as unstable angina*.

Etiology

An important cause of transient cerebral ischemia is embolization. In many patients with these attacks, a source is readily apparent in the heart or a major extracranial artery to the head, and emboli sometimes are visible in the retinal arteries. An embolic phenomenon explains why separate attacks may affect different parts of the territory supplied by the same major vessel. Cardiac causes of embolic ischemic attacks include atrial fibrillation, HF, infective and nonbacterial thrombotic endocarditis, atrial myxoma, and mural thrombi complicating MI. Atrial septal defects and patent foramen ovale may permit venous thromboemboli to reach the brain (**paradoxical emboli**). An ulcerated plaque on a major artery to the brain may serve as a source of emboli. In the anterior circulation, atherosclerotic changes occur most commonly in the region of the carotid bifurcation extracranially; these changes may cause a bruit. Atherosclerosis also affects the vertebrobasilar system and the major intracranial vessels including the middle and anterior cerebral arteries.

Less common abnormalities of blood vessels that may cause TIAs include fibromuscular dysplasia, which affects the cervical internal carotid artery; atherosclerosis of the aortic arch; inflammatory arterial disorders such as giant cell arteritis, polyarteritis, and granulomatous angiitis; Fabry disease; and meningovascular syphilis. Critical stenosis of a major extracranial or intracranial artery may cause TIA, especially in the setting of hypotension.

Hematologic causes of TIA include polycythemia, sickle cell disease, hyperviscosity syndromes, and the antiphospholipid antibody syndrome. Severe anemia may also lead to transient focal neurologic deficits in patients with preexisting cerebral arterial disease.

The **subclavian steal syndrome** may lead to transient vertebrobasilar ischemia. Symptoms develop when there is localized stenosis or occlusion of one subclavian artery proximal to the source of the vertebral artery, so that blood is “stolen” from the vertebral artery to supply the arm. A bruit in the supraclavicular fossa, unequal radial pulses, and a difference of 20 mm Hg or more between the systolic blood pressures in the arms should suggest the diagnosis in patients with vertebrobasilar TIAs.

Clinical Findings

A. Symptoms and Signs

The symptoms of TIAs vary markedly among patients; however, the symptoms in a given individual tend to be constant in type. Onset is abrupt and without warning, and recovery usually occurs rapidly, often within a few minutes. The specific symptoms depend on the arterial distribution affected, as outlined in the subsequent section on stroke. Of note, *TIA rarely causes loss of consciousness or acute confusion but is often erroneously blamed for such symptoms*.

B. Imaging

CT or MRI scan is indicated within 24 hours of symptom onset, in part to exclude the possibility of a small cerebral hemorrhage or a cerebral tumor masquerading as a TIA. MRI with diffusion-weighted sequences is sensitive for revealing acute or subacute infarction, which is seen in up to one-third of cases despite resolution of clinical symptoms and indicates a high risk of subsequent stroke. Noninvasive imaging of the cervical vasculature should also be performed; carotid duplex ultrasonography is useful for detecting significant stenosis of the internal carotid artery, and MR or CT angiography permits broader visualization of cervical and intracranial vasculature.

C. Laboratory and Other Studies

Clinical and laboratory evaluation must include assessment for hypertension, heart disease, hematologic disorders, diabetes mellitus, hyperlipidemia, and peripheral vascular disease. It should include CBC, fasting blood glucose, and serum cholesterol determinations, and may include serologic tests for syphilis and HIV infection. An ECG should be obtained. Echocardiography with agitated saline contrast is performed if a cardioembolic source is likely, and blood cultures are obtained if endocarditis is suspected. Ambulatory ECG monitoring is indicated to detect paroxysmal atrial fibrillation and, if the cause of the TIA remains elusive, *extended monitoring may detect paroxysmal atrial fibrillation in up to 20% of patients*.

Differential Diagnosis

Focal seizures usually cause abnormal motor or sensory phenomena such as clonic limb movements, paresthesias, or tingling, rather than weakness or loss of feeling. Symptoms generally spread ("march") up the limb and may lead to a generalized tonic-clonic seizure.

Classic migraine is easily recognized by the visual premonitory symptoms, followed by nausea, headache, and photophobia, but less typical cases may be hard to distinguish. Patients with migraine are typically younger, commonly have a history of episodes since adolescence, and report that other family members have a similar disorder.

Focal neurologic deficits may occur during periods of hypoglycemia in patients with diabetes receiving insulin or oral hypoglycemic agent therapy.

Treatment

A. Medical Measures

Medical treatment is aimed at preventing further attacks and stroke. Treat diabetes mellitus, hematologic disorders, and hypertension, preferably with an ACE inhibitor or ARB. Among patients with atherosclerosis and LDL > 100 mg/dL, atorvastatin 80 mg orally once daily should be started. The LDL should be measured every 3 to 12 months, and ezetimibe (10 mg once orally once daily) added if necessary to lower the LDL to < 70 mg/dL. In patients with at least two major atherosclerotic cardiovascular events (ischemic stroke, ACS or MI, peripheral arterial disease) or one major such event and multiple risk factors (age over 64 years, cardiac bypass surgery or percutaneous coronary intervention, heterozygous familial hypercholesterolemia, diabetes, hypertension, CKD, or active tobacco smoking), a proprotein convertase subtilisin/kexin type 9 inhibitor (eg, evolocumab or alirocumab) can be added. Cigarette smoking should be stopped, and cardiac sources of embolization should be treated appropriately. Weight reduction and regular physical activity should be encouraged when appropriate. An antiplatelet or anticoagulant should be started as soon as imaging has established the absence of hemorrhage (see Anticoagulation and Antiplatelet therapy below).

1. Hospitalization—Hospitalization should be considered for patients seen within a week of the attack, when they are at increased risk for early recurrence. One commonly used method to assess recurrence risk is the **ABCD^2 score;** points are assigned for each of the following criteria: age 60 years or older (1 point), blood pressure 140/90 mm Hg or higher (1 point), clinical symptoms of focal weakness (2 points) or speech impairment without weakness (1 point), duration of 60 minutes or longer (2 points) or 10–59 minutes (1 point), or diabetes mellitus (1 point). *An ABCD^2 score of 4 or more points has been suggested as a threshold for hospital admission.* The **ABCD^{2}I** (with an additional 3 points for any abnormal diffusion-weighted MRI finding or any infarct [new or old] on noncontrast CT) has been proposed as a better predictor of subsequent stroke risk. Admission is also advisable for patients with crescendo attacks, symptomatic carotid stenosis, or a known cardiac source of emboli or hypercoagulable state; such hospitalization facilitates early intervention for any recurrence and rapid institution of secondary prevention measures.

2. Anticoagulation—*The chief indication for anticoagulation after TIA is atrial fibrillation*. Patients with mechanical heart valves, left atrial or ventricular thrombus, LV assist devices, and the antiphospholipid antibody syndrome should also receive anticoagulation therapy. Treatment is with warfarin (target INR 2.0–3.0); bridging warfarin with heparin is *not* necessary, but some experts advocate treatment with aspirin until the INR becomes therapeutic. For long-term anticoagulation in the setting of atrial fibrillation in patients without moderate to severe mitral stenosis (Chapter 12) or a mechanical heart valve, apixaban (2.5–5 mg orally twice daily), dabigatran (150 mg orally twice daily), edoxaban (60 mg orally daily), and rivaroxaban (20 mg orally daily) are *preferred options over warfarin*. Combination antiplatelet-anticoagulation therapy is only indicated in select patients with mechanical heart valves or those with a separate indication for antiplatelet therapy such as a cardiac stent. In patients with cardiomyopathy and an EF under 35% without atrial fibrillation, warfarin (target INR 2.0–3.0) reduces ischemic stroke risk compared to aspirin but results in a roughly equivalent increase in the risk of major hemorrhage; treatment in this population should therefore be individualized.

3. Antiplatelet therapy—All patients in whom anticoagulation is not indicated should be treated with antiplatelet therapy to reduce the frequency of TIAs and the incidence of stroke. Dual antiplatelet therapy should be initiated within 12 hours after a high-risk TIA (ABCD^2 score ≥ 4) or minor stroke (defined by a NIH Stroke Scale of 3 or less) with an oral loading dose of clopidogrel (300–600 mg) followed by 75 mg/day orally plus aspirin (50–325 mg daily orally) for 21 days, followed by monotherapy with aspirin (81 mg daily orally), aspirin combined with extended-release dipyridamole (200 mg twice daily orally), or clopidogrel (75 mg daily orally). Dual antiplatelet therapy with aspirin and clopidogrel for 90 days after a TIA or stroke due to 70–99% stenosis of an intracranial artery is also recommended. Cilostazol (100 mg twice daily) had similar efficacy as aspirin at long-term stroke prevention in an Asian population with less risk of hemorrhage. Combining clopidogrel with aspirin beyond 90 days increases the risk of hemorrhagic complications and is *not* recommended.

B. Surgical or Endovascular Measures

1. Carotid revascularization—When arteriography reveals a surgically accessible high-grade stenosis (70–99% in luminal diameter) on the side appropriate to carotid ischemic attacks, operative treatment (**carotid endarterectomy**) or endovascular intervention reduces the risk of ipsilateral carotid stroke, especially when TIAs are of recent onset (< 1 month) and when the perioperative morbidity and mortality risk is estimated to be < 6%. Endovascular therapy carries a slightly higher procedural stroke risk than endarterectomy in patients older than 70 years and is generally reserved for younger patients whose neck anatomy is unfavorable for surgery. Patients with symptomatic carotid stenosis of 50–69% derive moderate benefit from intervention, but surgery is *not* indicated for mild stenosis (< 50%).

2. Closure of patent foramen ovale—Carefully selected patients with patent foramen ovale (PFO) and right-to-left shunt benefit from PFO closure and antiplatelet therapy. Patients should be considered for PFO closure if they are between 18 and 60 years old; have had a cryptogenic stroke or TIA; and do not have uncontrolled diabetes, hypertension, or a specific indication for long-term anticoagulation. A cryptogenic stroke does not have an identified mechanism, such as large artery atherosclerosis (≥ 30–50% stenosis of the intracranial or cervical arteries or a plaque ≥ 4 mm thick in the aortic arch), known cardioembolic source (eg, atrial fibrillation), small vessel arteriolosclerosis (eg, lacunar stroke smaller than 1.5 cm in diameter), hypercoagulable state, or dissection. Patients with moderate to large interatrial shunts or associated atrial septal aneurysms appear to benefit most from PFO closure. See also Chapter 10.

3. Left atrial appendage closure—The left atrial appendage is the source of embolism in most patients with atrial fibrillation. A meta-analysis of randomized trials showed percutaneous left atrial appendage closure was equivalent to anticoagulation in preventing stroke and systemic embolization, and several devices are approved for this indication in the United States and Europe. The procedure should be considered in patients with a contraindication to long-term anticoagulation, although short-term anticoagulation (45 days) followed by dual antiplatelet therapy (4.5 months) and then indefinite aspirin monotherapy is usually necessary after device placement.

▶ When to Refer

All patients should be referred for urgent investigation and treatment to prevent stroke.

▶ When to Admit

If seen within a week of a TIA, patients should be considered for admission when they have an ABCD^2 score of 4 points or more, when outpatient evaluation is impractical, or when there are multiple attacks, carotid stenosis of > 70%, or other concern for early recurrence or stroke.

STROKE

ESSENTIALS OF DIAGNOSIS

- Sudden onset of neurologic deficit of cerebrovascular origin.
- Patient often has hypertension, diabetes mellitus, tobacco use, atrial fibrillation, or atherosclerosis.
- Distinctive neurologic signs reflect the region of the brain involved.

▶ General Considerations

In the United States, stroke is the fifth leading cause of death and a leading cause of disability. Risk factors for stroke include hypertension, diabetes mellitus, hyperlipidemia, cigarette smoking, cardiac disease, HIV infection, trigeminal herpes zoster, recreational drug abuse, heavy alcohol consumption, and a family history of stroke.

Strokes are subdivided pathologically into **infarcts** and **hemorrhages.** The distinction may be difficult clinically; CT scanning is essential to clarify the pathologic basis (Table 27–4).

1. Lacunar Infarction

Lacunar infarcts are small lesions (usually < 1.5 cm in diameter) that occur in the distribution of short penetrating arterioles in the basal ganglia, pons, cerebellum, internal capsule, thalamus, and, less commonly, the deep cerebral white matter (Table 27–4). Lacunar infarcts are associated with poorly controlled hypertension or diabetes and have been found in several clinical syndromes, including contralateral pure motor hemiparesis or pure hemisensory deficit, ipsilateral ataxia with hemiparesis, and dysarthria with clumsiness of the hand. The neurologic deficit may progress over 24–36 hours before stabilizing.

Early mortality and risk of stroke recurrence is higher for patients with nonlacunar than lacunar infarcts. The prognosis for recovery from the deficit produced by a lacunar infarct is usually good, with partial or complete resolution occurring over the following 4–6 weeks in many instances. Treatment is as described for TIA (discussed in the section on TIA) and cerebral infarction.

Table 27–4. Features of the major stroke subtypes.

Stroke Type and Subtype	Clinical Features	Diagnosis	Treatment
Ischemic Stroke			
Lacunar infarct	Small (< 1.5 cm) lesions in the basal ganglia, pons, cerebellum, or internal capsule; less often in deep cerebral white matter; prognosis generally good; clinical features depend on location but may worsen over first 24–36 hours.	MRI with diffusion-weighted sequences usually defines the area of infarction; CT is insensitive acutely but can be used to exclude hemorrhage.	Antiplatelet; control risk factors (hypertension, tobacco use, hypercholesterolemia, and diabetes mellitus).
Carotid circulation obstruction	See text—signs vary depending on occluded vessel.	Noncontrast CT to exclude hemorrhage but findings may be normal during first 6–24 hours of an ischemic stroke; diffusion-weighted MRI is gold standard for identifying acute stroke; ECG, carotid duplex studies, echocardiography, blood glucose, CBC, and tests for hyperlipidemia are indicated; ambulatory ECG monitoring, including extended monitoring in selected instances; CTA, MRA, or conventional angiography in selected cases; tests for hypercoagulable states in selected cases.	0–4.5 hours: intravenous thrombolytics (approved in United States up to 3 hours and in Europe up to 4.5 hours). 0–6 hours: endovascular mechanical embolectomy. 6–24 hours: endovascular mechanical embolectomy in select cases. Secondary prevention: antiplatelet agent is first-line therapy; anticoagulation without heparin bridge for cardioembolic strokes due to atrial fibrillation and other select cases when no contraindications exist; control risk factors as above.
Vertebrobasilar occlusion	See text—signs vary based on location of occluded vessel.	As for carotid circulation obstruction.	As for carotid circulation obstruction.
Hemorrhagic Stroke			
Spontaneous intracerebral hemorrhage	Commonly associated with hypertension; also with bleeding disorders, amyloid angiopathy. Hypertensive hemorrhage is located commonly in the basal ganglia, pons, thalamus, cerebellum, and less commonly the cerebral white matter.	Noncontrast CT is superior to MRI for detecting bleeds of < 48 hours duration; laboratory tests to identify bleeding disorder: angiography may be indicated to exclude aneurysm or AVM in younger patients without hypertension. Do *not* perform lumbar puncture.	Lower systolic blood pressure to 140 mm Hg; cerebellar bleeds or hematomas with gross mass effect may require urgent surgical evacuation. AVM: surgical resection indicated to prevent further bleeding; other modalities to treat nonoperable AVMs available at specialized centers.
Subarachnoid hemorrhage	Present with sudden onset of worst headache of life, may lead rapidly to loss of consciousness; signs of meningeal irritation often present; etiology usually aneurysm or AVM, but 20% have no source identified.	CT to confirm diagnosis but may be normal in rare instances; if CT negative and suspicion high, perform lumbar puncture to look for RBCs or xanthochromia; angiography to determine source of bleed in candidates for treatment.	Lower systolic blood pressure to < 140 mm Hg immediately. Aneurysm: prevent further bleeding by clipping aneurysm or coil embolization; nimodipine helps prevent vasospasm; once aneurysm has been obliterated intravenous fluids and induced hypertension to prevent vasospasm; angioplasty may also reverse symptomatic vasospasm. AVM: as above.

AVMs, arteriovenous malformations; CTA, computed tomography angiography; MRA, magnetic resonance angiography.

2. Cerebral Infarction

Thrombotic or embolic occlusion of a major vessel leads to cerebral infarction. Causes are identical to the disorders predisposing to TIAs. The resulting deficit depends on the particular vessel involved and the extent of any collateral circulation. Cerebral ischemia leads to release of excitatory and other neuropeptides that may augment calcium flux into neurons, thereby leading to cell death and increasing the neurologic deficit.

▶ Clinical Findings

A. Symptoms and Signs

Onset is usually abrupt, and there may then be little progression except that due to brain swelling. Clinical evaluation should always include examination of the heart for murmurs and rhythm irregularities. Auscultating over the carotid or subclavian vessels may reveal a bruit but is not sensitive enough to substitute for vascular imaging.

1. Obstruction of carotid circulation—Occlusion of the **anterior cerebral artery** distal to its junction with the anterior communicating artery causes weakness and cortical sensory loss in the contralateral leg and sometimes mild weakness of the arm, especially proximally. There may be a contralateral grasp reflex, paratonic rigidity, abulia (lack of initiative), or frank confusion. Urinary incontinence is not uncommon, particularly if behavioral disturbances are conspicuous. Bilateral anterior cerebral infarction is especially likely to cause marked behavioral changes and memory disturbances. Unilateral anterior cerebral artery occlusion proximal to the junction with the anterior communicating artery is generally well tolerated because of the collateral supply from the other side.

Middle cerebral artery occlusion leads to contralateral hemiplegia, hemisensory loss, and homonymous hemianopia (ie, bilaterally symmetric loss of vision in half of the visual fields), with the eyes deviated to the side of the lesion. If the dominant hemisphere is involved, global aphasia is also present. It may be impossible to distinguish this clinically from occlusion of the internal carotid artery. With occlusion of either of these arteries, there may also be considerable swelling of the hemisphere during the first 72 hours. For example, an infarct involving one cerebral hemisphere may lead to such swelling that the function of the other hemisphere or the rostral brainstem is disturbed and coma results. Occlusions of different branches of the middle cerebral artery cause more limited findings. For example, involvement of the superior division in the dominant hemisphere leads to a predominantly expressive (**Broca**) aphasia and to contralateral paralysis and loss of sensations in the arm, the face and, to a lesser extent, the leg. Inferior branch occlusion in the dominant hemisphere produces a receptive (**Wernicke**) aphasia and a homonymous visual field defect. With involvement of the nondominant hemisphere, speech and comprehension are preserved, but there may be a left hemispatial neglect syndrome or constructional and visuospatial deficits.

Occlusion of the **ophthalmic or central retinal artery** leads to sudden painless visual loss with retinal pallor and a macular cherry red spot on fundoscopic examination. Sudden, transient vision loss in one eye (**amaurosis fugax**) is a TIA in this arterial territory.

2. Obstruction of vertebrobasilar circulation—Occlusion of the **posterior cerebral artery** may lead to a thalamic syndrome in which contralateral hemisensory disturbance occurs, followed by the development of spontaneous pain and hyperpathia. There is often a macular-sparing homonymous hemianopia and sometimes a mild, usually temporary, hemiparesis. Involuntary movements may occur if the subthalamic nucleus is involved and alexia if the infarct involves the left occipital lobe and the splenium of the corpus callosum. Occlusion of the main artery beyond the origin of its penetrating branches may lead solely to a macular-sparing hemianopia.

Vertebral artery occlusion below the origin of the anterior spinal and posterior inferior cerebellar arteries may be clinically silent because the circulation is maintained by the other vertebral artery. If the remaining vertebral artery is congenitally small or severely atherosclerotic, however, a deficit similar to that of basilar artery occlusion is seen unless there is good collateral circulation from the anterior circulation through the circle of Willis. An obstruction of the **posterior inferior cerebellar artery** or an obstruction of the vertebral artery just before it branches to this vessel leads to the **lateral medullary syndrome**, characterized by vertigo and nystagmus (vestibular nucleus), ipsilateral spinothalamic sensory loss involving the face (trigeminal nucleus and tract), dysphagia (nucleus ambiguus), limb ataxia (inferior cerebellar peduncle), and Horner syndrome (descending sympathetic fibers), combined with contralateral spinothalamic sensory loss involving the limbs.

Occlusion of **both vertebral arteries** or the **basilar artery** leads to coma with pinpoint pupils, flaccid quadriplegia and sensory loss, and variable cranial nerve abnormalities. With partial basilar artery occlusion, there may be diplopia, visual loss, vertigo, dysarthria, ataxia, weakness, or sensory disturbances in some or all of the limbs, and discrete cranial nerve palsies. In patients with hemiplegia of pontine origin, the eyes are often deviated to the paralyzed side, whereas in patients with a hemispheric lesion, the eyes commonly deviate from the hemiplegic side. When the small paramedian arteries arising from the basilar artery are occluded, contralateral hemiplegia and sensory deficit occur in association with an ipsilateral cranial nerve palsy at the level of the lesion.

Occlusion of any of the major **cerebellar arteries** produces vertigo, nausea, vomiting, nystagmus, and ipsilateral limb ataxia. Contralateral spinothalamic sensory loss in the limbs may also be present. Deafness due to cochlear infarction may follow occlusion of the anterior inferior cerebellar artery, which may also cause ipsilateral facial spinothalamic sensory loss and weakness. Massive cerebellar infarction may lead to obstructive hydrocephalus, coma, tonsillar herniation, and death.

B. Imaging

A CT scan of the head (without contrast) should be performed immediately, before the administration of aspirin or other antithrombotic agents, to exclude cerebral hemorrhage (Table 27–4). CT is relatively insensitive to acute ischemic stroke within the first 6–12 hours, and subsequent MRI with diffusion-weighted sequences helps define the distribution and extent of infarction as well as exclude tumor or other differential considerations. **CT angiography of the head and neck** should be performed to identify large vessel occlusions amenable to endovascular therapy in patients presenting within 6 hours of stroke onset and should be considered in those presenting between 6 and 24 hours, together with CT perfusion studies. Regardless of timing of presentation, imaging of the cervical vasculature is indicated as part of a search to identify the source of the stroke. In patients with a PFO and otherwise cryptogenic stroke, the intracranial vasculature must be imaged to rule out large vessel atherosclerosis before PFO closure can be considered.

C. Laboratory and Other Studies

Investigations should include a CBC, blood glucose determination, and fasting lipid panel. Serologic tests for syphilis and HIV infection may be included depending on the circumstances. Screening for antiphospholipid antibodies (lupus anticoagulants, anticardiolipin, and anti-β_2-glycoprotein antibodies); the factor V Leiden mutation; abnormalities of protein C, protein S, or antithrombin; or a prothrombin gene mutation is indicated only if a hypercoagulable disorder is suspected (eg, a young patient without apparent risk factors for stroke) or needs to be ruled out if PFO closure is under consideration. While elevated serum homocysteine is a risk factor for stroke, lowering homocysteine levels with vitamin supplementation has not been shown to decrease stroke risk, and therefore, routinely checking homocysteine is *not* recommended. ECG or continuous cardiac monitoring for at least 24 hours will help exclude a recent MI or a cardiac arrhythmia that might be a source of embolization. While atrial fibrillation will be discovered in approximately 10% of patients with ischemic stroke during their hospitalization, an arrhythmia will be found in an additional 10% with prolonged ambulatory ECG monitoring after discharge; this testing is indicated in cases where atrial fibrillation is suspected (eg, nonlacunar stroke and left atrial enlargement on echocardiography or lack of intracranial or carotid atherosclerosis) but has not been demonstrated. Echocardiography (with agitated saline contrast) should be performed in cases of nonlacunar stroke to exclude valvular disease, right-to-left shunting, and cardiac thrombus. Blood cultures should be performed if endocarditis is suspected but are not required routinely. Examination of the CSF may be helpful if cerebral vasculitis or another inflammatory or infectious cause of stroke is suspected but should be delayed until after CT or MRI to exclude any risk for herniation due to mass effect.

▶ Treatment

Management is divided into acute and chronic phases: the first is aimed at minimizing disability and the second at preventing recurrent stroke. A combination of thrombolysis and endovascular therapies is available to patients who present within 24 hours of stroke onset, determined by when the patient was last normal.

Intravenous thrombolytic therapy with recombinant tissue plasminogen activator (rtPA) improves the chance of recovery without significant disability at 90 days from 26% to 39% if given within 3 hours from stroke onset but is still effective up to 4.5 hours from stroke onset. Treatment should be initiated as soon as possible; *outcome is directly related to the time from stroke onset to treatment*. Alteplase (0.9 mg/kg to a maximum of 90 mg, with 10% given as a bolus over 1 minute and the remainder over 1 hour) is approved in Europe for use up to 4.5 hours from stroke onset but only for up to 3 hours in the United States, although off-label use during the 3- to 4.5-hour window is standard. Tenecteplase (0.25 mg/kg intravenously once within 4.5 hours from stroke onset, maximum dose 25 mg) is an rtPA non-inferior to alteplase that is used in some stroke centers but not approved for this indication in the United States or Europe. In patients with systolic pressure > 185 mm Hg or diastolic pressure > 110 mm Hg, the blood pressure should be lowered to < 185/110 mm Hg with intravenous labetalol or nicardipine to enable rtPA administration. Due to the risk of hemorrhage, rtPA should not be used beyond 4.5 hours, although some evidence suggests patients with ischemic but not infarcted tissue identified by automated perfusion imaging or MRI may be treated up to 9 hours after onset or upon awakening with stroke symptoms.

Several randomized trials have demonstrated an increased likelihood of achieving functional independence after **endovascular mechanical embolectomy** by stent retrievers as an adjunct to intravenous rtPA or as a standalone treatment in patients ineligible for rtPA. Patients with large vessel occlusion (about 20% of patients with acute ischemic stroke) in whom treatment can be initiated within 6 hours of stroke onset are eligible for embolectomy, as are patients who present between 6 and 24 hours and have a large ischemic penumbra identified by perfusion CT, perfusion MRI, or diffusion-weighted MRI.

Early management of a completed stroke otherwise requires general supportive measures. Management in a **stroke care unit** has been shown to improve outcomes, likely due to early rehabilitation and prevention of medical complications. During the acute stage, there may be marked brain swelling and edema, with symptoms and signs of increasing intracranial pressure, an increasing neurologic deficit, or herniation syndrome. Elevated intracranial pressure is managed by head elevation and osmotic agents such as mannitol. Maintenance of an adequate cerebral perfusion pressure helps prevent further ischemia. Early decompressive hemicraniectomy (within 48 hours of stroke onset) for malignant middle cerebral artery infarctions reduces mortality and improves functional outcome. Attempts to lower the blood pressure of hypertensive patients during the acute phase (ie, within 72 hours) of a stroke should generally be *avoided* unless the purpose is to enable the safe administration of rtPA, as there is loss of cerebral autoregulation, and lowering the blood pressure may further compromise ischemic areas. However, if the systolic pressure exceeds 220 mm Hg, it can be lowered using intravenous labetalol, nicardipine, or clevidipine with continuous monitoring to 170–200 mm Hg, and then after 72 hours, it can be reduced further to < 140/90 mm Hg. Blood pressure augmentation is usually not necessary in patients with relative hypotension but maintenance of hydration with intravenous fluids if necessary is important.

Prophylactic and medical measures are discussed in the section on TIAs and should guide management. Once hemorrhage has been excluded by CT, **aspirin** (325 mg orally daily) is started immediately unless the patient received thrombolysis, in which case aspirin is initiated after a follow-up CT has ruled out thrombolytic-associated hemorrhage at 24 hours. **Dual antiplatelet therapy** should be used for 21 days in patients with minor stroke (NIH Stroke Scale of 3 or less). **Anticoagulant** medications are started when indicated, as discussed in the section on TIAs. There is generally no advantage in delay, and the common fear of causing hemorrhage into a previously infarcted area is misplaced, since there is a far greater risk of further embolism to the cerebral circulation if treatment is withheld.

Physical therapy has an important role in the management of patients with impaired motor function. Passive movements at an early stage will help prevent contractures.

As cooperation increases and some recovery begins, active movements will improve strength and coordination. In all cases, early mobilization and active rehabilitation are important. **Occupational therapy** may improve morale and motor skills, while **speech therapy** may help expressive aphasia or dysarthria. Because of the risk for dysphagia following stroke, access to food and drink is typically restricted until an appropriate swallowing evaluation; the head of the bed should be kept elevated to prevent aspiration. Urinary catheters should *not* be placed and, if placed, removed within 24–48 hours.

Prognosis

The prognosis for survival after cerebral infarction is better than after cerebral or subarachnoid hemorrhage. Patients receiving treatment with rtPA are at least 30% more likely to have minimal or no disability at 3 months than those not treated by this means. Those treated with mechanical embolectomy are also at least 30% more likely to achieve functional independence. Loss of consciousness after a cerebral infarct implies a poorer prognosis than otherwise. The extent of the infarct governs the potential for rehabilitation. Patients who have had a cerebral infarct are at risk for additional strokes and for MIs. The prophylactic measures discussed in the section on treatment reduce this risk. Antiplatelet therapy reduces the recurrence rate by 30% among patients with stroke without a cardiac cause who are not candidates for carotid endarterectomy. Nevertheless, the cumulative risk of recurrence of noncardioembolic stroke is still 3–7% annually. Management is focused on palliative care when meaningful recovery from massive strokes is unlikely (see Chapter 5).

Jovin TG et al. Thrombectomy for anterior circulation stroke beyond 6 h from time last known well (AURORA): a systematic review and individual patient data meta-analysis. Lancet. 2022;399:249. [PMID: 34774198]

3. Intracerebral Hemorrhage

Spontaneous, nontraumatic intracerebral hemorrhage (ICH) in patients with no angiographic evidence of an associated vascular anomaly (eg, aneurysm or angioma) is usually due to hypertension. The pathologic basis for hemorrhage is probably the presence of microaneurysms that develop on perforating vessels in hypertensive patients. Hypertensive ICH occurs most frequently in the basal ganglia, pons, thalamus, and cerebellum, and less commonly in the cerebral white matter. Hemorrhage may extend into the ventricular system or subarachnoid space, and signs of meningeal irritation are then found. In older adults, cerebral amyloid angiopathy is another important and frequent cause of hemorrhage, which is usually lobar in distribution, sometimes recurrent, and associated with a better immediate prognosis than hypertensive hemorrhage. Arteriovenous malformations are an important cause of ICH in younger patients.

Other causes of nontraumatic ICH include hematologic and bleeding disorders (eg, leukemia, thrombocytopenia, hemophilia, or disseminated intravascular coagulation), anticoagulant therapy, liver disease, high alcohol intake, cocaine and methamphetamine abuse, herpes simplex encephalitis, vasculitis, Moyamoya disease, reversible cerebral vasoconstriction syndrome, and primary or secondary brain tumors. There is also an association with advancing age and male sex. Bleeding is primarily into the subarachnoid space when it occurs from an intracranial aneurysm, but it may be partly intraparenchymal as well. Hemorrhage can also occur into arterial and venous cerebral infarcts.

Clinical Findings

A. Symptoms and Signs

With hemorrhage into the cerebral hemisphere, consciousness is initially lost or impaired in about one-half of patients. Vomiting occurs frequently at the onset of bleeding, and headache is sometimes present. Focal symptoms and signs then develop, depending on the site of the hemorrhage. With hypertensive hemorrhage, there is generally a rapidly evolving neurologic deficit with hemiplegia or hemiparesis. A hemisensory disturbance is also present with more deeply placed lesions. With lesions of the putamen, loss of conjugate lateral gaze may be conspicuous. With thalamic hemorrhage, there may be a loss of upward gaze, downward or skew deviation of the eyes, lateral gaze palsies, and pupillary inequalities.

Cerebellar hemorrhage may present with sudden onset of nausea and vomiting, dysequilibrium, ataxia of gait, limbs, or trunk; headache; and loss of consciousness that may terminate fatally within 48 hours. Pontine hemorrhage causes some combination of lateral conjugate gaze palsies to the side of the lesion; small reactive pupils; contralateral hemiplegia; peripheral facial weakness; and periodic respiration. These signs may be bilateral with larger pontine hemorrhage, and the patient may become locked in, with quadriplegia and preserved consciousness.

B. Imaging

CT scanning (without contrast) or MRI with magnetic susceptibility weighted sequences (eg, gradient echo) is important not only in confirming that hemorrhage has occurred but also in determining the size and site of the hematoma. Additional vascular imaging is usually unnecessary, but CT or MR angiography to look for an underlying source of hemorrhage is recommended for the following patients: those under age 70 with lobar ICH, those under age 45 with deep or posterior fossa ICH, and those aged 45 to 70 years with deep or posterior fossa ICH and no history of hypertension. Conventional digital subtraction angiography should be considered when CT or MR angiography is normal, when a vascular lesion is detected on CT or MR angiography, or for cases of isolated intraventricular hemorrhage. CT or MR venography should be considered if the ICH location (eg, parasagittal or temporoparietal regions) suggests cerebral venous thrombosis. In patients with normal vascular imaging and no history of hypertension, a contrast-enhanced MRI may indicate a nonhypertensive cause, such as an underlying neoplasm or cerebral amyloid angiopathy.

C. Laboratory and Other Studies

A CBC, platelet count, prothrombin and partial thromboplastin times, liver biochemical tests, and kidney function tests may reveal a predisposing cause for the hemorrhage. *Lumbar puncture is contraindicated* because it may precipitate a herniation syndrome in patients with a large hematoma, and CT scanning is superior in detecting intracerebral hemorrhage.

Treatment

Patients should be admitted to an ICU for observation and supportive care. The systolic blood pressure should be lowered to 140 mm Hg with intravenous labetalol or nicardipine, although different randomized trials targeting systolic blood pressures of < 140 mm to 180 mm Hg have not shown a difference in outcomes. Lowering systolic blood pressure under 130 mm Hg, however, may be harmful. *Long-term treatment of hypertension is imperative to prevent recurrence.* Thrombocytopenia should be treated with platelet transfusion; the specific threshold for treatment and the goal platelet count after transfusion vary with patient characteristics and provider experience. Platelet transfusion should *not* be used to treat antiplatelet-associated ICH unless emergency surgery is necessary. Anticoagulation should be discontinued immediately, and coagulopathies should be reversed using fresh frozen plasma, prothrombin complex concentrates, vitamin K, or specific reversal agents (eg, protamine for heparin; idarucizumab for dabigatran; and andexanet alfa or 4-factor prothrombin complex concentrates for apixaban, edoxaban, and rivaroxaban). Activated charcoal can be administered if a direct oral anticoagulant was taken within 2 hours. Hemostatic therapy with recombinant activated factor VII in patients without underlying coagulopathy has not improved survival or functional outcome. Intracranial pressure may require monitoring and osmotic therapy. Ventricular drainage with or without intraventricular thrombolysis may be required in patients with intraventricular hemorrhage and acute hydrocephalus. Decompression or minimally invasive hematoma evacuation may be helpful when a superficial hematoma in cerebral white matter is exerting a mass effect and causing incipient herniation. In patients with cerebellar hemorrhage who are deteriorating neurologically or who have brainstem compression or hydrocephalus, prompt surgical evacuation of the hematoma is appropriate because spontaneous unpredictable deterioration may otherwise lead to a fatal outcome and because operative treatment may lead to complete resolution of the clinical deficit. The treatment of underlying structural lesions or bleeding disorders depends on their nature. There is no specific treatment for cerebral amyloid angiopathy.

Pradilla G et al. Trial of early minimally invasive removal of intracerebral hemorrhage. N Engl J Med. 2024;390:1277. [PMID: 38598795]

4. Spontaneous Subarachnoid Hemorrhage

ESSENTIALS OF DIAGNOSIS

- Sudden (“thunderclap”) severe headache.
- Signs of meningeal irritation usually present.
- Obtundation is common.
- Focal deficits frequently absent.

General Considerations

Between 5% and 10% of strokes are due to subarachnoid hemorrhage. Trauma is the most common cause of subarachnoid hemorrhage, the prognosis of which depends on the severity of the head injury. Spontaneous (nontraumatic) subarachnoid hemorrhage frequently results from the rupture of an **arterial saccular (“berry”) aneurysm** or from an **arteriovenous malformation.**

Clinical Findings

A. Symptoms and Signs

Subarachnoid hemorrhage has a characteristic clinical picture. Its onset is with sudden (“**thunderclap**”) headache of a severity never experienced previously by the patient. This may be followed by nausea and vomiting and by a loss or impairment of consciousness that can either be transient or progress inexorably to deepening coma and death. If consciousness is regained, the patient is often confused and irritable and may show other symptoms of an altered mental status. Neurologic examination generally reveals nuchal rigidity and other signs of meningeal irritation, except in deeply comatose patients.

Most aneurysms are asymptomatic until they rupture, but they may cause a focal neurologic deficit by compressing adjacent structures. Occasional patients with aneurysms have headaches, sometimes accompanied by nausea and neck stiffness, a few hours or days before massive subarachnoid hemorrhage occurs. This has been attributed to “warning leaks” of a small amount of blood from the aneurysm.

A higher risk of subarachnoid hemorrhage is associated with older age, female sex, non-White ethnicity, hypertension, tobacco smoking, high alcohol consumption (exceeding 150 g per week), previous symptoms, posterior circulation aneurysms, and larger aneurysms. Focal neurologic signs are usually absent but, when present, may relate either to a focal intracerebral hematoma (from arteriovenous malformations) or to ischemia in the territory of the vessel with a ruptured aneurysm.

B. Imaging

A CT scan (preferably with CT angiography) should be performed immediately to confirm that hemorrhage has occurred and to search for clues regarding its source. CT is preferable to MRI because it is faster and more sensitive in detecting hemorrhage in the first 24 hours. CT findings sometimes are normal in patients with suspected hemorrhage, and the CSF must then be examined for the presence of blood or xanthochromia before the possibility of subarachnoid hemorrhage is discounted.

Cerebral arteriography is undertaken to determine the source of bleeding. In general, bilateral carotid and vertebral arteriography are necessary because aneurysms are often multiple, while arteriovenous malformations may be supplied from several sources. The procedure allows an interventional radiologist to treat an underlying aneurysm or arteriovenous malformation by various techniques. If arteriograms show no abnormality, the examination should be repeated after 2 weeks because vasospasm or thrombus may have prevented detection of an aneurysm or other vascular anomaly during the initial study. CT or MR angiography may also be revealing but is less sensitive than conventional arteriography.

C. Laboratory and Other Studies

The CSF demonstrates an elevated RBC count. Subarachnoid hemorrhage can be differentiated from a traumatic lumbar puncture by the lack of clearing of RBCs from the first and fourth tube of CSF or by the presence of xanthochromia, which occurs due to lysis of RBCs and takes at least 2 hours to develop. The absolute RBC count is also helpful: in the absence of xanthochromia, an RBC count of < 2000/mcL (2.0×10^9/L) is unlikely to be due to subarachnoid hemorrhage. ECG evidence of arrhythmias or myocardial ischemia has been well described and probably relates to excessive sympathetic activity. Peripheral leukocytosis and transient glycosuria are also common findings.

▶ Treatment

All patients should be hospitalized and seen by a neurologist. The measures outlined below in the section on stupor and coma are applied to comatose patients. Conscious patients are confined to bed, advised against any exertion or straining, treated symptomatically for headache and anxiety, and given laxatives or stool softeners. The systolic blood pressure should be lowered to 140 mm Hg until the aneurysm is treated definitively. Seizure prophylaxis is *not* necessary unless a convulsion has occurred (see Table 27–3). Patients are generally hospitalized for at least 14 days to monitor, prevent, and treat vasospasm.

The major aim of treatment is to prevent further hemorrhage. The risk of further hemorrhage from a ruptured aneurysm is greatest within a few days of the first hemorrhage; approximately 20% of patients will have further bleeding within 2 weeks and 40% within 6 months. Definitive treatment, ideally within 2 days of the hemorrhage, requires surgical clipping of the aneurysm or endovascular treatment by coil embolization; the latter is sometimes feasible even for inoperable aneurysms and has a lower morbidity than surgery.

▶ Complications

Spontaneous subarachnoid hemorrhage may result in severe complications, so monitoring is necessary, usually in an ICU. Hemiplegia or other focal deficit sometimes may follow aneurysmal bleeding after a delay of 2–14 days due to focal arterial spasm. The etiology of **vasospasm** is uncertain and likely multifactorial, and it sometimes leads to significant cerebral ischemia or infarction and may further aggravate any existing increase in intracranial pressure. Transcranial Doppler ultrasound may be used to screen noninvasively for vasospasm, but conventional arteriography is required to document and treat vasospasm when the clinical suspicion is high. *Nimodipine has been shown to reduce the incidence of ischemic deficits from arterial spasm*; a dose of 60 mg every 4 hours orally for 21 days is given prophylactically to all patients. After surgical obliteration of all aneurysms, symptomatic vasospasm may also be treated by intravascular volume expansion and induced hypertension; transluminal balloon angioplasty of involved intracranial vessels is also helpful.

Acute hydrocephalus, which sometimes occurs due to CSF outflow disruption by the subarachnoid blood, should be suspected if the patient deteriorates clinically; a repeat CT scan should be obtained. Acute hydrocephalus frequently causes intracranial hypertension severe enough to require temporary, and less commonly prolonged or permanent, intraventricular CSF shunting. **Cerebral salt-wasting** is another complication of subarachnoid hemorrhage that may develop abruptly during the first several days of hospitalization. The resulting hyponatremia and cerebral edema may exacerbate intracranial hypertension and may require carefully titrated treatment with oral sodium chloride or intravenous hyperosmotic sodium solution. Daily measurement of the serum sodium level allows for the early detection of this complication. **Hypopituitarism** may occur as a late complication of subarachnoid hemorrhage.

Hoh BL et al. Guideline for the management of patients with aneurysmal subarachnoid hemorrhage: a guideline from the American Heart Association/American Stroke Association. Stroke. 2023;54:e314. [PMID: 37212182]

5. Intracranial Venous Thrombosis

Intracranial venous thrombosis may occur in association with intracranial or maxillofacial infections, hypercoagulable states, polycythemia, sickle cell disease, cyanotic congenital heart disease, and in pregnancy or during the puerperium. Genetic factors are also important. Cases of intracranial venous thrombosis with thrombocytopenia and antiplatelet factor 4 antibodies have rarely been observed after administration of SARS-CoV-2 adenoviral vector vaccines. The disorder is characterized by headache, focal or generalized convulsions, drowsiness, confusion, increased intracranial pressure, and focal neurologic deficits—and sometimes by evidence of meningeal irritation. The diagnosis is confirmed by CT or MR venography or angiography.

Treatment includes anticonvulsants if seizures have occurred (Table 27–3) and—if necessary—measures to reduce intracranial pressure. Anticoagulation with dose-adjusted intravenous heparin or weight-adjusted subcutaneous low-molecular-weight heparin, followed by oral warfarin anticoagulation for 6 months reduces morbidity and mortality of venous sinus thrombosis. Direct oral anticoagulants are likely acceptable alternatives to warfarin based on one randomized trial comparing dabigatran to warfarin and many observational studies comparing rivaroxaban, apixaban, and dabigatran to warfarin showing similar efficacy. Measurement of antiplatelet factor 4 antibodies and treatment with a non-heparin anticoagulant and intravenous immunoglobulin (1 g/kg daily for 2 days) or therapeutic plasma exchange for 5 to 7 days is recommended in cases following SARS-CoV-2 vaccination. *Concomitant intracranial hemorrhage related to the venous thrombosis does not contraindicate anticoagulant therapy.* In cases refractory to anticoagulation, endovascular techniques including catheter-directed thrombolytic therapy (urokinase) and thrombectomy are sometimes helpful but may increase the risk for major hemorrhage.

Saposnik G et al. Diagnosis and management of cerebral venous thrombosis: a scientific statement from the American Heart Association. Stroke. 2024;55:e77. [PMID: 38284265]

6. Infarction of the Spinal Cord

ESSENTIALS OF DIAGNOSIS

- Sudden onset of back or limb pain and neurologic deficit in limbs.
- Motor, sensory, or reflex changes in limbs depending on level of lesion.
- Imaging studies distinguish between infarct and hematoma.

Infarction of the spinal cord is rare and typically occurs in the territory of the anterior spinal artery; this vessel, which supplies the anterior two-thirds of the cord, is itself supplied by only a limited number of feeders. Infarction usually results from interrupted flow in one or more of these feeders (eg, with aortic dissection, aortic aneurysm, aortography, polyarteritis, severe hypotension, or after surgical repair of the thoracic or abdominal aorta). The paired posterior spinal arteries, by contrast, are supplied by numerous arteries at different levels of the cord. Spinal cord hypoperfusion may lead to a central cord syndrome with distal weakness of lower motor neuron type and loss of pain and temperature appreciation, with preserved posterior column function.

Since the anterior spinal artery receives numerous feeders in the cervical region, infarcts almost always occur caudally. Clinical presentation is characterized by acute onset of flaccid, areflexive paraplegia that evolves after a few days or weeks into a spastic paraplegia with extensor plantar responses. There is an accompanying dissociated sensory loss, with impairment of appreciation of pain and temperature but preservation of sensations of vibration and joint position.

The risk of spinal cord infarction in the setting of abdominal aortic surgery and thoracic endovascular repair may be reduced by intraoperative CSF drainage through a catheter placed in the lumbar subarachnoid space to reduce intraspinal pressure. If signs of infarction are noted after surgery, blood pressure augmentation for 24–48 hours in addition to lumbar drainage has been noted anecdotally to improve outcomes. CSF drainage and blood pressure augmentation are also sometimes attempted in patients with spinal cord infarction due to other causes. Treatment is otherwise symptomatic.

Jadhav AP. Vascular myelopathies. Continuum (Minneap Minn). 2024;30:160. [PMID: 38330477]

7. Spinal Epidural or Subdural Hemorrhage

Epidural or subdural hemorrhage may lead to sudden severe back pain followed by an acute compressive myelopathy necessitating urgent spinal MRI or myelography and surgical evacuation. It may occur in patients with bleeding disorders or those who are taking anticoagulants, sometimes following trauma or lumbar puncture. Epidural hemorrhage may also be related to a vascular malformation or tumor deposit.

Benzon HT et al. Literature review of spinal hematoma case reports: causes and outcomes in pediatric, obstetric, neuraxial and pain medicine cases. Reg Anesth Pain Med. 2024;49:900. [PMID: 38267076]

When to Refer

All patients with stroke should be referred.

When to Admit

All patients should be hospitalized, preferably in a stroke care unit.

ANEURYSMS & VASCULAR MALFORMATIONS

1. Intracranial Aneurysm

ESSENTIALS OF DIAGNOSIS

- Subarachnoid hemorrhage or focal deficit.
- Abnormal imaging studies.

General Considerations

Saccular aneurysms (**"berry" aneurysms**) tend to occur at arterial bifurcations, are frequently multiple (20% of cases), and are usually asymptomatic. They are associated with polycystic kidney disease, Moyamoya disease, familial aldosteronism type 1, and coarctation of the aorta. Risk factors for aneurysm formation include cigarette smoking, hypertension, and female sex. Most aneurysms are located on the anterior part of the circle of Willis—particularly on the anterior or posterior communicating arteries, at the bifurcation of the middle cerebral artery, and at the bifurcation of the internal carotid artery. Mycotic aneurysms resulting from septic embolism occur in more distal vessels and often at the cortical surface. *The most significant complication of intracranial aneurysms is a subarachnoid hemorrhage*, which is discussed in the preceding section.

Clinical Findings

A. Symptoms and Signs

Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. Its manifestations, complications, and management were outlined in the preceding section.

B. Imaging

Definitive evaluation is by **digital subtraction angiography** (bilateral carotid and vertebral studies), which generally indicates the size and site of the lesion, sometimes reveals multiple aneurysms, and may show arterial spasm if rupture has occurred. Visualization by CT or MR angiography is not usually adequate if operative treatment is under consideration because lesions may be multiple and small lesions are sometimes missed, but these modalities can be used to screen patients who have two or more first-degree relatives with intracranial aneurysms.

Treatment

The major aim of treatment is to prevent hemorrhage. Management of ruptured aneurysms was described in the section on subarachnoid hemorrhage. Symptomatic but unruptured aneurysms merit prompt treatment, either surgically or by endovascular techniques. The decision to treat or monitor asymptomatic aneurysms discovered incidentally is complicated and depends on aneurysm size, location, risk factors for rupture, and treatment-related morbidity; risk scores to guide decision-making are available.

Reddy A et al. Endovascular and medical management of unruptured intracranial aneurysms. Semin Neurol. 2023;43:480. [PMID: 37517406]

2. Cerebral Arteriovenous Malformations

ESSENTIALS OF DIAGNOSIS

- Sudden onset of subarachnoid and intracerebral hemorrhage.
- Distinctive neurologic signs reflect the region of the brain involved.
- Signs of meningeal irritation in patients presenting with subarachnoid hemorrhage.
- Seizures or focal deficits may occur.

General Considerations

Arteriovenous malformations are congenital vascular malformations that result from a localized maldevelopment of part of the primitive vascular plexus and consist of abnormal arteriovenous communications without intervening capillaries. They vary in size, ranging from massive lesions that are fed by multiple vessels and involve a large part of the brain to lesions so small that they are hard to identify at arteriography, surgery, or autopsy. In approximately 10% of cases, there is an associated arterial aneurysm, while 1–2% of patients presenting with aneurysms have associated arteriovenous malformations. Clinical presentation may relate to hemorrhage from the malformation or an associated aneurysm or may relate to cerebral ischemia due to diversion of blood by the anomalous arteriovenous shunt or due to venous stagnation. Regional maldevelopment of the brain, compression or distortion of adjacent cerebral tissue by enlarged anomalous vessels, and progressive gliosis due to mechanical and ischemic factors may also be contributory.

Clinical Findings

Most cerebral arteriovenous malformations are supratentorial, usually lying in the territory of the middle cerebral artery. *Up to 70% bleed at some point in their natural history*, most commonly before the patient reaches the age of 40 years. Arteriovenous malformations that have bled once are more likely to bleed again, at an approximate rate of 4.5% annually. A higher risk of bleeding is also observed if there is an associated aneurysm, deep venous drainage, or deep brain location; size of the malformation and sex are not associated with risk of hemorrhage.

A. Symptoms and Signs

Initial symptoms consist of hemorrhage in 30–60% of cases, recurrent seizures in 20–40%, headache in 5–25%, and miscellaneous complaints (including focal deficits) in 10–15%. Hemorrhage is commonly intracerebral as well as into the subarachnoid space and is fatal in about 10% of cases. Seizures are more likely with frontal or parietal arteriovenous malformations. Headaches are especially likely when the external carotid arteries are involved in the malformation. These sometimes simulate migraine, but more commonly are nonspecific in character, with nothing about them to suggest an underlying structural lesion. Brainstem and cerebellar arteriovenous malformations may cause obstructive hydrocephalus.

In patients presenting with subarachnoid hemorrhage, examination may reveal an abnormal mental status and signs of meningeal irritation. Additional findings may help localize the lesion and sometimes indicate that intracranial pressure is increased. *A cranial bruit always suggests the possibility of a cerebral arteriovenous malformation*, but bruits may also be found with aneurysms, meningiomas, acquired arteriovenous fistulas, and arteriovenous malformations involving the scalp, calvarium, or orbit. Bruits are best heard over the ipsilateral eye or mastoid region and are of some help in lateralization but of no help in localization. Absence of a bruit *does not exclude* the possibility of arteriovenous malformation.

B. Imaging

In patients with suspected hemorrhage, CT scanning indicates whether subarachnoid or intracerebral bleeding has recently occurred, helps localize its source, and may reveal the arteriovenous malformation. When intracranial hemorrhage is confirmed but the source of hemorrhage is not evident on the CT scan, arteriography is necessary to exclude aneurysm or arteriovenous malformation. MR and CT angiography are not sensitive enough for this purpose. Even if the findings on CT scan suggest arteriovenous malformation, arteriography is required to establish the nature of the lesion with certainty and to determine its anatomic features so that treatment can be planned. The examination must generally include bilateral opacification of the internal and external carotid arteries and the vertebral arteries.

In patients presenting without hemorrhage, CT scan or MRI usually reveals the underlying abnormality, and MRI frequently also shows evidence of old or recent hemorrhage that may have been asymptomatic. The nature and detailed anatomy of any focal lesion identified by these means are delineated by angiography, especially if operative treatment is under consideration.

C. Laboratory and Other Studies

Electroencephalography is usually indicated in patients presenting with seizures and may show consistently focal or lateralized abnormalities resulting from the underlying cerebral arteriovenous malformation. This should be followed by CT scanning.

Treatment

Surgical treatment to prevent further hemorrhage is justified in patients with arteriovenous malformations that have bled, provided that the lesion is accessible and the patient has a reasonable life expectancy. Surgical treatment is also appropriate if intracranial pressure is increased and to prevent further progression of a focal neurologic deficit. In patients presenting solely with seizures, anticonvulsant treatment is usually sufficient (Table 27–3), and operative treatment is unnecessary unless seizures cannot be controlled medically.

Definitive operative treatment consists of excision of the arteriovenous malformation if it is surgically accessible. Stereotactic radiosurgery is used to treat inoperable cerebral arteriovenous malformations. Arteriovenous malformations that are inoperable because of their location are sometimes treated solely by embolization; although the risk of hemorrhage is not reduced, neurologic deficits may be stabilized or even reversed by this procedure. Embolization is more commonly performed as an adjunct to surgery or radiosurgery; it is also used to treat aneurysms associated with the arteriovenous malformations.

Nguyen TN. Management of unruptured intracranial aneurysms and brain arteriovenous malformations. Continuum (Minneap Minn). 2023;29:584. [PMID: 37039411]

3. Spinal Dural Arteriovenous Fistulae

Spinal dural arteriovenous fistulae are congenital lesions that present with spinal subarachnoid hemorrhage or myeloradiculopathy. Since most of these malformations are located in the thoracolumbar region, they lead to motor and sensory disturbances in the legs and to sphincter disorders. Pain in the legs or back is often severe. Examination reveals an upper, lower, or mixed motor deficit in the legs; sensory deficits are also present and are usually extensive, although occasionally they are confined to a radicular distribution. Cervical spinal dural arteriovenous fistulae lead also to symptoms and signs in the arms. Spinal MRI may not detect the spinal dural arteriovenous fistula, although most cases show either T2 hyperintensity in the cord or perimedullary flow voids. Myelography (performed with the patient prone and supine) may detect serpiginous filling defects due to enlarged vessels. **Selective spinal arteriography** is required to confirm the diagnosis and plan treatment. Most lesions are extramedullary, are posterior to the cord (lying either intradurally or extradurally), and can be treated easily by ligation of feeding vessels and excision of the fistulous anomaly or by embolization procedures. Delay in treatment may lead to increased and irreversible disability or to death from recurrent subarachnoid hemorrhage.

Mamaril-Davis J et al. Recurrence rates following treatment of spinal vascular malformations: a systematic review and meta-analysis. World Neurosurg. 2023;173:e250. [PMID: 36787855]

When to Refer

All patients should be referred.

When to Admit

- All patients with a subarachnoid or cerebral hemorrhage.
- All patients undergoing surgical or endovascular treatment.

INTRACRANIAL & SPINAL MASS LESIONS

1. Primary Intracranial Tumors

ESSENTIALS OF DIAGNOSIS

- Generalized or focal disturbance of cerebral function, or both.
- Increased intracranial pressure in some patients.
- Neuroradiologic evidence of space-occupying lesion.

General Considerations

Roughly one-third of all primary intracranial neoplasms (Table 27–5) are meningiomas, one-quarter are gliomas, and the remainder are pituitary adenomas (see Chapter 29), neurofibromas, and other tumors. Certain tumors, especially neurofibromas, hemangioblastomas, and retinoblastomas, may have a familial basis, and congenital factors bear on the development of craniopharyngiomas. Tumors may occur at any age, but certain gliomas show particular age predilections.

Table 27–5. Primary intracranial tumors (listed by major histology grouping and by incidence within each group).

Tumor	Clinical Features	Treatment and Prognosis
Tumors of Meninges		
Meningioma	Originates from the dura mater or arachnoid; compresses rather than invades adjacent neural structures. Increasingly common with advancing age. Tumor size varies greatly. Symptoms vary with tumor site—eg, unilateral proptosis (sphenoidal ridge); anosmia and optic nerve compression (olfactory groove). Tumor is usually benign and readily detected by CT scanning; may lead to calcification and bone erosion visible on plain radiographs of skull.	Treatment is surgical. Tumor may recur if removal is incomplete.
Tumors of Neuroepithelial Origin		
Glioblastoma multiforme	Presents commonly with nonspecific complaints and increased intracranial pressure. As it grows, focal deficits develop. O^6-methylguanine-DNA methyltransferase promoter methylation positivity (seen in 40% of cases) and isocitrate dehydrogenase 1/2 mutations (seen in 10% of cases) carry better prognosis.	Course is rapidly progressive, with poor prognosis (< 20% survival at 2 years). Total surgical removal is usually not possible. Radiation therapy and temozolamide may prolong survival. Tumor treatment fields added to temozolamide after completion of radiation therapy prolong survival.
Astrocytoma	Presentation similar to glioblastoma multiforme but course more protracted, often over several years. Cerebellar astrocytoma may have a more benign course. Isocitrate dehydrogenase 1/2 mutations (seen in most cases) carry better prognosis in grade II and III tumors.	Prognosis is variable. By the time of diagnosis, total excision is usually impossible; tumor may be radiosensitive and temozolamide; procarbazine, lomustine, plus vincristine; or vorasidenib may be used. In cerebellar astrocytoma, total surgical removal is often possible.
Ependymoma	Glioma arising from the ependyma of a ventricle, especially the fourth ventricle; leads to early signs of increased intracranial pressure. Arises also from central canal of cord.	Tumor is best treated surgically if possible. Radiation therapy may be used for residual tumor.
Oligodendroglioma	Slow-growing. Usually arises in cerebral hemisphere in adults. Calcification may be visible on skull radiograph. Co-deletion of 1p/19q and isocitrate dehydrogenase 1/2 mutation required for diagnosis.	Treatment is surgical and usually successful. Radiation and chemotherapy (temozolamide; procarbazine, lomustine, plus vincristine; or vorasidenib) may be used.
Brainstem glioma	Presents during childhood with cranial nerve palsies and then with long tract signs in the limbs. Signs of increased intracranial pressure occur late.	Tumor is inoperable; treatment is by irradiation and shunt for increased intracranial pressure.
Neuronal and mixed neuronal-glial tumors	Slow-growing; usually arise in cerebral hemispheres; often associated with seizures. Some are benign (eg, dysembryoblastic neuroepithelial tumors) and some have malignant potential (eg, ganglioglioma).	Resection is not always necessary for benign tumors unless seizures are medically refractory but is indicated for those with malignant potential.
Medulloblastoma	Seen most frequently in children. Generally arises from roof of fourth ventricle and leads to increased intracranial pressure accompanied by brainstem and cerebellar signs. May seed subarachnoid space. Wingless activated tumors carry best prognosis (> 90% 5-year survival).	Treatment consists of surgery combined with radiation therapy and chemotherapy; 5-year survival exceeds 70%. Wingless activated tumors may require less aggressive treatment.
Pineal tumor	Presents with increased intracranial pressure, sometimes associated with impaired upward gaze (Parinaud syndrome) and other deficits indicative of midbrain lesion.	Ventricular decompression by shunting is followed by surgical approach to tumor; irradiation is indicated if tumor is malignant. Prognosis depends on histopathologic findings and extent of tumor.
Tumors of the Sellar Region		
Pituitary adenoma	Functioning adenomas present with symptoms of hormone secretion; nonfunctioning adenomas present with symptoms of local mass effect (eg, bitemporal hemianopsia, hypopituitarism) or are found incidentally.	Prolactin-secreting adenomas are treated with bromocriptine or cabergoline. Others are surgically resected. Pituitary hormone replacement may be required.
Craniopharyngioma	Originates from remnants of Rathke pouch above the sella, depressing the optic chiasm. May present at any age but usually in childhood, with endocrine dysfunction and bitemporal visual field defects.	Treatment is surgical, but total removal may not be possible. Radiation may be used for residual tumor.

(*continued*)

Table 27–5. Primary intracranial tumors (listed by major histology grouping and by incidence within each group). (continued)

Tumor	Clinical Features	Treatment and Prognosis
Germ cell tumors (germinomas and nongerminomatous germ cell tumors)	Two most common locations are pineal and suprasellar regions. The pineal region presentation is as described in pineal tumors, above. Suprasellar tumors present with hypothalamic and pituitary dysfunction such as diabetes insipidus, delayed or precocious puberty, or growth hormone deficiency.	Germinomas are treated with radiation; prognosis is good for localized tumors. Chemotherapy is added for nongerminomatous germ cell tumors.
Tumors of Cranial and Spinal Nerves		
Acoustic neurinoma (also referred to as acoustic neuroma)	Ipsilateral hearing loss is most common initial symptom. Subsequent symptoms may include tinnitus, headache, vertigo, facial weakness or numbness, and long tract signs. (May be familial and bilateral when related to neurofibromatosis.) Most sensitive screening tests are MRI and brainstem auditory evoked potential.	Treatment is excision by translabyrinthine surgery, craniectomy, or a combined approach. Outcome is usually good.
Lymphomas		
Primary cerebral lymphoma	Associated with AIDS and other immunodeficient states. Presentation may be with focal deficits or with disturbances of cognition and consciousness. May be indistinguishable from cerebral toxoplasmosis.	Treatment is high-dose methotrexate and corticosteroids followed by radiation therapy. Prognosis depends on CD4 count at diagnosis.
Unclassified		
Cerebellar hemangioblastoma	Presents with dysequilibrium, ataxia of trunk or limbs, and signs of increased intracranial pressure. Sometimes familial. May be associated with retinal and spinal vascular lesions, polycythemia, and renal cell carcinoma.	Treatment is surgical. Radiation is used for residual tumor.

Clinical Findings

A. Symptoms and Signs

Intracranial tumors typically present with headache, seizures, or focal neurologic deficits. New headaches or symptoms of elevated intracranial pressure, such as headaches awaking a patient from sleep or worsening with Valsalva maneuver, cough, or recumbency, are suggestive of brain tumor. Intracranial tumors may also lead to a generalized disturbance of cerebral function with personality changes, intellectual decline, emotional lability, nausea, and malaise.

1. Frontal lobe lesions—Tumors of the frontal lobe often lead to progressive intellectual decline, slowing of mental activity, personality changes, and contralateral grasp reflexes. They may lead to expressive aphasia if the posterior part of the left inferior frontal gyrus is involved. Anosmia may also occur as a consequence of pressure on the olfactory nerve. Precentral lesions may cause focal motor seizures or contralateral pyramidal deficits.

2. Temporal lobe lesions—Tumors of the uncinate region may be manifested by seizures with olfactory or gustatory hallucinations, motor phenomena such as licking or smacking of the lips, and some impairment of external awareness without actual loss of consciousness. Temporal lobe lesions also lead to depersonalization, emotional changes, behavioral disturbances, sensations of déjà vu or jamais vu, micropsia or macropsia (objects appear smaller or larger than they are), visual field defects (crossed upper quadrantanopia), and auditory illusions or hallucinations. Left-sided lesions may lead to dysnomia and receptive aphasia, while right-sided involvement sometimes disturbs the perception of musical notes and melodies.

3. Parietal lobe lesions—Tumors in this location characteristically cause contralateral disturbances of sensation and may cause sensory seizures, sensory loss or inattention, or some combination of these symptoms. The sensory loss is cortical in type and involves postural sensibility and tactile discrimination, so that the appreciation of shape, size, weight, and texture is impaired. Objects placed in the hand may not be recognized (astereognosis). Extensive parietal lobe lesions may produce contralateral hyperpathia and spontaneous pain (**thalamic syndrome**). Involvement of the optic radiation leads to a contralateral homonymous field defect that sometimes consists solely of lower quadrantanopia. Lesions of the left angular gyrus cause **Gerstmann syndrome** (a combination of alexia, agraphia, acalculia, right-left confusion, and finger agnosia), whereas involvement of the left submarginal gyrus causes ideational apraxia. Anosognosia (the denial, neglect, or rejection of a paralyzed limb) is seen in patients with lesions of the nondominant (right) hemisphere. Constructional apraxia and dressing apraxia may also occur with right-sided lesions.

4. Occipital lobe lesions—Tumors of the occipital lobe characteristically produce contralateral homonymous hemianopia or a partial field defect. With left-sided or bilateral lesions, there may be visual agnosia both for objects and for colors, while irritative lesions on either side can cause unformed visual hallucinations. Bilateral occipital lobe involvement causes cortical blindness in which there is preservation of pupillary responses to light and lack of awareness of the defect by the patient. There may also be loss of color perception, prosopagnosia (inability to identify a familiar face), simultagnosia (inability to integrate and interpret a composite scene as opposed to its individual elements), and Balint syndrome (failure to turn the eyes to a particular point in space, despite preservation of spontaneous and reflex eye movements). The denial of blindness or a field defect constitutes **Anton syndrome**.

5. Brainstem and cerebellar lesions—Brainstem lesions lead to cranial nerve palsies, ataxia, incoordination, nystagmus, and pyramidal and sensory deficits in the limbs on one or both sides. Intrinsic brainstem tumors, such as gliomas, tend to produce an increase in intracranial pressure only late in their course. Cerebellar tumors produce marked ataxia of the trunk if the vermis cerebelli is involved and ipsilateral appendicular deficits (ataxia, incoordination, and hypotonia of the limbs) if the cerebellar hemispheres are affected.

6. Herniation syndromes—If the pressure is increased in a particular cranial compartment, brain tissue may herniate into a compartment with lower pressure. The most familiar syndrome is herniation of the temporal lobe uncus through the tentorial hiatus, which causes compression of the third cranial nerve, midbrain, and posterior cerebral artery. The earliest sign of this is ipsilateral pupillary dilation, followed by stupor, coma, decerebrate posturing, and respiratory arrest. Another important herniation syndrome consists of displacement of the cerebellar tonsils through the foramen magnum, which causes medullary compression leading to apnea, circulatory collapse, and death.

7. False localizing signs—Tumors may lead to neurologic signs other than by direct compression or infiltration, thereby leading to errors of clinical localization. These false localizing signs include third or sixth nerve palsy and bilateral extensor plantar responses produced by herniation syndromes, and an extensor plantar response occurring ipsilateral to a hemispheric tumor as a result of compression of the opposite cerebral peduncle against the tentorium.

B. Imaging

MRI with gadolinium enhancement is the preferred method to detect the lesion and to define its location, shape, and size; the extent to which normal anatomy is distorted; and the degree of any associated cerebral edema or mass effect. CT scanning with radiocontrast enhancement could be performed; however, it is less helpful than MRI for small lesions or tumors in the posterior fossa. The characteristic appearance of meningiomas on MRI or CT scanning is virtually diagnostic, ie, a lesion in a typical site (parasagittal and sylvian regions, olfactory groove, sphenoidal ridge, tuberculum sellae) that appears as a homogeneous area of increased density in noncontrast scans and enhances uniformly with contrast. Additional MRI sequences that may be helpful in differentiating gliomas from other intracranial pathology include perfusion imaging, magnetic resonance spectroscopy, and diffusion-weighted imaging, although none are specific enough to obviate the need for tissue sampling. Arteriography is largely reserved for presurgical embolization of highly vascular tumors. In patients with normal hormone levels and an intrasellar mass, angiography is sometimes necessary to distinguish with confidence between a pituitary adenoma and an arterial aneurysm.

C. Laboratory and Other Studies

When glial neoplasms are suspected, biopsy is necessary for definitive histologic diagnosis and molecular analysis. The WHO classifies glial tumors by both histology and genetic characteristics. Lumbar puncture is rarely necessary; the findings are seldom diagnostic, and the procedure carries the risk of causing a herniation syndrome. Suspected intracranial germ cell tumors are an exception. If lumbar puncture can be performed safely, cytology and determination of α-fetoprotein and β-human chorionic gonadotropin should be performed in CSF; tumor markers should be examined in serum as well.

▶ Treatment

Treatment depends on the type, grade, genetics, and site of the tumor (Table 27–5) and the condition of the patient. Some benign tumors, especially meningiomas discovered incidentally during brain imaging for another purpose, may be monitored with serial annual imaging. For symptomatic tumors, complete surgical removal may be possible if the tumor is extra-axial (eg, meningioma, acoustic neuroma) or is not in a critical or inaccessible region of the brain (eg, cerebellar hemangioblastoma). Surgery also permits the diagnosis to be verified and tumor genetics to be determined. Even if the neoplasm cannot be removed, surgery may be beneficial in reducing intracranial pressure and relieving symptoms. Clinical deficits are sometimes due in part to obstructive hydrocephalus, in which case simple surgical shunting procedures often produce dramatic benefit. In patients with malignant gliomas, survival correlates to the extent of initial resection.

Radiation therapy increases median survival rates regardless of any preceding surgery, and its combination with chemotherapy provides additional benefit. Indications for irradiation in the treatment of patients with other primary intracranial neoplasms depend on tumor type and accessibility and the feasibility of complete surgical removal. Long-term neurocognitive deficits may complicate radiation therapy. Temozolomide is a commonly used oral and intravenous chemotherapeutic for gliomas. The addition of low-intensity, 200 kHz frequency alternating electric fields (tumor treatment fields) delivered extracranially at least 18 hours daily improves progression-free survival by 2.7 months and median survival by 4.9 months compared to temozolomide alone in glioblastoma. Bevacizumab is approved in the United States but not in Europe for use in recurrent high-grade glioma.

Tumor genetics guide medical treatment. In patients with glioblastoma with methylated methylguanine-DNA methyltransferase (MGMT) promoter, combination therapy with lomustine and temozolomide improved median survival from 31 to 48 months in an RCT. Combination therapy with procarbazine, lomustine, and vincristine improves median survival when given with radiation to patients with isocitrate dehydrogenase (IDH)–mutant astrocytoma and IDH–mutant, p1/19q co-deleted oligodendroglioma. Grade 2 IDH-mutant astrocytomas and oligodendrogliomas may also be treated with the IDH inhibitor vorasidenib (40 mg once daily orally), which prolongs progression-free survival.

Corticosteroids help reduce cerebral edema and are usually started before surgery. Herniation is treated with intravenous dexamethasone (10–20 mg as a bolus, followed by 4 mg every 6 hours) and intravenous mannitol (20% solution given in a dose of 1.5 g/kg over about 30 minutes).

Anticonvulsants are also commonly administered in standard doses (see Table 27–3) but are not indicated for prophylaxis in patients who have no history of seizures. For those patients with difficult to treat symptoms or those needing help with advance care planning, specialty palliative care consultation is appropriate (see Chapter 5).

Mellinghoff IK et al. Vorasidenib in IDH1- or IDH2-mutant low-grade glioma. N Engl J Med. 2023;389:589. [PMID: 37272516]

Swensen SN et al. Treatment options for IDH-mutant malignant gliomas. Curr Treat Options Oncol. 2024;25:1594. [PMID: 39612163]

2. Metastatic Intracranial Tumors

A. Cerebral Metastases

Metastatic brain tumors present in the same way as other cerebral neoplasms, ie, with increased intracranial pressure, with focal or diffuse disturbance of cerebral function, or with both of these manifestations. Indeed, in patients with a single cerebral lesion, the metastatic nature of the lesion may become evident only on histopathologic examination. In other patients, there is evidence of widespread metastatic disease, or an isolated cerebral metastasis develops during treatment of the primary neoplasm.

The most common source of intracranial metastasis is carcinoma of the lung; other primary sites are the breast, kidney, skin (melanoma), and GI tract. Most cerebral metastases are located supratentorially. Laboratory and radiologic studies used to evaluate patients with metastases are those described for primary neoplasms. They include MRI and CT scanning performed both with and without contrast. Lumbar puncture is necessary only in patients with suspected carcinomatous meningitis. In patients with verified cerebral metastasis from an unknown primary, investigation is guided by symptoms and signs. In women, mammography is indicated; in men under 50, germ cell origin is sought.

Treatment of brain metastases is rapidly evolving and a multidisciplinary approach between neurosurgery, radiation oncology, oncology, and palliative care is necessary. In patients with only a single, surgically accessible cerebral metastasis who are otherwise well (ie, a high level of functioning and little or no evidence of extracranial disease), it may be possible to remove the lesion and then treat with irradiation; the latter may also be selected as the sole treatment. Systemic immunotherapy may also be an acceptable initial option in select cases. In patients with multiple metastases or widespread systemic disease, stereotactic radiosurgery, whole-brain radiotherapy, or both may help in some instances; systemic chemotherapy or immunotherapy may be options in others, but in many, treatment is palliative only. *Memantine (5 mg once daily orally titrated by 5 mg weekly to 10 mg twice daily) reduced cognitive toxicity associated with whole-brain radiotherapy in a randomized trial and is recommended*; this effect can be augmented through intensity modulated radiation therapy with hippocampal avoidance.

B. Leptomeningeal Metastases (Carcinomatous Meningitis)

The neoplasms metastasizing most commonly to the leptomeninges are carcinoma of the breast and lung, lymphomas, and leukemia (see Chapter 44*)*. Leptomeningeal metastases lead to multifocal neurologic deficits, which may be associated with infiltration of cranial and spinal nerve roots, direct invasion of the brain or spinal cord, obstructive or communicating hydrocephalus, or some combination of these factors.

The diagnosis is confirmed by examination of the CSF. Findings may include elevated CSF pressure, pleocytosis, increased protein concentration, and decreased glucose concentration. Cytologic studies may indicate that malignant cells are present; if not, lumbar puncture should be repeated at least twice to obtain further samples for analysis.

CT scans showing contrast enhancement in the basal cisterns or showing hydrocephalus without any evidence of a mass lesion support the diagnosis. Gadolinium-enhanced MRI is more sensitive and frequently shows enhancing foci in the leptomeninges. Myelography may show deposits on multiple nerve roots.

Treatment is by irradiation to symptomatic areas, combined with intrathecal chemotherapy in select patients. The long-term prognosis is poor—only about 10% of patients survive for 1 year—and palliative care is therefore important (see Chapter 5).

Kumthekar P et al. Brain metastases and leptomeningeal disease. Continuum (Minneap Minn). 2023;29:1727. [PMID: 38085896]

3. Intracranial Mass Lesions in Patients with AIDS

Primary cerebral lymphoma is a common complication in patients with AIDS. This leads to disturbances in cognition or consciousness, focal motor or sensory deficits, aphasia, seizures, and cranial neuropathies. Similar clinical disturbances may result from **cerebral toxoplasmosis**, which is also a common complication in patients with AIDS (see Chapters 36 and 39). **Cryptococcal meningitis** is a common opportunistic infection in patients with AIDS. Clinically, it may resemble cerebral toxoplasmosis or lymphoma, but cranial CT scans are usually normal (see Chapter 41).

4. Primary & Metastatic Spinal Tumors

ESSENTIALS OF DIAGNOSIS

- Paraparesis or quadriparesis or a spinal sensory level, or both.
- New bowel or bladder dysfunction.

General Considerations

Approximately 10% of spinal tumors are intramedullary. Ependymoma is the most common type of intramedullary tumor; the remainder are other types of glioma. Extramedullary tumors may be extradural or intradural in location. Among the primary extramedullary tumors, neurofibromas and meningiomas are relatively common, benign, and may be intradural or extradural. Carcinomatous metastases, lymphomatous or leukemic deposits, and myeloma are usually extradural; in the case of metastases, the prostate, breast, lung, and kidney are common primary sites.

Tumors may lead to spinal cord dysfunction by direct compression, by ischemia secondary to arterial or venous obstruction and, in the case of intramedullary lesions, by invasive infiltration.

Clinical Findings

A. Symptoms and Signs

Symptoms usually develop insidiously. Pain is often conspicuous with extradural lesions; is characteristically aggravated by coughing or straining; may be radicular, localized to the back, or felt diffusely in an extremity; and may be accompanied by motor deficits, paresthesias, or numbness, especially in the legs. Bladder, bowel, and sexual dysfunction may occur. When sphincter disturbances occur, they are usually disabling. Pain, however, often precedes specific neurologic symptoms from epidural metastases.

Examination may reveal localized spinal tenderness. A segmental lower motor neuron deficit or dermatomal sensory changes (or both) are sometimes found at the level of the lesion, while an upper motor neuron deficit and sensory disturbance are found below it.

B. Imaging

MRI with contrast or CT myelography is used to identify and localize the lesion. *The combination of known tumor elsewhere in the body, back pain, and either abnormal plain films of the spine or neurologic signs of cord compression is an indication to perform this on an urgent basis.*

C. Laboratory Findings

The CSF is often xanthochromic and contains a greatly increased protein concentration with normal cell content and glucose concentration.

Treatment

Intramedullary tumors are treated by decompression and surgical excision (when feasible) and by irradiation. The prognosis depends on the cause and severity of cord compression before it is relieved.

Treatment of epidural spinal metastases consists of surgical decompression, radiation, or both. Dexamethasone is also given in a high dosage (eg, 10–96 mg once intravenously, followed by 4–25 mg four times daily for 3 days orally or intravenously, followed by rapid tapering of the dosage, depending on initial dose and response) to reduce cord swelling and relieve pain. Radiation alone is often all that is required in patients with radiosensitive tumors. Surgical decompression is reserved for patients with tumors that are unresponsive to irradiation or who have previously been irradiated, for those with spinal instability, and for patients in whom there is some uncertainty about the diagnosis. The long-term outlook is poor, but treatment may at least delay the onset of major disability.

Haro-Perez P et al. Surgery with or without radiotherapy versus radiotherapy alone for malignant spinal cord compression: an updated meta-analysis. Spine (Phila). 2025;50:277. [PMID: 39477818]

5. Brain Abscess

ESSENTIALS OF DIAGNOSIS

- Signs of expanding intracranial mass.
- Signs of primary infection or congenital heart disease are sometimes present.
- Fever may be absent.

General Considerations

Brain abscess presents as an intracranial space-occupying lesion and arises as a sequela of dental, ear, or nose infection, may be a complication of infection elsewhere in the body, or may result from infection introduced intracranially by trauma or surgical procedures. The most common infective organisms are streptococci, staphylococci, and anaerobes; mixed infections also occur.

Clinical Findings

A. Symptoms and Signs

Headache, drowsiness, inattention, confusion, and seizures are early symptoms, followed by signs of increasing intracranial pressure and then a focal neurologic deficit. There may be little or no systemic evidence of infection.

B. Imaging and Other Investigations

A CT scan of the head characteristically shows an area of contrast enhancement surrounding a low-density core. Similar abnormalities may be found in patients with metastatic neoplasms. MRI findings often permit earlier recognition of focal cerebritis or an abscess. Stereotactic needle aspiration may enable a specific etiologic organism to be identified. Examination of the CSF does not help in diagnosis and may precipitate a herniation syndrome. Peripheral leukocytosis is sometimes present.

Treatment

Treatment consists of intravenous antibiotics combined with surgical drainage (aspiration or excision), if necessary, to reduce the mass effect or sometimes to establish the diagnosis. *Abscesses smaller than 2 cm can often be cured medically.* Broad-spectrum antibiotics, selected based on risk factors and likely organisms, are used if the infecting organism is unknown (see Chapter 38). An initial empiric multi-antibiotic regimen typically includes ceftriaxone (2 g intravenously every 12 hours), metronidazole (15 mg/kg intravenous loading dose, followed by 7.5 mg/kg intravenously every 6 hours), and vancomycin (1 g intravenously every 12 hours). The regimen is altered once culture and sensitivity data are available. Antimicrobial treatment is usually continued parenterally for 6–8 weeks and is followed by oral treatment for certain infections, such as nocardiosis, actinomycosis, fungal infections, and tuberculosis. The patient should be monitored by serial CT scans or MRI every 2 weeks and at deterioration. Dexamethasone (4–25 mg four times daily intravenously or orally, depending on severity, followed by tapering of dose, depending on response) may reduce any associated edema, but intravenous mannitol is sometimes required.

When to Refer

All patients should be referred.

When to Admit

- All patients with increased intracranial pressure.
- All patients requiring biopsy, surgical treatment, or shunting procedures.

Omland LH et al. Update and approach to patients with brain abscess. Curr Opin Infect Dis. 2024;37:211. [PMID: 38547383]

NONMETASTATIC NEUROLOGIC COMPLICATIONS OF MALIGNANT DISEASE

A variety of nonmetastatic neurologic complications of malignant disease can occur. **Metabolic encephalopathy** due to electrolyte abnormalities, infections, drug overdose, or the failure of some vital organ may be reflected by drowsiness, lethargy, restlessness, insomnia, agitation, confusion, stupor, or coma. The mental changes are usually associated with tremor, asterixis, and multifocal myoclonus. The electroencephalogram is generally diffusely slowed. Laboratory studies are necessary to detect the cause of the encephalopathy, which must then be treated appropriately.

Immune suppression resulting from either the malignant disease or its treatment (eg, by chemotherapy) predisposes patients to brain abscess, progressive multifocal leukoencephalopathy, meningitis, herpes zoster infection, and other opportunistic infectious diseases. Moreover, an overt or occult CSF fistula, as occurs with some tumors, may also increase the risk of infection. MRI or CT scanning aids in the early recognition of a brain abscess, but metastatic brain tumors may have a similar appearance. Examination of the CSF is essential in the evaluation of patients with meningitis and encephalitis but is of no help in the diagnosis of brain abscess.

Cerebrovascular disorders that cause neurologic complications in patients with systemic cancer include nonbacterial thrombotic endocarditis, septic embolization, and cerebral infarcts due to malignancy-induced hypercoagulability. Cerebral, subarachnoid, or subdural hemorrhages may occur in patients with myelogenous leukemia and may be found in association with metastatic tumors, especially melanoma. Spinal subdural hemorrhage sometimes occurs after lumbar puncture in patients with marked thrombocytopenia.

Disseminated intravascular coagulation occurs most commonly in patients with acute promyelocytic leukemia or with some adenocarcinomas and is characterized by a fluctuating encephalopathy, often with associated seizures, that frequently progresses to coma or death. There may be few accompanying neurologic signs. **Venous sinus thrombosis**, which usually presents with convulsions and headaches, may also occur in patients with leukemia or lymphoma. Examination commonly reveals papilledema and focal or diffuse neurologic signs.

Autoimmune paraneoplastic disorders occur when the immune system reacts against neuronal antigens expressed by tumor cells. The clinical manifestations depend on the autoantibody. Symptoms may precede those due to the neoplasm itself. Several distinct syndromes are common, each associated with specific antibodies and tumors (Table 27–6). Identification of an antibody is not always possible in a suspected autoimmune paraneoplastic condition, and a search for an underlying neoplasm should be undertaken. Treatment of the neoplasm offers the best hope for stabilization or improvement of the neurologic symptoms, which often are not completely reversible. Specific treatment of the antibody-mediated symptoms by intravenous immunoglobulin (IVIG) administration, plasmapheresis, corticosteroids, or other immunosuppressive regimens is frequently attempted despite limited evidence of efficacy. Many of the disorders listed in Table 27–6 can occur either as paraneoplastic phenomena or in isolation; when they occur in the absence of a tumor, the response to immunotherapy is typically more favorable.

Autoimmune disorders may also be triggered as a result of cancer immunotherapy; encephalitis, hypophysitis, meningitis, transverse myelitis, acute and chronic inflammatory demyelinating polyneuropathy, autonomic neuropathy, myasthenia gravis, and myositis have all been described.

McCombe JA et al. Neurologic manifestations of autoimmunity with immune checkpoint inhibitors. Handb Clin Neurol. 2024;200:449. [PMID: 38494296]

IDIOPATHIC INTRACRANIAL HYPERTENSION (Pseudotumor Cerebrl)

ESSENTIALS OF DIAGNOSIS

- Headache, worse on straining.
- Visual obscurations or diplopia may occur.
- Examination reveals papilledema.
- Abducens palsy is commonly present.

General Considerations

There are many causes of this disorder. Thrombosis of the transverse venous sinus as a complication of otitis media or chronic mastoiditis is one cause, and sagittal sinus thrombosis may lead to a clinically similar picture. Other causes include chronic pulmonary disease, SLE, uremia, endocrine disturbances such as hypoparathyroidism, hypothyroidism,

Table 27–6. Autoimmune paraneoplastic disorders and their associated antibodies and tumors (listed in alphabetical order).

Syndrome	Clinical Features	Associated Antibodies	Typical Associated Tumors
Anti-NMDA receptor–associated encephalitis	Paranoia, delusions, behavioral disturbance, seizure, orofacial dyskinesias, athetosis, dysautonomia, hypoventilation	NMDA receptor[1]	Ovarian teratoma, lung, breast, ovary, testicle
Autoimmune necrotizing myopathy	Weakness	SRP,[1] HMGCR[1]	Lung, breast, GI, bladder
Autonomic neuropathy	Postural hypotension, gastroparesis	Hu, ganglionic AChR[1]	
Cerebellar degeneration	Ataxia, dysarthria, nystagmus	GAD65,[1] KLHL11, mGluR1,[1] NIF,[1] Ri, Tr, VGCC,[1] Yo	Lung, breast, thymus, ovary, testicle, Hodgkin lymphoma
Dermatomyositis	Weakness, heliotrope skin rash	TIF-1 γ	Lung, breast, ovary, GI, lymphoma
Lambert-Eaton myasthenic syndrome	Fatigable weakness, ptosis, diplopia, dry mouth, constipation	VGCC,[1] SOX-1	Lung
Limbic encephalitis/encephalomyelitis	Short-term memory loss, hallucinations, seizures, behavioral disturbance, encephalopathy	AMPA receptor,[1] Caspr2,[1] CV2/CRMP5, DPPX,[1] GABA$_A$ receptor,[1] GABA$_B$ receptor,[1] GAD65,[1] GFAP,[1] Hu, LGI1,[1] Ma2, mGluR5,[1] NIF,[1] thyroglobulin[1]/thyroperoxidase[1]	Lung, breast, thymus, ovary, testicle, Hodgkin lymphoma
Myasthenia gravis	Fatigable weakness, ptosis, diplopia	AChR,[1] LRP4,[1] MuSK[1]	Thymus
Myelitis	Paraparesis, bowel and bladder dysfunction; sensory level	Amphiphysin,[1] aquaporin 4,[1] CRMP-5, GFAP,[1] Hu, MOG,[1] Yo	Lung, breast, lymphoma, leukemia, thyroid, renal
Opsoclonus/myoclonus	Erratic, conjugate saccadic eye movements and limb myoclonus	Ri	Lung, breast, ovary, testicle, neuroblastoma (children)
Retinopathy	Vision loss	Anti-recoverin, anti-retinal bipolar cell	Small cell lung, melanoma
Sensorimotor neuropathy	Numbness with or without weakness; may be mild and chronic or acute and severe	Hu, MAG[1]	Small cell lung, monoclonal gammopathy
Sensory neuronopathy	Pain, numbness, sensory ataxia, hearing loss	Hu	Lung
Stiff person syndrome	Co-contraction of antagonist and agonist muscles	Amphiphysin,[1] GAD65,[1] GlyR[1]	Small cell lung, breast, thymus, lymphoma

AChR, acetylcholine receptor; AMPA, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid; Caspr2, contactin associated protein-like 2; CRMP, collapsin response-mediator protein; DPPX, dipeptidyl-peptidase-like protein-6; GABA, γ-aminobutyric acid; GAD, glutamic acid decarboxylase; GFAP, glial fibrillary acidic protein; GlyR, glycine receptor; HMGCR, 3-hydroxy-3-methylglutaryl-coenzyme A reductase; KLHL11, kelch-like protein 11; LGI1, leucine rich glioma inactivated; LRP4, LDL receptor-related protein 4; mGluR, metabotropic glutamate receptor; MAG, myelin-associated glycoprotein; MOG, myelin oligodendrocyte glycoprotein; MuSK, muscle-specific tyrosine kinase; NIF, neuronal intermediate filament; NMDA, *N*-methyl-D-aspartate; REM, rapid eye movement; SOX-1, Sry-like high mobility group box transcription factor 1; SRP, signal recognition particle; TIF-1, human transcription intermediary factor-1; VGCC, voltage-gated calcium channel.

[1] Can occur in absence of tumor.

or Addison disease, vitamin A toxicity, and the use of tetracycline or oral contraceptives. Cases have also followed withdrawal of corticosteroids after long-term use. In most instances, however, no specific cause can be found, and the disorder remits spontaneously after several months. This idiopathic variety occurs most commonly among overweight women aged 20–44. *In all cases, screening for a space-occupying lesion of the brain is important.*

Clinical Findings

A. Symptoms and Signs

Symptoms consist of headache, diplopia, and other visual disturbances due to papilledema and abducens nerve dysfunction. Pulse-synchronous tinnitus may also occur. Examination reveals papilledema and some enlargement of the blind spots, but patients otherwise look well.

B. Imaging

Investigations reveal no evidence of a space-occupying lesion. CT or MRI may show small or normal ventricles, an empty sella turcica, tortuous optic nerves, distension of the optic nerve sheath, and posterior globe flattening. MR venography is important in screening for thrombosis of the intracranial venous sinuses. In some cases, stenosis of one or more of the venous sinuses will be observed.

C. Laboratory Findings

Lumbar puncture is necessary to confirm the presence of intracranial hypertension, but the CSF is normal. Laboratory studies help exclude some of the other causes mentioned earlier.

Treatment

Untreated intracranial hypertension sometimes leads to secondary optic atrophy and permanent visual loss. Acetazolamide (250–500 mg orally three times daily, increasing slowly to a maintenance dose of up to 4000 mg daily, divided two to four times daily) reduces formation of CSF. Like acetazolamide, the antiepileptic medication topiramate (Table 27–3) is a carbonic anhydrase inhibitor and was shown to be similarly effective in an open-label study; topiramate has the added benefit of causing weight loss. Furosemide (20–40 mg daily) may be helpful as adjunct therapy. Corticosteroids (eg, prednisone 60–80 mg daily) are sometimes prescribed, but side effects and the risk of relapse on withdrawal have discouraged their use. Weight loss is important: bariatric surgery led to a decrease in both intracranial pressure and weight at 2 years compared with a community weight management program in a randomized trial and may be considered in patients with a BMI of 35 or greater. Repeated lumbar puncture to lower the intracranial pressure by removal of CSF is effective as a temporizing measure, but pharmacologic approaches to treatment provide better long-term relief. Treatment is monitored by checking visual acuity and visual fields, funduscopic appearance, and pressure of the CSF. The disorder may worsen after a period of stability, indicating the need for long-term follow-up.

If medical treatment fails to control the intracranial pressure, surgical placement of a lumboperitoneal or ventriculoperitoneal shunt or optic nerve sheath fenestration should be undertaken to preserve vision. Patients with venous sinus stenosis may benefit from stenting.

In addition to the above measures, any specific cause of intracranial hypertension requires appropriate treatment. Thus, hormone therapy should be initiated if there is an underlying endocrine disturbance. Discontinuing the use of tetracycline, oral contraceptives, or vitamin A will allow for resolution of intracranial hypertension due to these agents. If corticosteroid withdrawal is responsible, the medication should be reintroduced and then tapered more gradually.

When to Refer

All patients should be referred.

When to Admit

All patients with worsening vision requiring surgical treatment should be hospitalized.

Azzam AY et al. Venous sinus stenting for idiopathic intracranial hypertension: an updated meta-analysis. J Neurol Sci. 2024;459:122948. [PMID: 38457956]

SELECTED NEUROCUTANEOUS DISEASES

Because the nervous system develops from the epithelial layer of the embryo, a number of congenital diseases include both neurologic and cutaneous manifestations. Among these disorders, three are discussed below, and **von Hippel-Lindau** disease is discussed in Chapter 29.

1. Tuberous Sclerosis

Tuberous sclerosis may occur sporadically or on a familial basis with autosomal dominant inheritance. Neurologic presentation is with seizures and progressive psychomotor delay beginning in early childhood. The cutaneous abnormality adenoma sebaceum becomes manifest usually between 5 and 10 years of age and typically consists of reddened nodules on the face (cheeks, nasolabial folds, sides of the nose, and chin) and sometimes on the forehead and neck. Other typical cutaneous lesions include subungual fibromas, shagreen patches (leathery plaques of subepidermal fibrosis, situated usually on the trunk), and leaf-shaped hypopigmented spots. Associated abnormalities include retinal lesions and tumors, benign rhabdomyomas of the heart, lung cysts, benign tumors in the viscera, and bone cysts.

The disease is slowly progressive and leads to increasing mental deterioration. Anticonvulsants are indicated to control seizures. Everolimus, a mammalian target of rapamycin (mTOR) inhibitor, is approved in the United States and Europe for medically refractory epilepsy and inoperable subependymal giant cell astrocytomas due to tuberous sclerosis.

Sasongko TH et al. Rapamycin and rapalogs for tuberous sclerosis complex. Cochrane Database Syst Rev. 2023;7:CD011272. [PMID: 37432030]

2. Neurofibromatosis

Neurofibromatosis may occur either sporadically or on a familial basis with autosomal dominant inheritance. Two distinct forms are recognized: **Type 1 (Recklinghausen disease)** is characterized by multiple hyperpigmented macules, Lisch nodules, and neurofibromas; **type 2 (NF2-associated schwannomatosis)** is characterized by bilateral eighth nerve tumors, often accompanied by other intracranial or intraspinal tumors.

Neurologic presentation is usually with symptoms and signs of tumor. Multiple neurofibromas characteristically are present and may involve spinal or cranial nerves, especially the eighth nerve. Examination of the superficial cutaneous nerves usually reveals palpable mobile nodules. In some cases, there is marked overgrowth of subcutaneous tissues (**plexiform neuromas**), sometimes with an underlying bony abnormality. Associated cutaneous lesions include axillary freckling and patches of cutaneous pigmentation (**café au lait spots**). Malignant degeneration of neurofibromas occasionally occurs and may lead to peripheral sarcomas. Meningiomas, gliomas (especially optic nerve gliomas), bone cysts, pheochromocytomas, scoliosis, and obstructive hydrocephalus may also occur. Selumetinib, a mitogen-activated protein kinase inhibitor, causes plexiform neurofibromas to shrink by at least 20% in two-thirds of patients and is approved by the FDA for treatment of inoperable plexiform neurofibromas in children 2 years of age and older. Studies in adults are ongoing. Bevacizumab has been used effectively for rapidly growing vestibular schwannomas in patients with neurofibromatosis type 2.

Han Y et al. Efficacy and safety of selumetinib in patients with neurofibromatosis type 1 and inoperable plexiform neurofibromas: a systematic review and meta-analysis. J Neurol. 2024;271:2379. [PMID: 38502338]

3. Sturge-Weber Syndrome

Sturge-Weber syndrome consists of a congenital, usually unilateral, cutaneous capillary angioma involving the upper face, leptomeningeal angiomatosis, and, in many patients, choroidal angioma. It has no sex predilection and usually occurs sporadically. The cutaneous angioma sometimes has a more extensive distribution over the head and neck and is often quite disfiguring, especially if there is associated overgrowth of connective tissue. Focal or generalized seizures are the usual neurologic presentation and may commence at any age. There may be contralateral homonymous hemianopia, hemiparesis and hemisensory disturbance, ipsilateral glaucoma, and mental subnormality. Skull radiographs taken after the first 2 years of life usually reveal gyriform (**"tramline"**) intracranial calcification, especially in the parieto-occipital region, due to mineral deposition in the cortex beneath the intracranial angioma.

Treatment is aimed at controlling seizures pharmacologically (Table 27–3), but surgical treatment may be necessary. Ophthalmologic advice should be sought concerning the management of choroidal angioma and of increased intraocular pressure.

Yeom S et al. Updates on Sturge-Weber syndrome. Stroke. 2022;53:3769. [PMID: 36263782]

MOVEMENT DISORDERS

1. Essential (Familial) Tremor

ESSENTIALS OF DIAGNOSIS

- Postural tremor of hands, head, or voice.
- Family history common.
- May improve temporarily with alcohol.
- No abnormal findings other than tremor.

General Considerations

The cause of essential tremor is uncertain, but it is sometimes inherited in an autosomal dominant manner. Various responsible genes have been identified.

Clinical Findings

Tremor may begin at any age and is enhanced by emotional stress. The tremor usually involves one or both hands, the head, or the hands and head, while the legs tend to be spared. Except in advanced cases, the tremor typically is *not present at rest* but emerges with action. Examination reveals no other abnormalities. Ingestion of a small quantity of alcohol commonly provides remarkable but short-lived relief by an unknown mechanism.

The tremor typically becomes more conspicuous with time. Occasionally, it interferes with manual skills and leads to impairment of handwriting. Speech may also be affected if the laryngeal muscles are involved.

Treatment

Treatment is often unnecessary. When it is required because of disability, propranolol (60–240 mg daily orally) may be helpful. Long-term therapy is typical; however, intermittent therapy is sometimes useful in patients whose tremor becomes exacerbated in specific predictable situations. Primidone may be helpful when propranolol is ineffective, but patients with essential tremor are often sensitive to it. Therefore, the starting dose is 50 mg daily orally, and the daily dose is increased by 50 mg every 2 weeks depending on the patient's response; a maintenance dose of 125 mg three times daily orally is commonly effective. Occasional patients do not respond to these measures but are helped by alprazolam (up to 3 mg daily orally in divided doses), topiramate (titrated up to a dose of 400 mg daily orally in divided doses over about 8 weeks), or gabapentin (1800 mg daily orally in divided doses). Botulinum toxin A may reduce tremor, but adverse effects include dose-dependent weakness of the injected muscles.

Disabling tremor unresponsive to medical treatment may be helped by high-frequency thalamic stimulation ("deep brain stimulation") on one or both sides, according to the laterality of symptoms. Focused transcranial ultrasound thalamotomy using MRI guidance is also effective, as is stereotactic radiosurgery for unilateral upper extremity tremor.

Frei K et al. Medications used to treat tremors. J Neurol Sci. 2022;435:120194. [PMID: 35279634]

Kondapavulur S et al. A systematic review comparing focused ultrasound surgery with radiosurgery for essential tremor. Neurosurgery. 2023;93:524. [PMID: 37010324]

2. Parkinson Disease

ESSENTIALS OF DIAGNOSIS

- Any combination of tremor, rigidity, bradykinesia, and progressive postural instability ("parkinsonism").
- Cognitive impairment is sometimes prominent.

General Considerations

Parkinsonism is a relatively common disorder that occurs in all ethnic groups, with an approximately equal sex distribution. The most common variety, idiopathic Parkinson disease, begins most often between 45 and 65 years of age and is a progressive disease.

Etiology

Parkinsonism may rarely occur on a familial basis, and the parkinsonian phenotype may result from mutations of several different genes. Postencephalitic parkinsonism is becoming increasingly rare. Exposure to certain toxins (eg, manganese dust, carbon disulfide) and severe carbon monoxide poisoning may lead to parkinsonism. Reversible parkinsonism may develop in patients receiving neuroleptic medications (see Chapter 28), reserpine, or metoclopramide. Only rarely is hemiparkinsonism the presenting feature of a progressive space-occupying lesion.

In idiopathic Parkinson disease, *dopamine depletion due to degeneration of the dopaminergic nigrostriatal system leads to an imbalance of dopamine and acetylcholine*, which are neurotransmitters normally present in the corpus striatum. Treatment of the motor disturbance is directed at redressing this imbalance by blocking the effect of acetylcholine with anticholinergic medications or by the administration of levodopa, the precursor of dopamine. Prior use of ibuprofen is associated with a *decreased* risk of developing Parkinson disease; age, family history, male sex, ongoing herbicide/pesticide exposure, and significant prior head trauma are risk factors.

Clinical Findings

A. Symptoms and Signs

Tremor, rigidity, bradykinesia, and postural instability are the cardinal motor features of parkinsonism and may be present in any combination. Nonmotor manifestations include affective disorders (depression, anxiety, and apathy), psychosis, cognitive changes, fatigue, sleep disorders, anosmia, autonomic disturbances, sensory complaints or pain, and seborrheic dermatitis. Dementia or mild cognitive impairment will eventually develop in many patients.

The tremor of about four to six cycles per second is *most conspicuous at rest*, is enhanced by emotional stress, and is often less severe during voluntary activity. Although it may ultimately be present in all limbs, the tremor is commonly confined to one limb or to the limbs on one side for months or years before it becomes more generalized. In some patients, tremor is absent.

Rigidity (an increase in resistance to passive movement) is responsible for the characteristically flexed posture seen in many patients, but *the most disabling symptoms of parkinsonism are due to bradykinesia*, manifested as a slowness of voluntary movement and a reduction in automatic movements such as swinging of the arms while walking. Curiously, however, effective voluntary activity may briefly be regained during an emergency (eg, the patient is able to leap aside to avoid an oncoming motor vehicle).

Clinical diagnosis of the well-developed syndrome is usually simple. The patient has a relatively immobile face with widened palpebral fissures, infrequent blinking, and a fixity of facial expression. Seborrhea of the scalp and face is common. There is often mild blepharoclonus, and a tremor may be present about the mouth and lips. Repetitive tapping (about twice per second) over the bridge of the nose produces a sustained blink response (**Myerson sign**). Other findings may include saliva drooling from the mouth, perhaps due to impairment of swallowing; soft and poorly modulated voice; a variable rest tremor and rigidity in some or all of the limbs; slowness of voluntary movements; impairment of fine or rapidly alternating movements; and micrographia. There is typically no muscle weakness (provided that sufficient time is allowed for power to be developed) and no alteration in the tendon reflexes or plantar responses. The patient has difficulty rising from a sitting position and when beginning to walk. The gait itself is characterized by small shuffling steps and a loss of the normal automatic arm swing; there may be unsteadiness on turning, difficulty in stopping, and a tendency to fall.

B. Imaging

There are no routine diagnostic imaging tests for Parkinson disease, although brain MRI scan may exclude an underlying structural lesion. Striatal dopamine transporter imaging (DaT scan) is sometimes helpful when the clinical diagnosis is not clear but is usually unnecessary. In Parkinson disease it shows reduced uptake by striatal dopaminergic neurons of a specific radioactive tracer injected into the blood on single photon emission computerized tomography (SPECT).

C. Laboratory Findings

Misfolded α-synuclein, the neuropathological hallmark of Parkinson disease, may be detected in other tissues such as skin and CSF. An assay using CSF is commercially available in the United States (SYNTap). Parkinson disease may occur on a hereditary basis involving various genes (*SNCA*, *Parkin*, *DJ-1*, *PINK1*, *LRRK2*, *GBA1*), but the role of genetic testing in patients either at risk of or with suspected Parkinson disease is unclear and based on individual preferences. Current treatment is unrelated to genetic factors although therapy for specific genetic forms of the disease is being evaluated.

Differential Diagnosis

Diagnostic problems may occur in mild cases, especially if tremor is minimal or absent. For example, mild hypokinesia or slight tremor is commonly attributed to old age. Depression, with its associated expressionless face, poorly modulated voice, and reduction in voluntary activity, can be difficult to distinguish from mild parkinsonism, especially since the two disorders may coexist. The family history, the character of the tremor, and lack of other neurologic signs should distinguish essential tremor from parkinsonism. Wilson disease can be distinguished by its early age at onset, the presence of other abnormal movements, Kayser-Fleischer rings, and chronic hepatitis, and by increased concentrations of copper in the tissues. Huntington disease presenting with rigidity and bradykinesia may be mistaken for parkinsonism unless the family history and accompanying dementia are recognized. In multisystem atrophy (previously called the Shy-Drager syndrome), autonomic insufficiency (leading to postural hypotension, anhidrosis, disturbances of sphincter control, erectile dysfunction, etc) may be accompanied by parkinsonism, pyramidal deficits, lower motor neuron signs, or cerebellar dysfunction. In progressive supranuclear palsy, bradykinesia and rigidity are accompanied by a supranuclear disorder of eye movements, pseudobulbar palsy, pseudo-emotional lability (**pseudobulbar affect**), and axial dystonia. Creutzfeldt-Jakob disease may be accompanied by features of parkinsonism, but progression is rapid, dementia is usual, myoclonic jerking is common, ataxia and pyramidal signs may be conspicuous, and the MRI and electroencephalographic findings are usually characteristic. In corticobasal degeneration, asymmetric parkinsonism is accompanied by conspicuous signs of cortical dysfunction (eg, apraxia, sensory inattention, dementia, aphasia). Dementia with Lewy bodies is characterized by prominent visual hallucinations and cognitive impairment that begin before or within 1 year of onset of the motor features of parkinsonism.

Treatment

Treatment is symptomatic. There is great interest in developing disease-modifying therapies and gene therapies, but trials of several putative neuroprotective agents have shown little benefit.

A. Medical Measures

Medication is not required early in the course of Parkinson disease, but the nature of the disorder and the availability of medical treatment for use when necessary should be discussed with the patient.

1. Amantadine—Patients with mild symptoms but no disability may be helped by amantadine (100 mg orally two to three times daily [immediate release] or once daily [extended release]). This medication improves all of the clinical features of parkinsonism, but its mode of action is unclear. Side effects are uncommon but may include restlessness, confusion, depression, skin rashes, edema, nausea, constipation, anorexia, postural hypotension, and disturbances of cardiac rhythm. Amantadine also ameliorates dyskinesias resulting from long-term levodopa therapy.

2. Levodopa—Levodopa, which is converted in the body to dopamine, improves all of the major features of parkinsonism, including bradykinesia, but *does not stop progression* of the disorder. The most common early side effects of levodopa are nausea, vomiting, and hypotension, but cardiac arrhythmias may also occur. Dyskinesias, restlessness, confusion, and other behavioral changes tend to occur somewhat later and become more common with time. **Levodopa-induced dyskinesias** may take any conceivable form, including chorea, athetosis, dystonia, tremor, tics, and myoclonus. An even later complication is the **wearing off effect** or the **on-off phenomenon**, in which abrupt but transient fluctuations in the severity of parkinsonism occur unpredictably but frequently during the day. *The "off" period of marked bradykinesia* has been shown to relate in some instances to falling plasma levels of levodopa. During the *"on" phase*, dyskinesias are often conspicuous but mobility is increased. However, such response fluctuations may relate to advancing disease rather than to levodopa therapy itself.

Carbidopa, which inhibits the enzyme responsible for the breakdown of levodopa to dopamine, does not cross the blood-brain barrier. When levodopa is given in combination with carbidopa, the extracerebral breakdown of levodopa is diminished. This reduces the amount of levodopa required daily for beneficial effects and lowers the incidence of nausea, vomiting, hypotension, and cardiac irregularities. Such a combination does not prevent the development of response fluctuations and the incidence of other side effects (dyskinesias or psychiatric complications) may actually be increased.

Sinemet, a commercially available preparation that contains carbidopa and levodopa in a fixed ratio (1:10 or 1:4), is generally used. Treatment is started with a small dose—eg, one tablet of Sinemet 25/100 (containing 25 mg of carbidopa and 100 mg of levodopa) three times daily—and gradually increased depending on the response. Sinemet CR is a controlled-release formulation (containing 25 or 50 mg of carbidopa and 100 or 200 mg of levodopa) and is mainly useful when taken at bedtime to lessen motor disability upon awakening. Formulations of carbidopa/levodopa containing both immediate- and delayed-release beads (Rytary or Crexont) provides a smoother response in patients with fluctuations. The commercially available combination of levodopa with both carbidopa and entacapone (Stalevo) may also be helpful in this context and is discussed in the following section on COMT inhibitors. Response fluctuations are also reduced by keeping the daily intake of *protein* at the recommended minimum and taking the main protein meal as the last meal of the day. A continuous infusion of a carbidopa-levodopa enteral suspension through a percutaneous gastrojejunostomy tube by a portable infusion pump reduces "off" time in patients with advanced Parkinson disease. A continuous subcutaneous infusion of foslevodopa-foscarbidopa also reduces "off" time and improves the amount of "on" time without troublesome dyskinesias. Levodopa can also be taken as a dispersible tablet placed sublingually for a faster response, or by inhalation (Inbrija) as a rescue medication for patients developing severe akinesia (off periods).

The dyskinesias and behavioral side effects of levodopa are dose-related, but reduction in dose may eliminate any therapeutic benefit. Levodopa-induced dyskinesias may also respond to amantadine.

Levodopa therapy is contraindicated in patients with psychotic illness or narrow-angle glaucoma. It should not be given to patients taking MAO inhibitors or within 2 weeks of their withdrawal, because hypertensive crises may result. Sudden discontinuation of levodopa can precipitate neuroleptic malignant syndrome and should be avoided.

3. Dopamine agonists—Dopamine agonists, such as pramipexole and ropinirole, act directly on dopamine receptors, and their use in parkinsonism is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. They are effective in both early and advanced stages of Parkinson disease. They are often given either before the introduction of levodopa or with a low dose of Sinemet 25/100 (carbidopa 25 mg and levodopa 100 mg, one tablet three times daily) when dopaminergic therapy is first introduced in patients younger than 60; the dose of Sinemet is kept constant, while the dose of the agonist is gradually increased.

Pramipexole is started at a dosage of 0.125 mg three times daily orally, and the dose is built up gradually to between 0.5 and 1.5 mg three times daily. Ropinirole is begun at 0.25 mg three times daily orally and gradually increased; most patients require between 2 and 8 mg three times daily for benefit. Extended-release, once-daily formulations of pramipexole and ropinirole have similar efficacy and tolerability as the immediate release versions. Rotigotine is a dopamine agonist absorbed transdermally from a skin patch; it is started at 2 mg once daily and increased weekly by 2 mg daily until achieving an optimal response, up to a maximum of 8 mg daily. Apomorphine can be administered by continuous subcutaneous infusion (starting at 1 mg/hour and titrated to a maximum of 6 mg/hour for up to 16 hours per day, with up to three extra 0.5 to 2 mg bolus doses per day separated by at least three hours), which reduces "off" time in patients with motor fluctuations, and by subcutaneous injection for relief of sudden "off" symptoms (starting with a 1 mg test dose given under medical supervision). It usually is prescribed by experienced providers. Premedication with an antiemetic for 3 days prior to starting apomorphine is recommended. Adverse effects of these various agonists include fatigue, somnolence, nausea, peripheral edema, dyskinesias, confusion, and postural hypotension. Less commonly, an irresistible urge to sleep may occur, sometimes in inappropriate and hazardous circumstances. Impulse control disorders involving gambling, shopping, or sexual activity also occur. Local skin reactions may occur with the rotigotine patch. The **dopamine agonist withdrawal syndrome** develops occasionally in patients in whom a dopamine agonist is tapered. It consists of a combination of distressing physical and psychological symptoms that are refractory to levodopa and other dopaminergic medications and may persist for months or longer. There is no effective treatment. The dopamine agonist should be reintroduced and tapered more gradually if possible.

4. Selective MAO inhibitors—Rasagiline, a selective MAO-B inhibitor, has a clear symptomatic benefit in some patients at a daily oral dose of 1 mg, taken in the morning; it may also be used for adjunctive therapy in patients with response fluctuations to levodopa. Selegiline (5 mg orally with breakfast and lunch) and safinamide (50 mg orally daily, increased to 100 mg daily after 14 days) are also approved as adjunctive treatments. By inhibiting the metabolic breakdown of dopamine, these medications may improve fluctuations or declining response to levodopa.

Studies have suggested (but failed to show conclusively) that rasagiline may slow the progression of Parkinson disease, and it appears to delay the need for other symptomatic therapies. For these reasons, rasagiline is often started early, particularly for patients who are young or have mild disease.

5. COMT inhibitors—Catecholamine-*O*-methyltransferase (COMT) inhibitors reduce the metabolism of levodopa to 3-*O*-methyldopa and thereby alter the plasma pharmacokinetics of levodopa, leading to more sustained plasma levels and more constant dopaminergic stimulation of the brain. Treatment with entacapone or tolcapone results in reduced response fluctuations, with a greater period of responsiveness to administered levodopa. Tolcapone is given in a dosage of 100 mg or 200 mg three times daily orally, and entacapone is given as 200 mg with each dose of Sinemet. Opicapone, a long-acting, peripherally selective COMT inhibitor, is taken once daily (50 mg) at bedtime at least 1 hour before or after eating. The dose of Sinemet taken concurrently may have to be reduced by up to one-third to avoid side effects. Diarrhea is sometimes troublesome. Because rare cases of fulminant hepatic failure have followed its use, tolcapone should be *avoided* in patients with preexisting liver disease. Serial liver biochemical tests should be performed at 2-week intervals for the first year and at longer intervals thereafter in patients receiving the medication—as recommended by the manufacturer. Serious hepatotoxicity has not been reported with entacapone or opicapone.

Stalevo, the commercial preparation of levodopa combined with both carbidopa and entacapone, is best used in patients already stabilized on equivalent doses of carbidopa/levodopa and entacapone. Stalevo is available in three strengths and thus can be tailored to the patient's needs.

6. Istradefylline—This adenosine A_{2A} receptor antagonist (20–40 mg orally once daily) is given to patients taking levodopa or a dopamine agonist to reduce off time; total off time is typically reduced by < 1 hour per day.

7. Anticholinergic medications—Anticholinergics are more helpful in alleviating tremor and rigidity than bradykinesia. Trihexyphenidyl and benztropine are commonly used formulations. Treatment is started with a small dose and gradually increased until benefit occurs or side effects limit further increments. If treatment is ineffective, the medication is gradually withdrawn and another preparation then tried. However, these medications are often poorly tolerated, especially in older adults.

Side effects limit the routine use of these medications, and include dryness of the mouth, nausea, constipation, palpitations, cardiac arrhythmias, urinary retention, confusion, agitation, restlessness, drowsiness, mydriasis, increased intraocular pressure, and defective accommodation. Anticholinergic medications are contraindicated in patients with prostatic hyperplasia, narrow-angle glaucoma, or obstructive GI disease and are often tolerated poorly by older adults. They are best avoided whenever cognitive impairment or a predisposition to delirium exists.

8. Antipsychotics—Confusion and psychotic symptoms may occur as a side effect of dopaminergic therapy or as a part of the underlying illness. Pimavanserin (34 mg once daily), a serotonin(2A) agonist, is approved by the FDA specifically for treating the psychosis of Parkinson disease. This may also respond to the atypical antipsychotic agents clozapine and quetiapine, which have few extrapyramidal side effects and do not block the effects of dopaminergic medication. Clozapine may rarely cause marrow suppression, and weekly blood counts are therefore necessary for patients taking it. The patient is started on 6.25 mg at bedtime and the dosage increased to 25–100 mg/day as needed. In low doses, clozapine may also improve iatrogenic dyskinesias. Typical antipsychotic agents and the second-generation antipsychotic agents risperidone and olanzapine may cause worsening of motor symptoms and should be avoided.

B. General Measures

Physical therapy, occupational therapy, and speech therapy helps many patients. A meta-analysis of 15 RCTs and six nonrandomized controlled trials concluded that there were beneficial effects of **tai chi** in improving motor function, depression, balance, and functional mobility in patients with Parkinson disease. Cognitive impairment and psychiatric symptoms may be helped by a cholinesterase inhibitor, such as rivastigmine (3–12 mg orally daily or 4.6 or 9.5 mg/24 hours transdermally daily). Affective disorders, which may be conspicuous during off periods, should be treated by antidepressants or antianxiety agents as necessary. The quality of life can often be improved by the provision of simple aids to daily living, eg, rails or banisters placed strategically about the home, special table cutlery with large handles, nonslip rubber table mats, and devices to amplify the voice.

C. Stimulation and Ablative Treatments

High-frequency stimulation of the subthalamic nuclei or globus pallidus internus may benefit many of the motor features of the disease but does not affect its natural history. Electrical stimulation of the brain has the advantage over ablative thalamotomy and pallidotomy procedures of being reversible and of causing minimal or no damage to the brain; it is therefore the preferred surgical approach to treatment. It is reserved for patients without cognitive impairment or psychiatric disorder who have a good response to levodopa, but in whom dyskinesias or response fluctuations are problematic. It frequently takes 3–6 months after surgery to adjust stimulator programming and to achieve optimal results. Side effects include depression, apathy, impulsivity, executive dysfunction, and decreased verbal fluency in a subset of patients. Focused ultrasound thalamotomy or stereotactic radiosurgery may help patients with medically refractory tremor-predominant parkinsonism who are reluctant to undergo surgery.

3. Huntington Disease

ESSENTIALS OF DIAGNOSIS

- Gradual onset and progression of chorea and dementia or behavioral change.
- Family history of the disorder.

General Considerations

Huntington disease is characterized by chorea and dementia. It is inherited in an autosomal dominant manner and occurs throughout the world, in all ethnic groups, with a prevalence rate of about 5 per 100,000. There is an expanded and unstable CAG trinucleotide repeat in the huntingtin gene at 4p16.3; longer repeat lengths correspond to an earlier age of onset and faster disease progression.

Clinical Findings

A. Symptoms and Signs

Clinical onset is usually between 30 and 50 years of age. The disease is progressive and usually leads to a fatal outcome within 15–20 years. The initial symptoms may consist of either abnormal movements or intellectual changes, but ultimately both occur. The earliest mental changes are often behavioral, with irritability, moodiness, antisocial behavior, or a psychiatric disturbance, but a more obvious dementia subsequently develops. The dyskinesia may initially be no more than an apparent fidgetiness or restlessness, but eventually choreiform movements and some dystonic posturing occur. A parkinsonian syndrome with progressive rigidity and akinesia (rather than chorea) sometimes occurs in association with dementia, especially in cases with childhood onset. The diagnosis is established with a widely available genetic test, although such testing should be pursued under the guidance of a licensed genetic counselor.

B. Imaging

CT scanning or MRI usually demonstrates cerebral atrophy and atrophy of the caudate nucleus in established cases. PET has shown reduced striatal metabolic rate.

Differential Diagnosis

Chorea developing with no family history of choreoathetosis should not be attributed to Huntington disease, at least not until other causes of chorea have been excluded clinically and by appropriate laboratory studies. Nongenetic causes of chorea include stroke, SLE and antiphospholipid antibody syndrome, paraneoplastic syndromes, infection with HIV, and various medications. In younger patients, self-limiting Sydenham chorea develops after group A streptococcal infections on rare occasions. If a patient presents solely with progressive intellectual failure, it may not be possible to distinguish Huntington disease from other causes of dementia unless there is a characteristic family history or a dyskinesia develops.

Huntington disease–like (HDL) disorders resemble Huntington disease but are caused by other genetic mutations. A clinically similar autosomal dominant disorder (**dentatorubral-pallidoluysian atrophy**), manifested by chorea, dementia, ataxia, and myoclonic epilepsy, is uncommon except in persons of Japanese ancestry. Treatment is as for Huntington disease.

Treatment

There is no cure for Huntington disease; progression cannot be halted; and treatment is purely symptomatic, although studies of antisense oligonucleotides inhibiting production of mutant huntingtin protein are ongoing. The reported biochemical changes suggest a relative underactivity of neurons containing GABA and acetylcholine or a relative overactivity of dopaminergic neurons. Chorea is treated with vesicular monoamine transporter type 2 (VMAT2) inhibitors, three of which are approved in the United States. Tetrabenazine is initiated at 12.5 mg twice or three times daily orally, increasing by 12.5 mg every 5 days depending on response and tolerance; the usual maintenance dose is 25 mg three times daily. Deutetrabenazine's starting dose is 6 mg once daily orally, increased to 6 mg twice daily after 1 week and by 6-mg increments weekly thereafter, to a maximum of 24 mg twice daily. Valbenazine is started at 40 mg once daily orally, increased by 20 mg every 2 weeks to a maximum of 80 mg daily. Side effects of VMAT2 inhibitors include depression, postural hypotension, drowsiness, and parkinsonian features; they should not be given within 14 days of taking MAO inhibitors and are not indicated for the treatment of levodopa-induced dyskinesias. Treatment with medications blocking dopamine receptors, such as phenothiazines or haloperidol, may control the dyskinesia and any behavioral disturbances. Haloperidol treatment is usually begun with a dose of 1 mg once or twice daily orally, which is then increased every 3 or 4 days depending on the response; alternatively, atypical antipsychotic agents such as quetiapine (increasing from 25 mg daily orally up to 100 mg twice daily orally as tolerated) may be tried. Amantadine in a dose of 200 mg to 400 mg daily orally is sometimes helpful for chorea. Deep brain stimulation has been used successfully to treat chorea in a small number of patients. Behavioral disturbances may respond to clozapine.

Offspring should be offered genetic counseling. Genetic testing permits presymptomatic detection and definitive diagnosis of the disease.

Ferreira JJ et al. An MDS evidence-based review on treatments for Huntington's disease. Mov Disord. 2022;37:25. [PMID: 34842303]

4. Idiopathic Torsion Dystonia

ESSENTIALS OF DIAGNOSIS

- Dystonic movements and postures.
- Normal birth and developmental history. No other neurologic signs.
- Investigations (including CT scan or MRI) reveal no cause of dystonia.

General Considerations

Idiopathic torsion dystonia may occur sporadically or on a hereditary basis, with autosomal dominant, autosomal recessive, and X-linked recessive modes of transmission. Symptoms may begin in childhood or later and persist throughout life.

Clinical Findings

The disorder is characterized by the onset of abnormal movements and postures in a patient with a normal birth and developmental history, no relevant past medical illness, and no other neurologic signs. Investigations (including CT scan) reveal no cause for the abnormal movements. Dystonic movements of the head and neck may take the form of torticollis, blepharospasm, facial grimacing, or forced opening or closing of the mouth. The limbs may also adopt abnormal but characteristic postures. The age at onset influences both the clinical findings and the prognosis. With onset in childhood, there is usually a family history of the disorder, symptoms commonly commence in the legs, and progression is likely until there is severe disability from generalized dystonia. In contrast, when onset is later, a positive family history is unlikely, initial symptoms are often in the arms or axial structures, and severe disability does not usually occur, although generalized dystonia may ultimately develop in some patients. If all cases are considered together, about one-third of patients eventually become so severely disabled that they are confined to chair or bed, while another one-third are affected only mildly.

Differential Diagnosis

Perinatal anoxia, birth trauma, and kernicterus are common causes of dystonia, but abnormal movements usually then develop before the age of 5, the early development of the patient is usually abnormal, and a history of seizures is not unusual. Moreover, examination may reveal signs of mental retardation or pyramidal deficit in addition to the movement disorder. Dystonic posturing may also occur in Wilson disease, Huntington disease, or parkinsonism; as a sequela of encephalitis lethargica or previous neuroleptic medication therapy; and in certain other disorders. In these cases, diagnosis is based on the history and accompanying clinical manifestations.

Treatment

Idiopathic torsion dystonia usually responds poorly to medications. A distinct variety of dystonia is remarkably responsive to levodopa; therefore, *a levodopa trial is warranted in all dystonic patients* (Sinemet 25/100 mg start 0.5 tablet orally once daily and increase depending on response). Failing this, diazepam, clonazepam, anticholinergic medication such as trihexyphenidyl or benztropine (in high dosage), or baclofen is occasionally helpful; if not, a trial of treatment with tetrabenazine may be worthwhile. In each case, the dose has to be individualized, depending on response and tolerance. However, the doses of these latter medications that are required for benefit lead usually to mild parkinsonism. Pallidal deep brain stimulation is helpful for disabling generalized dystonia and has a lower morbidity than stereotactic thalamotomy, which is sometimes helpful in patients with predominantly unilateral limb dystonia. Potential adverse events of deep brain stimulation include cerebral infection or hemorrhage, broken leads, affective changes, and dysarthria.

Stephen CD. The dystonias. Continuum (Mineap Minn). 2022;28:1435. [PMID: 36222773]

5. Focal Torsion Dystonia

A number of the dystonic manifestations that occur in idiopathic torsion dystonia may also occur as isolated phenomena. They are best regarded as focal dystonias that either occur as formes frustes of idiopathic torsion dystonia in patients with a positive family history or represent a focal manifestation of the adult-onset form of that disorder when there is no family history. Medical treatment is generally unsatisfactory. A trial of the medications used in idiopathic torsion dystonia is worthwhile, however, since a few patients do show some response. In addition, with restricted dystonias such as blepharospasm or torticollis, local injection of botulinum A toxin into the overactive muscles may produce worthwhile benefit for several weeks or months and can be repeated as needed.

Both **blepharospasm** and **oromandibular dystonia** may occur as an isolated focal dystonia. The former is characterized by spontaneous involuntary forced closure of the eyelids for a variable interval. Oromandibular dystonia is manifested by involuntary contraction of the muscles about the mouth causing, for example, involuntary opening or closing of the mouth, roving or protruding tongue movements, and retraction of the platysma. **Cervical dystonia** (spasmodic torticollis), usually with onset between 25 and 50 years of age, is characterized by a tendency for the neck to twist to one side. This initially occurs episodically, but eventually the neck is held to the side. Some patients have a sensory trick ("geste antagoniste") that lessens the dystonic posture, eg, touching the side of the face. Spontaneous resolution may occur in the first year or so. The disorder is otherwise usually lifelong. Local injection of botulinum A toxin provides benefit in most cases. Deep brain stimulation of the globus pallidus interna is an option if medical treatment and botulinum toxin injection are unsuccessful.

Writer's cramp is characterized by dystonic posturing of the hand and forearm when the hand is used for writing and sometimes when it is used for other tasks, eg, playing the piano or using a screwdriver or eating utensils. Medication treatment is usually unrewarding, and patients are often best advised to learn to use the other hand for activities requiring manual dexterity. Injections of botulinum A toxin are helpful in some instances.

Kassaye SG. The effectiveness of physiotherapy for patients with isolated cervical dystonia: an updated systematic review and meta-analysis. BMC Neurol. 2024;24:53. [PMID: 38302911]

6. Myoclonus

Occasional myoclonic jerks may occur in anyone, especially when drifting into sleep. **General or multifocal myoclonus** is common in patients with idiopathic epilepsy and is especially prominent in certain hereditary disorders characterized by seizures and progressive intellectual decline, such as the lipid storage diseases. It is also a feature of subacute sclerosing panencephalitis and Creutzfeldt-Jakob disease. Generalized myoclonic jerking may accompany uremic and other metabolic encephalopathies, result from therapy with levodopa or tricyclic antidepressants, occur in alcohol or drug withdrawal states, or follow anoxic brain damage. It also occurs on a hereditary or sporadic basis as an isolated phenomenon in otherwise healthy subjects.

Segmental myoclonus is a rare manifestation of a focal spinal cord lesion. It may also be the clinical expression of **epilepsia partialis continua**, a disorder in which a repetitive focal epileptic discharge arises in the contralateral sensorimotor cortex, sometimes from an underlying structural lesion. An electroencephalogram is often helpful in clarifying the epileptic nature of the disorder, and CT or MRI scan may reveal the causal lesion.

Myoclonus may respond to certain anticonvulsant medications, especially valproic acid or levetiracetam, or to one of the benzodiazepines, particularly clonazepam (see Table 27–3). It may also respond to piracetam (up to 16.8 g daily; not available in the United States). Myoclonus following anoxic brain damage is often responsive to oxitriptan (5-hydroxytryptophan), the precursor of serotonin, and sometimes to clonazepam. Oxitriptan is given in gradually increasing doses up to 1–1.5 mg daily. In patients with segmental myoclonus, a localized lesion should be searched for and treated appropriately.

Vellieux G et al. Multimodal assessment of the origin of myoclonus in Lance-Adams syndrome. Neurology. 2024;103:e209994. [PMID: 39499871]

7. Wilson Disease

In this metabolic disorder, abnormal movement and posture may occur with or without coexisting signs of liver involvement. Psychiatric and neuropsychological manifestations are common. Wilson disease is discussed in Chapter 18.

8. Drug-Induced Abnormal Movements

Medications may produce a wide variety of abnormal movements, including tremor, parkinsonism, akathisia (ie, motor restlessness), acute dystonia, chorea, myoclonus, and tardive dyskinesias or dystonia. **Medication-induced tremor** is usually postural with a low amplitude and high frequency and may occur with β-2-adrenergic agonists, sympathomimetics, serotonergic agents, glucocorticoids, thyroid hormone, antiseizure medications, antiarrhythmics, antipsychotics, chemotherapeutics, immunosuppressants, hypoglycemic agents, and other medications such as lithium, caffeine, and theophylline.

Drug-induced parkinsonism is usually bilateral at onset, tends to have a lower incidence of tremor, and is poorly responsive to levodopa. It may be caused by antidopaminergic medications (eg, typical and atypical antipsychotics, antiemetics, central monoamine depleting agents), serotonergic agents, calcium channel blockers, and lithium.

Chorea may develop in patients receiving antidopaminergic medications (eg, typical and atypical antipsychotics, antiemetics), levodopa, dopamine agonists, anticholinergic medications, certain antiseizure medications, lithium, amphetamines, or oral contraceptives.

Acute dystonia may be produced by antidopaminergic medications (eg, phenothiazines and their derivatives, butyrophenones, metoclopramide) and dopaminergic medications (eg, levodopa, bromocriptine), serotonergic agents, phenytoin, carbamazepine, and lithium. Dyskinesias related to psychiatric medications are discussed in Chapter 28. *With the exception of tardive dyskinesia and dystonia, the movement disorder usually resolves with withdrawal of the offending substance, but parkinsonism may take many months to do so.* When severe, acute dystonia and akathisia are treated with intravenous or intramuscular benztropine or diphenhydramine, drug-induced parkinsonism is treated with oral benztropine, and tardive dyskinesia is treated with deutetrabenazine or valbenazine.

Conn H et al. Drug-induced parkinsonism: diagnosis and treatment. Expert Opin Drug Saf. 2023;23:1503. [PMID: 39419777]

9. Restless Legs Syndrome

This common disorder, affecting 1–5% of people, may occur as a primary (idiopathic) disorder or in relation to Parkinson disease, pregnancy, iron deficiency anemia, or peripheral neuropathy (especially uremic or diabetic). Restless legs syndrome may have a hereditary basis, and several genetic loci have been associated with the disorder. Restlessness and curious sensory disturbances lead to an irresistible urge to move the limbs, especially during periods of relaxation; movement of the limbs provides relief. The urge occurs exclusively in the evening and at night or is worse at night than during the day. Most patients also have **periodic limb movements of sleep** and one-third have periodic limb movements during relaxed wakefulness; both consist of brief involuntary flexion at the ankle, knee, and hip. Disturbed nocturnal sleep and excessive daytime somnolence may result. *Ferritin levels should always be measured*; treatment with oral iron sulfate in patients with ferritin levels ≤ 75 mcg/L (13.4 mcmol/L) and transferrin saturation below 45% should be attempted prior to initiation of other pharmacotherapies. In patients who do not respond to or are ineligible for iron therapy, gabapentin enacarbil (300–1200 mg orally each evening), gabapentin (starting with 300 mg orally daily, increasing to approximately 1800 mg daily, depending on response and tolerance), or pregabalin (150–300 mg orally divided twice to three times daily) should be tried next. Therapy with nonergot dopamine agonists, such as pramipexole (0.125–0.5 mg orally once daily), ropinirole (0.25–4 mg orally once daily 2–3 hours before bedtime), or rotigotine (1–3 mg/24 hours transdermal patch once daily), is helpful but may lead to an augmentation of symptoms. Levodopa also is helpful but also leads to augmentation, so its use is generally reserved for those who do not respond to other measures. Extended-release oxycodone-naloxone (2.5–5 mg to 5–10 mg orally twice daily) is useful in patients with severe symptoms or those who are refractory to first-line therapies.

Winkelman JW et al. Treatment of restless legs syndrome and periodic limb movement disorder: an American Academy of Sleep Medicine systematic review, meta-analysis, and GRADE assessment. J Clin Sleep Med. 2025;21:153. [PMID: 39324664]

10. Gilles de la Tourette Syndrome

ESSENTIALS OF DIAGNOSIS

- Multiple motor and phonic tics.
- Symptoms begin before age 18 years.
- Tics occur frequently for at least 1 year.
- Tics vary in number, frequency, and nature over time.

Clinical Findings

Simple tics occur transiently in up to 25% of children, remit within weeks to months, and do not require treatment. Tourette syndrome is a more complex disorder. **Motor tics** are the initial manifestation in 80% of cases and most commonly involve the face, whereas in the remaining 20%, the initial symptoms are **phonic tics;** ultimately a combination of different motor and phonic tics develop in all patients. Tics are preceded by an urge that is relieved upon performance of the movement or vocalization; they can be temporarily suppressed but eventually the urge becomes overwhelming. These are noted first in childhood, generally between the ages of 2 and 15. Motor tics occur especially about the face, head, and shoulders (eg, sniffing, blinking, frowning, shoulder shrugging, head thrusting). Phonic tics commonly include grunts, barks, hisses, throat-clearing, and coughs, and sometimes also verbal utterances, including coprolalia (obscene speech). There may also be echolalia (repetition of the speech of others), echopraxia (imitation of others' movements), and palilalia (repetition of words or phrases). Some tics may be self-mutilating in nature, such as nail-biting, hair-pulling, or biting of the lips or tongue. The disorder is chronic, but the course may be punctuated by relapses and remissions. OCD and attention deficit hyperactivity disorder (ADHD) are commonly associated and may be more disabling than the tics themselves. A family history is sometimes obtained.

Examination usually reveals no abnormalities other than the tics. In addition to OCD, psychiatric disturbances may occur because of the associated cosmetic and social embarrassment. The diagnosis of the disorder is often delayed for years, the tics being interpreted as psychiatric illness or some other form of abnormal movement. Patients are thus often subjected to unnecessary treatment before the disorder is recognized. The tic-like character of the abnormal movements and the absence of other neurologic signs should differentiate this disorder from other movement disorders presenting in childhood. Wilson disease, however, can simulate the condition and should be excluded.

Treatment

Treatment is symptomatic and may need to be continued indefinitely. Habit reversal training or other forms of behavioral therapy can be effective alone or in combination with pharmacotherapy. α-Adrenergic agonists, such as clonidine (start 0.05 mg orally at bedtime, titrating to 0.3–0.4 mg orally daily, divided three to four times per day) or guanfacine (start 0.5 mg orally at bedtime, titrating to a maximum of 3–4 mg orally daily, divided twice daily), are first-line therapies because of a favorable side-effect profile compared with typical antipsychotics, and are FDA-approved therapies for the disorder. They also have the advantage of improving the symptoms of concomitant ADHD. When a typical antipsychotic is required in cases of severe tics, haloperidol is generally regarded as the medication of choice. It is started in a low dose (0.25 mg daily orally) that is gradually increased (by 0.25 mg every 4 or 5 days) until there is maximum benefit with a minimum of side effects or until side effects limit further increments. A total daily oral dose of between 2 mg and 8 mg is usually optimal, but higher doses are sometimes necessary. Aripiprazole (2.5–20 mg orally daily), fluphenazine (1–15 mg orally daily), pimozide (1–10 mg orally daily), and risperidone (1–6 mg daily orally) are alternatives; haloperidol, aripiprazole, and pimozide are FDA-approved for Tourette syndrome. Typical antipsychotics can cause significant weight gain and carry a risk of tardive dyskinesias and other long-term, potentially irreversible motor side effects. Therefore, many specialists favor the use of a VMAT2 inhibitor (see dosing in the discussion of Huntington disease); tetrabenazine is approved for Tourette syndrome in Canada but not the United States. Small, randomized trials or observational studies have reported benefit from topiramate, nicotine, tetrahydrocannabinol, baclofen, and clonazepam.

Injection of botulinum toxin type A at the site of the most distressing tics is sometimes worthwhile and has fewer side effects than systemic antipsychotic therapy. Bilateral high-frequency deep brain stimulation at various sites has been helpful in some, otherwise intractable, cases.

Lenka A et al. An update on the pharmacological management of Tourette syndrome and emerging treatment paradigms. Expert Rev Neurother. 2024;24:1025. [PMID: 39034647]

When to Refer

- Patients with essential tremor, Parkinson disease, and restless legs syndrome unresponsive to first-line therapy.
- All patients with Huntington disease, Wilson disease, Gilles de la Tourette syndrome, and dystonia.

When to Admit

Patients undergoing surgical treatment should be admitted.

DEMENTIA

ESSENTIALS OF DIAGNOSIS

- Progressive intellectual decline.
- Not due to delirium or psychiatric disease.
- Age is the main risk factor, followed by family history and vascular disease risk factors.

General Considerations

Dementia is a progressive decline in intellectual function that is severe enough to compromise social or occupational functioning. **Mild cognitive impairment** describes a decline that has not resulted in a change in the level of function. Although a few patients identify a precipitating event, most experience an insidious onset and gradual progression of symptoms.

Dementia typically begins after age 60, and the prevalence doubles approximately every 5 years thereafter; in persons aged 85 and older, around half have dementia (see Chapter 4). In older patients with gradually progressive cognitive symptoms and no other complaint or sign, a neurodegenerative disease is likely (Table 27–7). These conditions are defined by their underlying neuropathology, and their clinical presentation reflects the locations in the brain where the pathology typically accumulates.

Dementia is distinct from delirium and psychiatric disease. **Delirium** is an acute confusional state that often occurs in response to an identifiable trigger, such as drug or alcohol intoxication or withdrawal (eg, Wernicke encephalopathy, described below), medication side effects (especially medications with anticholinergic properties, antihistamines, benzodiazepines, sleeping aids, opioids, neuroleptics, corticosteroids, and other sedative or psychotropic agents), infection (consider occult UTI or pneumonia in older patients), metabolic disturbance (including an electrolyte abnormality; hypo- or hyperglycemia; or a nutritional, endocrine, renal, or hepatic disorder), sleep deprivation, or other neurologic disease (seizure, including a postictal state, or stroke). Delirium typically involves *fluctuating* levels of arousal, including drowsiness or agitation, and it improves after removal or treatment of the precipitating factor. Patients with dementia are especially susceptible to episodes of delirium, but recognition of dementia is not possible until delirium lifts. For this reason, dementia is typically diagnosed in outpatients who are otherwise medically stable, rather than in acutely ill patients in the hospital.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs of the common causes of dementia are detailed in Table 27–7. Clinicians should be aware that a

Table 27–7. Common causes of age-related dementia (listed by prevalence).

Disorder	Pathology	Clinical Features
Alzheimer disease	Plaques containing β-amyloid peptide, and neurofibrillary tangles containing tau protein, occur throughout the neocortex.	• Most common age-related neurodegenerative disease; incidence doubles every 5 years after age 60. • Short-term memory impairment is early and prominent in most cases. • Variable deficits of executive function, visuospatial function, and language.
Vascular dementia	Multifocal ischemic change.	• Stepwise or progressive accumulation of cognitive deficits in association with repeated strokes. • Symptoms depend on localization of strokes.
Dementia with Lewy bodies	Histologically indistinguishable from Parkinson disease: α-synuclein-containing Lewy bodies occur in the brainstem, midbrain, olfactory bulb, and neocortex. Alzheimer pathology may coexist.	• Cognitive dysfunction, with prominent visuospatial and executive deficits. • Psychiatric disturbance, with anxiety, visual hallucinations, and fluctuating delirium. • Parkinsonian motor deficits with or after other features. • Cholinesterase inhibitors lessen delirium; poor tolerance of neuroleptics and dopaminergics.
Frontotemporal dementia (FTD)	Neuropathology is variable and defined by the protein found in intraneuronal aggregates. Tau protein, TAR DNA-binding protein 43 (TDP-43), or fused-in-sarcoma (FUS) protein account for most cases.	• Peak incidence in the sixth decade; approximately equal to Alzheimer disease as a cause of dementia in patients under 60 years old. • Familial cases result from mutations in genes for tau, progranulin, or others. **Behavioral variant FTD** • Deficits in empathy, social comportment, insight, abstract thought, and executive function. • Behavior is disinhibited, impulsive, and ritualistic, with prominent apathy and increased interest in sex or sweet/fatty foods. • Relative preservation of memory. • Focal right frontal atrophy. • Association with amyotrophic lateral sclerosis. **Semantic variant primary progressive aphasia** • Deficits in word-finding, single-word comprehension, object and category knowledge, and face recognition. • Behaviors may be similar to behavioral variant FTD. • Focal, asymmetric temporal pole atrophy. **Nonfluent/agrammatic variant primary progressive aphasia** • Speech is effortful with dysarthria, phonemic errors, sound distortions, and poor grammar. • Focal extrapyramidal signs and apraxia of the right arm and leg are common; overlaps with corticobasal degeneration. • Focal left frontal atrophy.

patient's insight into a cognitive change may be vague or absent, and *collateral history is essential to a proper evaluation*. As patients age, primary care clinicians should inquire periodically about the presence of any cognitive symptoms.

Symptoms depend on the area of the brain affected. **Short-term memory loss**, involving the repeating of questions or stories and a diminished ability to recall the details of recent conversations or events, frequently results from pathologic changes in the hippocampus and is most commonly a sign of Alzheimer disease. **Word-finding difficulty** often involves difficulty recalling the names of people, places, or objects, with low-frequency words affected first, eventually resulting in speech laden with pronouns and circumlocutions. This problem is thought to arise from pathology at the temporoparietal junction of the left hemisphere. When aphasia is an early or prominent symptom of dementia, the most frequent underlying disorders are Alzheimer disease and frontotemporal dementia. Problems with articulation, fluency, comprehension, or word meaning are anatomically distinct and less common. **Visuospatial dysfunction** may result in poor navigation and getting lost in familiar places, impaired recognition of previously familiar faces and buildings, or trouble discerning an object against a background. The occipital and right parietal lobes are two of the brain areas implicated in such symptoms and are commonly affected by Alzheimer disease and dementia with Lewy bodies. **Executive dysfunction** may manifest by easy distractibility, impulsivity, mental inflexibility, concrete thought, slowed processing speed, poor planning and organization, or impaired judgment. Localization may vary and could include the frontal lobes or subcortical areas like the basal ganglia or cerebral white matter, which accounts for the prevalence of executive dysfunction in vascular dementia. **Apathy** or indifference, separate from depression, is common and may have a similar anatomy as executive dysfunction. **Apraxia**, or the loss of learned motor behaviors, may result from dysfunction of the frontal or parietal lobes, especially the left parietal lobe.

The time of symptom onset must be established, but subtle, early symptoms are often apparent only in retrospect. Another event, such as an illness or hospitalization, may lead to new recognition of existing symptoms. Symptoms often accumulate over time, and *the nature of the earliest symptom is most helpful in forming the differential diagnosis.* The history should establish risk factors for dementia, including family history, other chronic illnesses, and vascular disease risk factors. Finally, it is important to document the patient's current capacity to perform **basic and instrumental activities of daily living** (see Chapter 4) and to note the extent of decline from the premorbid level of function. Indeed, *this functional assessment defines the presence and severity of dementia*.

The physical examination is important to identify any occult medical illness. In addition, eye movement abnormalities, parkinsonism, or other motor abnormalities may help identify an underlying neurologic condition. The workup should prioritize the exclusion of conditions that are reversible or require separate therapy. Screening for depression is necessary, along with imaging and laboratory workup, as indicated below.

B. Neuropsychologic Assessment

Brief quantification of cognitive impairment is indicated in a patient reporting cognitive symptoms or if caregivers raise similar concerns. The **Folstein Mini Mental State Exam (MMSE), Montreal Cognitive Assessment (MoCA), Mini-Cog**, and other similar tests are brief, objective, and widely translated and used, but have important limitations: they are insensitive to mild cognitive impairment, they may be biased negatively by the presence of language or attention problems, and they do not correlate with functional capacity (see Chapter 4 for further details).

Psychiatric disease sometimes leads to complaints of impaired cognition (**pseudodementia**). Impaired attention is usually to blame, and in some patients with depression or anxiety, poor focus and concentration may even be a primary complaint. Screening for depression and anxiety in patients presenting with cognitive complaints is imperative.

A **neuropsychiatric evaluation** by a trained neuropsychologist or psychometrician may be appropriate. The goal of such testing is to enhance localization by defining the cognitive domains that are impaired as well as to quantify the degree of impairment. There is no standard battery of tests, but a variety of metrics is commonly used to assess the symptom types highlighted above. Assessments are most accurate when a patient is well rested, comfortable, and otherwise medically stable.

C. Imaging

Brain imaging with MRI or CT without contrast is indicated in any patient with a new, progressive cognitive complaint. The goal is to exclude occult cerebrovascular disease, tumor, or other identifiable structural abnormality, rather than to provide positive evidence of a neurodegenerative disease. Global or focal brain atrophy may be worse than expected for age and could suggest a particular neurodegenerative process, but such findings are rarely specific.

PET with fluorodeoxyglucose (FDG) does not confirm or exclude any specific cause of dementia but may be useful as an element of the workup in specific clinical circumstances, such as discriminating between Alzheimer disease and frontotemporal dementia in a patient with some symptoms of each. PET imaging with a radiolabeled ligand for β-amyloid, one of the pathologic proteins in Alzheimer disease, is highly sensitive to amyloid pathology and may provide positive evidence for Alzheimer disease in a patient with cognitive decline. However, after age 60 or 70, amyloid plaques can accumulate in the absence of cognitive impairment; thus, the specificity of a positive amyloid scan diminishes with age. Single-photon emission CT offers similar information as FDG-PET but is less sensitive. PET imaging with radiolabeled ligands for tau, a pathogenic protein in Alzheimer disease, progressive supranuclear palsy, and some forms of frontotemporal dementia, also may help refine premortem diagnostic accuracy.

D. Laboratory Findings

Serum levels of vitamin B_{12}, free T_4, and TSH should be measured for any patient with cognitive symptoms. A serum rapid plasma reagin (RPR) and testing for HIV should be considered. Other testing should be driven by clinical suspicion, and often includes a CBC, serum electrolytes, glucose, and lipid profile.

Elevated serum phosphorylated Tau217 is correlated with positive amyloid PET and supports the diagnosis of Alzheimer disease in a patient with characteristic symptoms and signs. Spinal fluid protein measurements (with decreased β-amyloid and increased tau protein) also may support the diagnosis of Alzheimer disease in the appropriate clinical context, but testing shares some of the same concerns as amyloid PET imaging. Dementia with Lewy bodies may be suggested by the presence of misfolded α synuclein in spinal fluid.

Although the presence of one or two ApoE ε-4 alleles indicates an increased risk of Alzheimer disease. ApoE genotyping is clinically available; however, it is of *limited clinical utility.* In a young patient with dementia, finding an ApoE ε-4 allele might raise the index of suspicion for Alzheimer disease, but in an older patient obtaining a genotype is unlikely to be helpful. Until a preventative therapy becomes available, testing of an asymptomatic patient as a marker of risk for Alzheimer disease is inappropriate.

▶ Differential Diagnosis

A. Decline Before Age 60 or Atypical Course

Decline beginning before age 60, rapid progression, fluctuating course, unintended weight loss, systemic complaints, or other unexplained symptoms or signs raise suspicion for a process other than a neurodegenerative disease. In this case, the differential is broad and includes infection or inflammatory disease, neoplasm or a paraneoplastic condition, endocrine or metabolic disease, drugs or toxins, or other conditions. A lumbar puncture should be considered to screen for cells or antibodies in the spinal fluid, to measure β-amyloid and tau, and to measure the opening pressure if hydrocephalus is suspected.

Normal pressure hydrocephalus is an important but difficult diagnosis to establish. Symptoms include gait apraxia (sometimes described as a "magnetic" gait, as if the feet are stuck to the floor), urinary incontinence, and dementia. CT scanning or MRI of the brain reveals ventricles that are enlarged in obvious disproportion to sulcal widening and overall brain atrophy. When drainage of a large volume (30–50 mL) of CSF by lumbar puncture results in objective improvement of gait (such as in the time to walk 20 feet), consideration often is given to the placement of a lumboperitoneal or ventriculoperitoneal shunt. Unfortunately, gait disorders, incontinence, and cognitive dysfunction often occur together nonspecifically in older patients, and distinguishing normal pressure hydrocephalus from cerebral atrophy is not straightforward. Because of the surgical risks associated with shunt placement, as well as a strong risk for future shunt malfunction requiring further surgical intervention, the procedure should be avoided except in clear-cut cases. In general, it is the gait apraxia that is most likely to improve after surgery; the cognitive impairment is least likely to respond.

B. Rapidly Progressive Dementia

When dementia develops quickly, with obvious decline over a few weeks to a few months, the syndrome may be classified as a **rapidly progressive dementia**. The differential diagnosis for typical dementias is still relevant, but additional etiologies must be considered, including prion disease; infections; toxins; neoplasms; and autoimmune and inflammatory diseases, including corticosteroid-responsive (Hashimoto) encephalopathy and antibody-mediated paraneoplastic and nonparaneoplastic encephalitis (Table 27–6). Workup should begin with brain MRI with contrast and diffusion-weighted imaging, routine laboratory studies (serum vitamin B_{12}, free T_4, and TSH levels), serum RPR, HIV antibody, Lyme serology, rheumatologic tests (ESR, CRP, and antinuclear antibody), anti-thyroglobulin and anti-thyroperoxidase antibody levels, paraneoplastic and nonparaneoplastic autoimmune antibodies (Table 27–6), and CSF studies (cell count and differential; protein and glucose levels; protein electrophoresis for oligoclonal bands; IgG index [spinal-fluid-to-serum-γ-globulin level] ratio; and VDRL). Depending on the clinical context, it may be necessary to exclude Wilson disease (24-hour urine copper level); heavy metal intoxication (urine heavy metal panel); and infectious encephalitis due to atypical bacteria, viruses, fungi, and mycobacteria.

Creutzfeldt-Jakob disease is a relatively common cause of rapidly progressive dementia (see Chapter 37). Family history is important since mutations in *PRNP*, the gene for the prion protein, account for around 15% of cases. Diffusion-weighted MRI is the most helpful diagnostic tool, classically revealing cortical ribboning (a gyral pattern of hyperintensity) as well as restricted diffusion in the caudate and anterior putamen. An electroencephalogram often shows periodic complexes. Real-time quaking induced conversion (RT-QuIC), in which patient CSF is mixed with recombinant prion protein and aggregation of prion protein is detected, is a sensitive and specific diagnostic test. Reflecting the high rate of neuronal death, CSF levels of the intraneuronal proteins tau, 14-3-3, and neuron-specific enolase are often elevated, although this finding is neither sensitive nor specific.

▶ Treatment

A. Anti-amyloid Therapy

Two anti-amyloid therapies are approved in the United States. Lecanemab (10 mg/kg intravenously every 2 weeks) and donanemab (700 mg intravenously every 4 weeks for 3 doses; then 1400 mg intravenously every 4 weeks) modestly slowed cognitive decline in patients with early Alzheimer disease and reduced brain amyloid burden measured by amyloid PET compared with placebo. Aducanumab previously was approved by the FDA despite mixed results in clinical trials but was discontinued by the manufacturer in 2024. The use of these therapies is limited to patients with mild cognitive impairment or mild dementia and amyloid pathology proven by amyloid PET or CSF analysis. Patients and prescribers must adhere to a monitoring regime including frequent brain MRI due to a high risk of complications such as cerebral edema and hemorrhage. Caution should be used in patients with a history of cerebral hemorrhage, evidence of microhemorrhages or superficial siderosis on pretreatment brain MRI, anticoagulant or antiplatelet use other than aspirin, any bleeding disorder, or an ApoE ε-4 allele. Cost effectiveness and long-term risk of these therapies remain uncertain.

B. Cholinesterase Inhibitors and Memantine

Cholinesterase inhibitors are first-line therapy for Alzheimer disease and dementia with Lewy bodies (Table 27–7). They provide modest, symptomatic treatment for cognitive dysfunction and may prolong the capacity for independence but do *not* prevent disease progression. Commonly used medications include donepezil, rivastigmine, and galantamine. Donepezil treatment starts at 5 mg orally daily for 4 weeks, then increases to 10 mg daily; a 23 mg daily dose is approved for moderate to severe Alzheimer disease, although its modest additional efficacy over the 10 mg dose is overshadowed by an increased risk of side effects. Rivastigmine treatment starts at 1.5 mg orally twice daily, then increases every 2 weeks by 1.5 mg twice daily to a goal of 3–6 mg twice daily; a once daily transdermal patch formulation (4.6, 9.5, or 13.3 mg/24 hours) is also available. Galantamine starts at 4 mg orally twice daily, then increases every 4 weeks by 4 mg twice daily to a goal of 8–12 mg twice daily; a once-daily extended-release formulation is also available. Cholinesterase inhibitors are *not* given for frontotemporal dementia because they may worsen behavioral symptoms. Nausea and diarrhea are common side effects; syncope and cardiac dysrhythmia are uncommon but more serious. An ECG is often obtained before and after starting therapy, particularly in a patient with cardiac disease or a history of syncope.

Memantine (start at 5 mg orally daily, then increase by 5 mg per week up to a target of 10 mg twice daily) is approved for the treatment of moderate to severe Alzheimer disease. It is typically used instead of, not in addition to, the cholinesterase inhibitors. In frontotemporal dementia, memantine is ineffective and may worsen cognition. There is some evidence that memantine may improve cognition and behavior among patients with dementia with Lewy bodies.

C. Other Therapies

Treatment for mood and behavioral disturbances is discussed in Chapter 4, where safety issues are also considered.

When to Refer

- All patients with new, unexplained cognitive decline should be referred, especially those with rapid progression.
- Patients with mild cognitive impairment or early dementia who may be candidates for anti-amyloid therapies.

When to Admit

Admission to the hospital should only occur when essential in patients with dementia due to increased risk of developing hospital-acquired delirium.

Heneka MT et al. Passive anti-amyloid β immunotherapy in Alzheimer's disease: opportunities and challenges. Lancet. 2024;404:2198. [PMID: 39549715]
Van Dyck CH et al. Lecanemab in early Alzheimer's disease. N Engl J Med. 2023;388:9. [PMID: 36449413]

WERNICKE ENCEPHALOPATHY & KORSAKOFF SYNDROME

Wernicke encephalopathy is characterized by confusion, ataxia, and nystagmus leading to ophthalmoplegia (lateral rectus muscle weakness, conjugate gaze palsies); peripheral neuropathy may also be present. It is *due to thiamine deficiency* and in the United States occurs most commonly in patients with alcohol use disorder. It may also occur in patients with AIDS or hyperemesis gravidarum, and after bariatric surgery. In suspected cases, thiamine (100 mg) is given intravenously immediately and then intramuscularly on a daily basis until a satisfactory diet can be ensured after which the same dose is given orally. Some guidelines recommend initial doses of 200–500 mg intravenously three times daily for the first 5–7 days of treatment. Intravenous glucose given *before* thiamine may precipitate the syndrome or worsen the symptoms. The diagnosis is confirmed by the response in 1 or 2 days to treatment, which must not be delayed while awaiting laboratory confirmation of thiamine deficiency from a blood sample obtained prior to thiamine administration. **Korsakoff syndrome** occurs in more severe cases; it includes anterograde and retrograde amnesia and sometimes confabulation and may not be recognized until after the initial delirium has lifted.

Eva L et al. Neuropsychiatric and neuropsychological aspects of alcohol-related cognitive disorders: an in-depth review of Wernicke's encephalopathy and Korsakoff's syndrome. J Clin Med. 2023;12:6101. [PMID: 37763040]

STUPOR & COMA

ESSENTIALS OF DIAGNOSIS

- Level of consciousness is depressed.
- Stuporous patients respond only to repeated vigorous stimuli.
- Comatose patients are unarousable and unresponsive.

General Considerations

The patient who is **stuporous** is unresponsive except when subjected to repeated vigorous stimuli, while the **comatose** patient is unarousable and unable to respond to external events or inner needs, although reflex movements and posturing may be present.

Coma is a major complication of serious CNS disorders. It can result from seizures, hypothermia, metabolic disturbances, meningoencephalitis, or structural lesions causing bilateral cerebral hemispheric dysfunction or a disturbance of the brainstem reticular activating system. A mass lesion involving one cerebral hemisphere may cause coma by compression of the brainstem.

Assessment & Emergency Measures

The diagnostic workup of the comatose patient must proceed concomitantly with management. Supportive therapy for respiration or blood pressure is initiated; in hypothermia, all such patients should be rewarmed before the prognosis is assessed.

The patient can be positioned on one side with the neck partly extended, dentures removed, and secretions cleared by suction; if necessary, the patency of the airways is maintained with an oropharyngeal airway. Blood is drawn for serum glucose, electrolyte, and calcium levels; ABGs; liver biochemical and kidney function tests; and toxicologic studies as indicated. Thiamine (100 mg), followed by dextrose 50% (25 g), and naloxone (0.4–1.2 mg) are given intravenously without delay.

Further details are then obtained from attendants of the patient's medical history, the circumstances surrounding the onset of coma, and the time course of subsequent events. Abrupt onset of coma suggests subarachnoid hemorrhage, brainstem stroke, or intracerebral hemorrhage, whereas a slower onset and progression occur with other structural or mass lesions. Urgent noncontrast CT scanning of the head should be performed to identify intracranial hemorrhage, brain herniation, or other structural lesions that may require immediate neurosurgical intervention, and CT angiogram is important to rule out basilar artery occlusion. A metabolic cause is likely with a preceding intoxicated state or agitated delirium. On examination, attention is paid to the behavioral response to painful stimuli, the pupils and their response to light, the response to touching the cornea with a wisp of sterile gauze, position of the eyes and their movement in response to passive movement of the head and ice-water caloric stimulation, and the respiratory pattern.

A. Response to Painful Stimuli

Purposeful limb withdrawal from painful stimuli implies that sensory pathways from and motor pathways to the stimulated limb are functionally intact. Unilateral absence of responses despite application of stimuli to both sides of the body in turn implies a corticospinal lesion; bilateral absence of responsiveness suggests brainstem involvement, bilateral pyramidal tract lesions, or psychogenic unresponsiveness. **Decorticate** (flexor) posturing may occur with lesions of the internal capsule and rostral cerebral peduncle and **decerebrate** (extensor) posturing with dysfunction or destruction of the midbrain and rostral pons. Decerebrate posturing occurs in the arms accompanied by flaccidity or slight flexor responses in the legs in patients with extensive brainstem damage extending down to the pons at the trigeminal level.

B. Ocular Findings

1. Pupils—Hypothalamic disease processes may lead to unilateral Horner syndrome, while bilateral diencephalic involvement or destructive pontine lesions may lead to small but reactive pupils. Ipsilateral pupillary dilation with no direct or consensual response to light occurs with compression of the third cranial nerve, eg, with uncal herniation. The pupils are slightly smaller than normal but responsive to light in many metabolic encephalopathies; however, they may be fixed and dilated following overdosage with atropine or scopolamine, and pinpoint (but responsive) with opioids.

2. Corneal reflex—Touching the cornea with a wisp of sterile gauze or cotton should elicit a blink reflex. The afferent limb of the arc is mediated by the fifth cranial nerve; the efferent limb by the seventh nerve. A unilateral absent corneal reflex implies damage to the ipsilateral pons or a trigeminal deficit. Bilateral loss can be seen with large pontine lesions or in deep pharmacologic coma.

3. Eye movements—Conjugate deviation of the eyes to the side suggests the presence of an ipsilateral hemispheric lesion, a contralateral pontine lesion, or ongoing seizures from the contralateral hemisphere. A mesencephalic lesion leads to downward conjugate deviation. Dysconjugate ocular deviation in coma implies a structural brainstem lesion unless there was preexisting strabismus.

The oculomotor responses to passive head turning and to caloric stimulation relate to each other and provide complementary information. In response to brisk rotation of the head from side to side and to flexion and extension of the head, normally conscious patients with open eyes do not exhibit contraversive conjugate eye deviation (**oculocephalic reflex**) unless there is voluntary visual fixation or bilateral frontal pathology. With cortical depression in lightly comatose patients, a brisk oculocephalic reflex is seen. With brainstem lesions, this oculocephalic reflex becomes impaired or lost, depending on the site of the lesion.

The **oculovestibular reflex** is tested by caloric stimulation using irrigation with ice water. In normal patients, jerk nystagmus is elicited for about 2 or 3 minutes, with the slow component toward the irrigated ear. In unconscious patients with an intact brainstem, the fast component of the nystagmus disappears, so that the eyes tonically deviate toward the irrigated side for 2–3 minutes before returning to their original position. With impairment of brainstem function, the response becomes abnormal and finally disappears. In metabolic coma, oculocephalic and oculovestibular reflex responses are preserved, at least initially.

C. Respiratory Patterns

Diseases causing coma may lead to respiratory abnormalities. **Cheyne-Stokes respiration** (in which episodes of deep breathing alternate with periods of apnea) may occur with bihemispheric or diencephalic disease or in metabolic disorders. **Central neurogenic hyperventilation** occurs with lesions of the brainstem tegmentum; **apneustic breathing** (in which there are prominent end-inspiratory pauses) suggests damage at the pontine level (eg, due to basilar artery occlusion); and **ataxic breathing** (a completely irregular pattern of breathing with deep and shallow breaths occurring randomly) is associated with lesions of the lower pontine tegmentum and medulla.

1. Stupor & Coma Due to Structural Lesions

Supratentorial mass lesions tend to affect brain function in a systematic way. There may initially be signs of hemispheric dysfunction, such as hemiparesis. As coma develops and deepens, cerebral function becomes progressively disturbed, producing a predictable progression of neurologic signs that suggest rostrocaudal deterioration.

Thus, as a supratentorial mass lesion begins to impair the diencephalon, the patient becomes drowsy, then stuporous, and finally comatose. There may be Cheyne-Stokes respiration; small but reactive pupils or an ipsilateral third nerve palsy due to uncal herniation; normal oculocephalic responses with side-to-side head movements but sometimes an impairment of reflex upward gaze with brisk flexion of the head; tonic ipsilateral deviation of the eyes in response to vestibular stimulation with cold water; and initially a positive response to pain but subsequently only decorticate posturing. With further progression, midbrain failure occurs. Motor dysfunction progresses from decorticate to bilateral decerebrate posturing in response to painful stimuli; Cheyne-Stokes respiration is gradually replaced by sustained central hyperventilation; the pupils become middle-sized and fixed; and the oculocephalic and oculovestibular reflex responses become impaired, abnormal, or lost. As the pons and then the medulla fail, the pupils remain unresponsive; oculovestibular responses are unobtainable; respiration is rapid and shallow; and painful stimuli may lead only to flexor responses in the legs. Finally, respiration becomes irregular and stops, the pupils often then dilating widely.

In contrast, a **subtentorial (ie, brainstem) lesion** may lead to an early, sometimes abrupt disturbance of consciousness without any orderly rostrocaudal progression of neurologic signs. Compressive lesions of the brainstem, especially cerebellar hemorrhage, may be clinically indistinguishable from intraparenchymal processes.

2. Stupor & Coma Due to Metabolic Disturbances

Patients with a metabolic cause of coma generally have signs of patchy, diffuse, and symmetric neurologic involvement that cannot be explained by loss of function at any single level or in a sequential manner, although focal or lateralized deficits may occur in hypoglycemia. Pupillary reactivity is usually preserved. Comatose patients with meningitis, encephalitis, or subarachnoid hemorrhage may also exhibit little in the way of focal neurologic signs, however, and clinical evidence of meningeal irritation is sometimes subtle in comatose patients. Examination of the CSF in such patients is essential to establish the correct diagnosis, once a CT scan has ruled out a structural lesion posing risk of cerebral herniation.

In patients with coma due to cerebral ischemia and hypoxia, the absence of pupillary light reflexes 24 hours after return of spontaneous circulation indicates that there is little chance of regaining independence; absent corneal reflexes or absent or extensor motor responses at 72 hours also indicate a grim prognosis. Physical findings are less reliable predictors of outcome among those treated with therapeutic hypothermia, although absent corneal or pupillary light reflexes at 72 hours after rewarming likely indicate a poor prognosis, as do bilaterally absent cortical somatosensory evoked potentials in response to median nerve stimulation after the patient has returned to normothermia.

Treatment of metabolic encephalopathy is of the underlying disturbance and is considered in other chapters. If the cause of the encephalopathy is obscure, all medications except essential ones may have to be withdrawn in case they are responsible for the altered mental status.

3. Brain Death (Neurologic Criteria)

Brain death occurs when there is complete and irreversible cessation of all brain function; although the organs can be maintained with mechanical ventilation for the purposes of donation, in most countries *the diagnosis of brain death is equivalent to a declaration of death.* To diagnose brain death, the cause of coma must be established, be compatible with a known cause of brain death, and be irreversible. Reversible coma simulating brain death may be seen with hypothermia (temperature lower than 32°C) and overdosage with CNS depressant drugs. These conditions must be excluded by warming the patient and allowing enough time for all sedating medications to be metabolized (ie, at least five half-lives) or by measuring serum levels. Severe blood pressure, electrolyte, acid-base, and endocrine derangements cannot be present.

Finally, a neurologic examination must demonstrate that the patient is comatose (ie, no eye opening and no response to central or peripheral pain); has lost all brainstem reflex responses, including the pupillary, corneal, oculovestibular, oculocephalic, oropharyngeal, and cough reflexes; and has no respiratory drive. The response to pain should be absent or only consist of spinal reflex movements; decerebrate or decorticate posturing is not consistent with brain death. Absence of respiratory drive is demonstrated with an **apnea test** (absence of spontaneous respiratory activity at a pH < 7.30, a $PaCO_2$ of at least 60 mm Hg and a rise of at least 20 mm Hg from baseline).

Certain ancillary tests may assist the determination of brain death if the pupillary light reflex cannot be assessed or an apnea test cannot be performed. These include demonstration of an absent cerebral circulation by intravenous radioisotope cerebral angiography or by four-vessel contrast cerebral angiography. An electroencephalogram, even when combined with brainstem auditory and somatosensory evoked potentials, does not fully evaluate brainstem function and should *not* be used to make a formal determination of brain death.

4. Persistent Vegetative State

Patients with severe bilateral hemispheric disease may show some improvement from an initially comatose state, so that, after a variable interval, they appear to be awake but lie motionless and without evidence of awareness or higher mental activity. This is called a **"persistent" vegetative state** once it has lasted over 4 weeks and has also been variously referred to as akinetic mutism, apallic state, or coma vigil. Patients in a vegetative state from a medical cause (eg, anoxic brain injury) for more than 3 months and from a traumatic brain injury for more than 12 months are said to be in a **"chronic" vegetative state**, from which a few patients may regain consciousness but remain severely disabled.

5. Minimally Conscious State

In this state, patients exhibit inconsistent evidence of consciousness. There is some degree of functional recovery of behaviors suggesting self- or environmental-awareness, such as basic verbalization or context-appropriate gestures, emotional responses (eg, smiling) to emotional but not neutral stimuli, or purposive responses to environmental stimuli (eg, a finger movement or eye blink apparently to command). Further improvement is manifest by the restoration of communication with the patient. The minimally conscious state may be temporary or permanent. Little information is available about its natural history or long-term outlook, which reflects the underlying cause. The likelihood of useful functional recovery diminishes with time; after 12 months, patients are likely to remain severely disabled and without a reliable means of communication. Prognostication is difficult. Amantadine (100–200 mg orally daily) may hasten recovery when given to patients in a vegetative or minimally conscious state 4–16 weeks after traumatic brain injury.

6. Locked-In Syndrome (De-efferented State)

Acute destructive lesions (eg, infarction, hemorrhage, demyelination, encephalitis) involving the ventral pons and sparing the tegmentum may lead to a mute, quadriparetic but conscious state in which the patient is capable of blinking and voluntary eye movement in the vertical plane, with preserved pupillary responses to light. Such a patient can mistakenly be regarded as comatose. Clinicians should recognize that "locked-in" individuals are fully aware of their surroundings. The prognosis is usually poor, but recovery has occasionally been reported in some cases, including resumption of independent daily life. A similar condition may occur with severe Guillain-Barré syndrome and has a better prognosis.

Greer DM et al. Pediatric and adult brain death/death by neurologic criteria consensus guideline: report of the AAN guidelines subcommittee, AAP, CNS, and SCCM. Neurology. 2023;101:1112. [PMID: 37821233]

HEAD INJURY

Trauma is the most common cause of death in young people, and head injury accounts for almost half of these trauma-related deaths. Head injury severity ranges from **concussion** to **severe traumatic brain injury (TBI).** Concussion is broadly defined as an alteration in mental status caused by trauma with or without loss of consciousness. The term concussion is often used synonymously with mild TBI. Grades of TBI are traditionally defined by the Glasgow Coma Scale (GCS) measured 30 minutes after injury (Table 27–8).

Head trauma may cause cerebral injury through a variety of mechanisms (Table 27–9). Central to management is determination of which patients need head imaging and observation. Of particular concern is identification of patients with epidural and subdural hematoma, who may present with normal neurologic findings shortly after injury (**lucid interval**) but rapidly deteriorate thereafter, and in whom surgical intervention is lifesaving.

Clinical Findings

A. Symptoms and Signs

Common symptoms of concussion that develop acutely include headache, nausea, vomiting, confusion, disorientation, dizziness, and imbalance. A period of amnesia encompassing the traumatic event and a variable period of time leading up to the trauma is typical. Loss of consciousness may occur. Additional symptoms of photophobia, phonophobia, difficulty concentrating, irritability, and sleep and mood disturbances may develop over the following hours to days. Examination is usually normal, although orientation and attention, short-term memory, and reaction time may be impaired. Persistent or progressive decline in the level of consciousness after the initial injury, or focal neurologic findings, suggests the need for urgent imaging and neurosurgical consultation.

Table 27–8. Glasgow Coma Scale.[1]

Points	Eye Opening	Verbal Response	Motor Response
1	None	None	None
2	To pain	Vocal but not verbal	Extension
3	To voice	Verbal but not conversational	Flexion
4	Spontaneous	Conversational but disoriented	Withdraws from pain
5	—	Oriented	Localizes pain
6	—	—	Obeys commands

[1] GCS score indicating severity of traumatic brain injury: **mild**, 13–15; **moderate**, 9–12; **severe**, ≤ 8.

Reproduced, with permission, from Aminoff MJ et al. *Clinical Neurology*, 9th ed, McGraw-Hill Education, 2015; data from Teasdale G, Jennett B. Assessment of coma and impaired consciousness. A practical scale. *Lancet*. 1974;304:81–84.

Patients should also be examined for signs of scalp lacerations, facial and skull fracture, and neck injury. The clinical signs of basilar skull fracture include bruising about the orbit (**raccoon sign**), blood in the external auditory meatus (**Battle sign**), and leakage of CSF (which can be identified by its glucose or β-2-transferrin content) from the ear or nose. Cranial nerve palsies (involving especially the first, second, third, fourth, fifth, seventh, and eighth nerves in any combination) may also occur. The head and neck should be immobilized until imaging can be performed.

B. Imaging and Other Investigations

Recommendations are that head CT be performed in patients with concussion and any of the following: GCS score < 15, focal neurologic deficit, seizure, coagulopathy, aged 60 or older, skull fracture, persistent headache or vomiting, retrograde amnesia exceeding 30 minutes, intoxication, soft tissue injury of the head or neck, or a dangerous mechanism of injury such as pedestrian struck by motor vehicle. Otherwise, patients can be sent home as long as a responsible caregiver can check the patient at *hourly intervals* for the next 24 hours. Patients requiring imaging should be admitted unless the head CT is normal, the GCS score is 15, there have been no seizures, there is no predisposition to bleeding, and they can be monitored by a caregiver at home.

Because injury to the spine may have accompanied head trauma, cervical spine radiographs (three views) or CT should always be obtained in comatose patients and in patients with severe neck pain or a deficit possibly related to cord compression.

Treatment

Head injury can often be prevented by helmets, seatbelts, and other protective equipment.

After intracranial bleeding has been excluded clinically or by head CT, treatment of mild TBI is aimed at promoting resolution of postconcussive symptoms and preventing recurrent injury, which increases the risk of chronic neurobehavioral impairment and delays recovery. Rarely, a recurrent concussion while a patient is still symptomatic from a first concussion may lead to fatal cerebral edema (**second impact syndrome**). These observations form the basis of the recommendation that patients at risk for recurrent concussion (eg, athletes) be held out of the risky activity until their concussive symptoms have fully resolved.

In patients hospitalized with moderate or severe TBI, management often requires a multidisciplinary approach

Table 27–9. Acute cerebral sequelae of head injury (listed in alphabetical order).

Sequelae	Clinical Features	Pathology
Cerebral contusion or laceration	Loss of consciousness longer than with concussion. Focal neurologic deficits are often present. May lead to death or severe residual neurologic deficit.	Bruising on side of impact (coup injury) or contralaterally (contrecoup injury). Vasogenic edema, multiple petechial hemorrhages, and mass effect. May have subarachnoid bleeding. Herniation may occur in severe cases. Cerebral laceration specifically involves tearing of the cerebral tissue and pia-arachnoid overlying a contusion.
Cerebral hemorrhage	Generally develops immediately after injury. Clinically resembles hypertensive hemorrhage. Surgery to relieve mass effect is sometimes necessary.	Hematoma, visible on CT scan.
Concussion	A transient, trauma-induced alteration in mental status that may or may not involve loss of consciousness. Symptoms and signs include headache, nausea, disorientation, irritability, amnesia, clumsiness, visual disturbances, and focal neurologic deficit.	Unknown; likely mild diffuse axonal injury and excitotoxic neuronal injury. Cerebral contusion may occur.
Diffuse axonal injury	Persistent loss of consciousness, coma, or persistent vegetative state resulting from severe rotational shearing forces or deceleration.	Imaging may be normal or may show tiny, scattered white matter hemorrhages. Histology reveals torn axons.
Epidural hemorrhage	Headache, confusion, somnolence, seizures, and focal deficits occur several hours after injury (lucid interval) and lead to coma, respiratory depression, and death unless treated by surgical evacuation.	Tear in meningeal artery, vein, or dural sinus, leading to hematoma visible on CT scan.
Subdural hemorrhage	Similar to epidural hemorrhage, but interval before onset of symptoms is longer. Neurosurgical consultation for consideration of evacuation.	Hematoma from tear in veins from cortex to superior sagittal sinus or from cerebral laceration, visible on CT scan.

due to multiple concomitant injuries. Elevated intracranial pressure can result from diffuse axonal injury or a hematoma requiring surgical evacuation, or from a variety of medical causes. Decompressive craniectomy may reduce otherwise refractory intracranial hypertension but does not improve neurologic outcome. Hypothermia is associated with worsened functional outcomes.

Because bridging veins between the brain and venous sinuses become more vulnerable to shear injury as the brain atrophies, a **subdural hematoma** may develop days or weeks following head injury in older patients or even occur spontaneously. Clinical presentation can be subtle, often with mental changes such as slowness, drowsiness, headache, confusion, or memory disturbance. Focal neurologic deficits such as hemiparesis or hemisensory disturbance are less common. Surgical intervention is indicated if the hematoma is 10 mm or more in thickness or there is a midline shift of 5 mm or more; if there is a decline in GCS score of 2 or more from injury to hospital admission; or if one or both pupils are fixed and dilated.

Scalp lacerations and depressed skull fractures should be treated surgically as appropriate. Simple skull fractures require no specific treatment. If there is any leakage of CSF, conservative treatment, with elevation of the head, restriction of fluids, and administration of acetazolamide (250 mg orally four times daily), is often helpful; if the leak continues for more than a few days, lumbar subarachnoid drainage may be necessary. Antibiotics are given if infection occurs, based on culture and sensitivity studies; vaccination against pneumococcus is recommended (see Table 35–7). Only occasional patients require intracranial repair of the dural defect because of persistence of the leak or recurrent meningitis.

Prognosis

Moderate and severe TBI may result in permanent cognitive and motor impairment depending on the severity and location of the initial injury. Initial GCS and head CT findings have prognostic value. Among patients with a GCS score of 8 or less at presentation, mortality approaches 30% and only one-third of survivors regain functional independence. Cognitive impairment tends to affect frontal and temporal lobe function, causing deficits in attention, memory, judgment, and executive function. Behavioral dysregulation, depression, and disinhibition can impair social functioning. Anosmia, presumably due to shearing of fibers from the nasal epithelium, is common.

Epilepsy can develop after TBI, especially with more severe injury. Among patients with severe TBI (typically loss of consciousness for at least 12–24 hours, intracranial hematoma, depressed skull fracture, or cerebral contusion), phenytoin or levetiracetam is typically given for 7 days to reduce the incidence of early posttraumatic seizures; this is done exclusively to minimize acute complications resulting from such seizures and does not prevent the development of posttraumatic epilepsy.

Among patients with mild TBI, symptoms of concussion resolve in most patients by 1 month and in the vast majority by 3 months. **Prolonged postconcussive symptoms** are uncommon, persisting at 1 year in 10–15% of patients. Risk factors for prolonged postconcussive symptoms include active litigation regarding the injury; repeated concussions; and GCS score of 13 or less at presentation. Headaches often have migrainous features and may respond to tricyclic antidepressants or β-blockers (see Table 27–1). Opioids should be avoided to minimize the risk of medication overuse headache. Mood symptoms may respond to antidepressants, anxiolytics, and cognitive behavioral therapy.

There appears to be an association between head trauma and the later development of neurodegenerative disease, such as Alzheimer disease, Parkinson disease, or amyotrophic lateral sclerosis (ALS). Normal pressure hydrocephalus may also occur. Repetitive, mild head injury, such as that which occurs in athletes or military personnel, can lead to **chronic traumatic encephalopathy**, a distinct pathologic entity associated with mood and cognitive changes and characterized by the abnormal aggregation of tau or other proteins either focally or globally in the cerebral cortex. Whether chronic traumatic encephalopathy is a static response to recurrent head injury or a progressive neurodegenerative disease is not known, but the severity of neuropathology appears to correlate to lifetime exposure to repetitive head injury.

When to Refer

- Patients with focal neurologic deficits, altered consciousness, or skull fracture.
- Patients with late complications of head injury, eg, posttraumatic seizure disorder or normal pressure hydrocephalus.

When to Admit

- Patients with concussion and GCS score < 15, predisposition to bleeding, seizure, or no responsible caregiver at home.
- Patients with abnormal head CT.

MULTIPLE SCLEROSIS

ESSENTIALS OF DIAGNOSIS

- ► Episodic neurologic symptoms.
- ► Patient usually < 55 years of age at onset.
- ► Single pathologic lesion cannot explain clinical findings.
- ► Multiple foci best visualized by MRI.

General Considerations

This common neurologic disorder, which probably has an autoimmune basis, has its greatest incidence in young adults. Epidemiologic studies indicate that multiple sclerosis is much more common in persons who live in temperate zones. Environmental factors hypothesized to increase risk for multiple sclerosis include reduced sunlight exposure, low vitamin D level, and infection with Epstein-Barr virus. A genetic susceptibility to the disease is present. Pathologically, focal—often perivenular—areas of demyelination with reactive gliosis (fibrous proliferation of glial cells in injured areas of the CNS) are found scattered in the white matter of the brain and spinal cord and in the optic nerves. Axonal damage also occurs.

Clinical Findings

A. Symptoms and Signs

The common initial presentation is weakness, numbness, tingling, or unsteadiness in a limb; spastic paraparesis; retrobulbar optic neuritis; diplopia; dysequilibrium; or a sphincter disturbance such as urinary urgency or hesitancy. Symptoms may disappear after a few days or weeks, although examination often reveals a residual deficit.

Several forms of the disease are recognized. In most patients, there is an interval of months or years after the initial episode before new symptoms develop or the original ones recur (**relapsing-remitting disease**). Eventually, however, relapses and usually incomplete remissions lead to increasing disability, with weakness, spasticity, and ataxia of the limbs, impaired vision, and urinary incontinence. The findings on examination at this stage commonly include optic atrophy; nystagmus; dysarthria; and pyramidal, sensory, or cerebellar deficits in some or all of the limbs. In some of these patients, the clinical course changes so that a steady deterioration occurs, unrelated to acute relapses (**secondary progressive disease**). Less commonly, symptoms are steadily progressive from their onset, and disability develops at a relatively early stage (**primary progressive disease**). The diagnosis cannot be made with confidence unless the total clinical picture indicates involvement of *different parts of the CNS at different times.* Fatigue is common in all forms of the disease.

A number of factors (eg, infection) may precipitate or trigger exacerbations. Relapses are reduced in pregnancy, are more likely during the 2 or 3 months following pregnancy, but are less likely in women who exclusively breastfeed their infants.

B. Imaging

MRI of the brain and cervical cord has a major role in excluding other causes of neurologic dysfunction and in demonstrating the presence of multiple lesions. In T1-weighted images, hypointense "black holes" probably represent areas of permanent axonal damage. Gadolinium-enhanced T1-weighted images may highlight areas of active inflammation with breakdown of the blood-brain barrier, which helps identify newer lesions. T2-weighted images provide information about disease burden or total number of lesions, which typically appear as areas of high signal intensity. CT scans are less helpful than MRI.

In patients with myelopathy alone and no clinical or laboratory evidence of more widespread disease, MRI or myelography is necessary to exclude a congenital or acquired surgically treatable lesion. In patients with mixed pyramidal and cerebellar deficits in the limbs, the foramen magnum region must be visualized to exclude the possibility of Arnold-Chiari malformation, in which parts of the cerebellum and lower brainstem are displaced into the cervical canal.

C. Laboratory and Other Studies

A definitive diagnosis can never be based solely on the laboratory findings. If there is clinical evidence of only a single lesion in the CNS, multiple sclerosis cannot properly be diagnosed unless it can be shown that other regions are affected subclinically. Visual, brainstem auditory, and somatosensory evoked potentials are helpful in this regard, but other disorders may also be characterized by multifocal electrophysiologic abnormalities reflecting disease of central white matter. Certain infections (eg, HIV, Lyme disease, syphilis), connective tissue diseases (eg, SLE, Sjögren syndrome), sarcoidosis, metabolic disorders (eg, vitamin B_{12} deficiency), and lymphoma may therefore require exclusion.

There may be mild lymphocytosis or a slightly increased protein concentration in the CSF, especially soon after an acute relapse. Elevated IgG in CSF and discrete bands of IgG (oligoclonal bands) are present in many patients. The presence of such bands is not specific, however, since they have been found in a variety of inflammatory neurologic disorders and occasionally in patients with vascular or neoplastic disorders of the nervous system.

Vitamin D deficiency may be associated with an increased risk of developing multiple sclerosis; randomized trials have *not* shown vitamin D supplementation reduces attack rate or progression in relapsing-remitting disease.

D. Diagnosis

Multiple sclerosis should not be diagnosed unless there is evidence that two or more different regions of the central white matter (*dissemination in space*) have been affected at different times (*dissemination in time*); the most widely used diagnostic algorithm is the **2017 revision to the McDonald criteria**. The diagnosis may be made in a patient with two or more typical attacks and objective evidence on clinical examination of two lesions (eg, optic disk atrophy and pyramidal weakness), or objective evidence of one lesion with clear-cut historical evidence the other attack was typical of multiple sclerosis and in a distinct neuroanatomic location, and when no alternative explanation for the patient's presentation has been found. To fulfill the criterion of dissemination in space in a patient with two clinical attacks but objective clinical evidence of only one lesion, MRI should demonstrate at least one lesion in at least two of four typical sites (periventricular, cortical or juxtacortical, infratentorial, or spinal); alternatively, an additional attack localized to a different site suffices. The criterion of dissemination in time in a patient with only one attack can be fulfilled by the simultaneous presence of gadolinium-enhancing and nonenhancing lesions at any time (including at initial examination); the presence of oligoclonal bands unique to the CSF; a new lesion on follow-up MRI; or a second attack. Lesions in the optic nerve on MRI in patients with optic neuritis cannot be used to fulfill the McDonald criteria for dissemination in space or time. Primary progressive disease requires at least a year of progression, plus two of three of the following: at least one typical brain lesion, at least two spinal lesions, or oligoclonal banding in the CSF.

In patients with a single clinical event who do not satisfy criteria for multiple sclerosis, a diagnosis of a **clinically isolated syndrome (CIS)** is made. Such patients are at risk for developing multiple sclerosis and are sometimes offered β-interferon or glatiramer acetate therapy, which may delay progression to clinically definite disease. Follow-up MRI should be considered 6–12 months later to assess for the presence of any new lesion. Patients without a typical clinical attack may be diagnosed with **radiologically isolated syndrome** if a brain MRI incidentally demonstrates findings consistent with multiple sclerosis. Teriflunomide and dimethyl fumarate were shown to delay time to first clinical attack compared to placebo in such patients.

Treatment

At least partial recovery from acute exacerbations can reasonably be expected, but further relapses may occur without warning. Some disability is likely to result eventually, but about half of all patients are without significant disability even 10 years after onset of symptoms. Treatments chiefly are aimed at preventing relapses, thereby reducing disability.

Recovery from acute relapses may be hastened by treatment with corticosteroids, but the extent of recovery is unchanged. Intravenous therapy is often given first—typically methylprednisolone 1 g daily for 3 days—followed by oral prednisone at 60–80 mg daily for 1 week with a taper over the ensuing 2–3 weeks, but randomized trials show similar efficacy whether the initial high dose is given orally or intravenously. Long-term treatment with corticosteroids provides no benefit and does not prevent further relapses. Transient exacerbation of symptoms relating to intercurrent infection or heat requires no added treatment.

In patients with relapsing disease, numerous medications have well-established efficacy at *reducing the frequency of attacks* (Table 27–10). The initial agent is chosen after considering medication tolerance and risks, patient preference, and disease severity. In general, the medications most effective at reducing relapses have stronger immunomodulatory effects and more serious, albeit rare, adverse effects. In a study conducted in Denmark and Sweden, early treatment with highly effective medications (rituximab, natalizumab, or fingolimod) reduced disability progression at 24 weeks compared with more moderately effective medications (teriflunomide, glatiramer acetate, or interferon β-1a). This raises the possibility that early more intensive treatment will lead to a more favorable prognosis. Many of these agents, especially those that deplete or interfere with B-cells, render vaccination ineffective. Prescription of these agents should be managed by a specialist.

Table 27–10. Treatment of multiple sclerosis (in alphabetical order within categories).[1]

Medication	Dose
Acute Episode, Including Relapse[2]	
Dexamethasone	160 mg orally daily for 3–5 days
Methylprednisolone	1 g intravenously or orally daily for 3–5 days
Plasmapheresis	
Disease-Modifying Therapy (FDA-Approved)	
Alemtuzumab (Lemtrada)[3,4]	12 mg intravenously daily for 5 days; 3-day course given 1 year later
Cladribine (Mavenclad)[3,5,6]	1.75 mg/kg orally divided between weeks 1 and 5, repeated once in 1 year
Dimethyl fumarate (Tecfidera)[3,5]	240 mg orally twice daily
Fingolimod (Gilenya)[3,4,5]	0.5 mg orally daily
Glatiramer acetate (Copaxone, Mylan, Glatopa)[5]	20 mg subcutaneously daily or 40 mg subcutaneously three times weekly
Interferon β-1a (Rebif)[5]	44 mcg subcutaneously three times per week
Interferon β-1a (Avonex)[5]	30 mcg intramuscularly once per week
Interferon β-1b (Betaseron, Extavia)[5]	0.25 mg subcutaneously on alternate days
Mitoxantrone[3]	12 mg/m^2 intravenously every 3 months; maximum lifetime dose, 140 mg/m^2
Natalizumab (Tysabri)[3,4]	300 mg intravenously monthly
Ocrelizumab (Ocrevus)[3,4,5,6,7]	300 mg intravenously on day 1 and day 15, followed by 600 mg every 6 months
Ofatumumab (Kesimpta)[3,4,5,6]	20 mg subcutaneously weeks 0, 1, 2, 4, and monthly thereafter
Ozanimod (Zeposia)[3,4,5,6]	0.23 mg orally daily on days 1–4, 0.46 mg daily on days 5–7, and 0.92 mg daily thereafter
Pegylated interferon β-1a (Plegridy)[5]	125 mg subcutaneously once every 2 weeks
Ponesimod (Ponvory)[3,4,5,6]	Titrate from 2 mg orally daily to 5 mg in 1-mg increments every 2 days, then by 1 mg daily to 10 mg by day 12, and then to 20 mg daily on day 15
Siponimod (Mayzent)[3,4,5,6]	0.25 mg orally daily, titrated over 5 or 6 days to 1 or 2 mg orally daily, depending on CYP2C9 genotype
Teriflunomide (Aubagio)[5]	14 mg or 7 mg orally daily
Ublituximab-xiiy (Briumvi)[3,4,5,6]	150 mg intravenously on day 1 and 450 mg on day 15, followed by 450 mg every 24 weeks (starting from the first 150 mg dose)

[1] Several of these agents require special monitoring or pretreatment; some should be avoided during pregnancy. Readers should refer to the manufacturer's guidelines.
[2] For corticosteroid-refractory relapses, plasmapheresis may be used.
[3] Relapse prevention for disease activity despite use of first-line treatment.
[4] High disease activity (typically with multiple gadolinium-enhancing lesions on MRI).
[5] Relapse prevention, first-line treatment.
[6] Active secondary progressive disease.
[7] Primary progressive disease.

Ocrelizumab is the only medication effective in slowing disability progression in primary progressive multiple sclerosis and is approved for this indication by the FDA. For patients with active secondary progressive disease, cladribine, ocrelizumab, ofatumumab, ozanimod, ponesimod, and siponimod can be used. Plasmapheresis is sometimes helpful in patients with severe relapses unresponsive to corticosteroids.

Symptomatic therapy for spasticity, neurogenic bladder, or fatigue may be required. Fatigue is especially common in multiple sclerosis, and modafinil (200 mg orally every morning) is an effective and FDA-approved therapy for this indication. Dalfampridine (an extended-release formulation of 4-aminopyridine administered as 10 mg orally twice daily) is efficacious at improving timed gait in multiple sclerosis. Depression and even suicidality can occur in multiple sclerosis and may worsen with interferon β-1a therapy; screening and conventional treatment of such symptoms are appropriate.

When to Refer

All patients, but especially those with progressive disease despite standard therapy, should be referred.

When to Admit

- Patients requiring plasma exchange for severe relapses unresponsive to corticosteroids.
- During severe relapses.
- Patients unable to manage at home.

Oh J. Diagnosis of multiple sclerosis. Continuum (Minneap Minn). 2022;28:1006. [PMID: 35938655]

NEUROMYELITIS OPTICA SPECTRUM DISORDER

This disorder is characterized by optic neuritis and acute myelitis with MRI changes that extend over at least three segments of the spinal cord. An isolated myelitis or optic neuritis may also occur. Previously known as **Devic disease** and once regarded as a variant of multiple sclerosis, neuromyelitis optica is associated with a specific antibody marker (NMO-IgG) targeting the water channel aquaporin-4 in 80% of cases, and with antibodies to myelin oligodendrocyte glycoprotein (MOG-IgG) in approximately 33% of NMO-IgG seronegative patients. MRI of the brain typically does not show widespread white matter involvement, but such changes do not exclude the diagnosis. Treatment is by long-term immunosuppression. Four medications are approved by the FDA for treatment of neuromyelitis optica based on placebo-controlled trials demonstrating a reduced annual relapse rate or time to first relapse. Eculizumab and ravulizumab are complement inhibitors, inebilizumab is a humanized anti-CD19 antibody that depletes B-cells, and satralizumab is an interleukin-6 receptor antagonist. Use of eculizumab or ravulizumab requires prior immunization against meningococcus. Off-label therapy is with rituximab (two 1-g intravenous infusions spaced by 2 weeks, or four weekly infusions of 375 mg/m^2; re-dosing may occur every 6 months or when CD19/20-positive or CD27-positive lymphocytes become detectable), mycophenolate mofetil (500–1500 mg orally twice daily, titrated until the absolute lymphocyte count falls below 1500/mcL [1.5×10^9/L]), or azathioprine (2.5–3 mg/kg orally). Acute relapses are treated with corticosteroids at doses similar to those outlined for multiple sclerosis and with plasma exchange for severe relapses unresponsive to corticosteroids.

Sechi E. NMOSD and MOGAD. Continuum (Minneap Minn). 2024;30:1052. [PMID: 39088288]

VITAMIN E DEFICIENCY

Vitamin E deficiency may produce a disorder somewhat similar to Friedreich ataxia. There is spinocerebellar degeneration involving the posterior columns of the spinal cord and leading to limb ataxia, sensory loss, absent tendon reflexes, slurring of speech, and, in some cases, pigmentary retinal degeneration. (See Chapter 34.)

SPASTICITY

The term “spasticity” is commonly used for an upper motor neuron deficit, but it properly refers to a velocity-dependent increase in resistance to passive movement that affects different muscles to a different extent, is not uniform in degree throughout the range of a particular movement, and is commonly associated with other features of pyramidal deficit. It is often a major complication of stroke, cerebral or spinal injury, static perinatal encephalopathy, and multiple sclerosis. Spasticity may be exacerbated by pressure injuries, urinary or other infections, and nociceptive stimuli.

Physical therapy with appropriate stretching programs is important during rehabilitation after the development of an upper motor neuron lesion and in subsequent management of the patient. The aim is to prevent joint and muscle contractures and perhaps to modulate spasticity.

Medication management is important also, but treatment may increase functional disability when increased extensor tone is providing additional support for patients with weak legs. Pharmacologic treatment with baclofen (5–10 mg twice daily orally titrated to 80 mg daily), tizanidine (2–8 mg three time daily orally), diazepam (2–10 mg three times daily orally), or dantrolene (25 mg once daily orally, titrated every 3 days as tolerated to a maximum of 100 mg four times daily) is often helpful. Dantrolene is best avoided in patients with poor respiratory function or severe myocardial disease. Cannabinoids (combination of tetrahydrocannabinol and cannabidiol) are also effective in reducing spasticity, but are associated with side effects, including dizziness, drowsiness, and fatigue. Intramuscular injection of botulinum toxin is used to relax targeted muscles.

In patients with severe spasticity that is unresponsive to other therapies and is associated with marked disability, intrathecal injection of phenol or alcohol may be helpful. Surgical options include implantation of an intrathecal baclofen pump, rhizotomy, or neurectomy. Severe contractures may be treated by surgical tendon release.

Marsden J et al. Treatment of spasticity. Handb Clin Neurol. 2023;196:497. [PMID: 37620087]

MYELOPATHIES IN AIDS

A variety of myelopathies may occur in patients with AIDS. These are discussed in Chapter 36.

MYELOPATHY OF HUMAN T-CELL LEUKEMIA VIRUS INFECTION

Human T-cell leukemia virus (HTLV-1), a human retrovirus, is transmitted by breastfeeding, sexual contact, blood transfusion, and contaminated needles. Most patients are asymptomatic, but after a variable latent period (which may be as long as several years), a myelopathy develops in some instances. The MRI, electrophysiologic, and CSF findings are similar to those of multiple sclerosis, but HTLV-1 antibodies are present in serum and spinal fluid. There is no specific treatment, but intravenous or oral corticosteroids may help in the initial inflammatory phase of the disease. Prophylactic measures are important. Needles or syringes should not be shared; infected patients should not breastfeed their infants or donate blood, semen, or other tissue. Infected patients should use condoms to prevent sexual transmission.

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

Subacute combined degeneration of the spinal cord is due to **vitamin B_{12} deficiency**, such as occurs in pernicious anemia. It is characterized by myelopathy with spasticity, weakness, proprioceptive loss, and numbness due to degeneration of the corticospinal tracts and posterior columns. Polyneuropathy, mental changes, or optic neuropathy also develops in some patients. Megaloblastic anemia may also occur, but this does *not* parallel the neurologic disorder, and the former may be obscured if folic acid supplements have been taken. Treatment is with vitamin B_{12}. For pernicious anemia, a convenient therapeutic regimen is 1000 mcg cyanocobalamin intramuscularly daily for 1 week, then weekly for 1 month, and then monthly for the remainder of the patient's life. Oral cyanocobalamin replacement is not advised for pernicious anemia when neurologic symptoms are present. A similar syndrome is caused by recreational abuse of inhaled nitrous oxide due to its interference with vitamin B_{12} metabolism. Copper deficiency, caused by malabsorption or excess zinc ingestion, may also be responsible.

Hassing LT et al. Nitrous-oxide-induced polyneuropathy and subacute combined degeneration of the spine: clinical and diagnostic characteristics in 70 patients, with focus on electrodiagnostic studies. Eur J Neurol. 2024;31:e16076. [PMID: 37754673]

SPINAL TRAUMA

ESSENTIALS OF DIAGNOSIS

- History of preceding trauma.
- Development of acute neurologic deficit.
- Signs of myelopathy on examination.

General Considerations

While spinal cord damage may result from whiplash injury, severe injury usually relates to fracture-dislocation causing compression or angular deformity of the cord either cervically or in the lower thoracic and upper lumbar regions. Extreme hypotension following injury may also lead to cord infarction.

Clinical Findings

Total cord transection results in immediate flaccid paralysis and loss of sensation below the level of the lesion. Reflex activity is lost for a variable period, and there is urinary and fecal retention. As reflex function returns over the following days and weeks, spastic paraplegia or quadriplegia develops, with hyperreflexia and extensor plantar responses, but a flaccid atrophic (lower motor neuron) paralysis may be found depending on the segments of the cord that are affected. The bladder and bowels also regain some reflex function, permitting urine and feces to be expelled at intervals. As spasticity increases, flexor or extensor spasms (or both) of the legs become troublesome, especially if the patient develops bed sores or a UTI. Paraplegia with the legs in flexion or extension may eventually result.

With lesser degrees of injury, patients may be left with mild limb weakness, distal sensory disturbance, or both. Sphincter function may also be impaired, urinary urgency and urge incontinence being especially common. More particularly, a unilateral cord lesion leads to an ipsilateral motor disturbance with accompanying impairment of proprioception and contralateral loss of pain and temperature appreciation below the lesion (**Brown-Séquard syndrome**). A central cord syndrome may lead to a lower motor neuron deficit at the level of the lesion and loss of pain and temperature appreciation below it, with sparing of posterior column functions. With more extensive involvement, posterior column sensation may also be impaired and pyramidal weakness develops. A radicular deficit may occur at the level of the injury—or, if the cauda equina is involved, there may be evidence of disturbed function in several lumbosacral roots.

Treatment

Treatment of the injury consists of immobilization and—if there is cord compression—early decompressive laminectomy and fusion (within 24 hours). Early treatment with high doses of corticosteroids (eg, methylprednisolone, 30 mg/kg by intravenous bolus, followed by 5.4 mg/kg/hour for 23 hours) may improve neurologic recovery if commenced within 8 hours after injury, although the evidence is limited and some neurosurgical guidelines do not recommend their use. Anatomic realignment of the spinal cord by traction and other orthopedic procedures is important. Subsequent care of the residual neurologic deficit—paraplegia or quadriplegia—requires treatment of spasticity and care of the skin, bladder, and bowels.

When to Refer

All patients with focal neurologic deficits should be referred.

When to Admit

- Patients with neurologic deficits.
- Patients with spinal cord injury, compression, or acute epidural or subdural hematoma.
- Patients with vertebral fracture-dislocation likely to compress the cord.

Izzy S. Traumatic spinal cord injury. Continuum (Minneap Minn). 2024;30:53. [PMID: 38330472]

SYRINGOMYELIA

Destruction or degeneration of gray and white matter adjacent to the central canal of the cervical spinal cord leads to cavitation and accumulation of fluid within the spinal cord. The precise pathogenesis is unclear, but many cases are associated with **Arnold-Chiari malformation**, in which there is displacement of the cerebellar tonsils, medulla, and fourth ventricle into the spinal canal, sometimes with accompanying meningomyelocele. In such circumstances, the cord cavity connects with and may merely represent a dilated central canal. In other cases, the cause of cavitation is less clear. There is a characteristic clinical picture, with segmental atrophy, areflexia, and loss of pain and temperature appreciation in a "cape" distribution, owing to the destruction of fibers crossing in front of the central canal in the mid-cervical spinal cord. Thoracic kyphoscoliosis is usually present. With progression, involvement of the long motor and sensory tracts occurs as well, so that a pyramidal and sensory deficit develops in the legs. Upward extension of the cavitation (**syringobulbia**) leads to dysfunction of the lower brainstem and thus to bulbar palsy, nystagmus, and sensory impairment over one or both sides of the face.

Syringomyelia, ie, cord cavitation, may also occur in association with an intramedullary tumor or following severe cord injury, and the cavity then does not communicate with the central canal.

In patients with Arnold-Chiari malformation, CT scans reveal a small posterior fossa and enlargement of the foramen magnum, along with other associated skeletal abnormalities at the base of the skull and upper cervical spine. MRI reveals the syrinx as well as the characteristic findings of the Arnold-Chiari malformation, including the caudal displacement of the fourth ventricle and herniation of the cerebellar tonsils through the foramen magnum. Focal cord enlargement is found at myelography or by MRI in patients with cavitation related to past injury or intramedullary neoplasms.

Treatment of Arnold-Chiari malformation with associated syringomyelia is by suboccipital craniectomy and upper cervical laminectomy, with the aim of decompressing the malformation at the foramen magnum. The cord cavity should be drained and, if necessary, an outlet for the fourth ventricle can be made. In cavitation associated with intramedullary tumor, treatment is surgical, but radiation therapy may be necessary if complete removal is not possible. Posttraumatic syringomyelia is also treated surgically if it leads to increasing neurologic deficits or to intolerable pain.

Yang M et al. Posterior fossa decompression and duraplasty with and without tonsillar resection for the treatment of adult Chiari malformation type I and syringomyelia. Medicine (Baltimore). 2022;101:e31394. [PMID: 36550873]

DEGENERATIVE MOTOR NEURON DISEASES

ESSENTIALS OF DIAGNOSIS

- Weakness.
- No sensory loss or sphincter disturbance.
- Progressive course.
- No identifiable underlying cause other than genetic basis in familial cases.

General Considerations

This group of degenerative disorders is characterized clinically by weakness and variable wasting of affected muscles, without accompanying sensory changes.

Motor neuron disease in adults generally commences between 30 and 60 years of age. There is degeneration of the anterior horn cells in the spinal cord, the motor nuclei of the lower cranial nerves, and the corticospinal and corticobulbar pathways. The disorder is usually sporadic, but familial cases may occur and several genetic mutations or loci have been identified. Cigarette smoking may be one risk factor.

Classification

Five varieties have been distinguished on clinical grounds.

A. Progressive Bulbar Palsy

Bulbar involvement predominates owing to disease processes affecting primarily the motor nuclei of the cranial nerves.

B. Pseudobulbar Palsy

Bulbar involvement predominates in this variety also, but it is due to bilateral corticobulbar disease and thus reflects upper motor neuron dysfunction. There may be a "**pseudobulbar affect**," with uncontrollable episodes of laughing or crying to stimuli that would not normally have elicited such marked reactions.

C. Progressive Spinal Muscular Atrophy

This is characterized primarily by a lower motor neuron deficit in the limbs due to degeneration of the anterior horn cells in the spinal cord.

D. Primary Lateral Sclerosis

There is a purely upper motor neuron deficit in the limbs.

E. Amyotrophic Lateral Sclerosis (ALS)

A mixed upper and lower motor neuron deficit is found in the limbs. This disorder is sometimes associated with cognitive decline (in a pattern consistent with frontotemporal dementia), a pseudobulbar affect, or parkinsonism. Up to 10% of ALS cases are familial and have been associated with mutations at several different genetic loci, including a hexanucleotide repeat on chromosome 9 that also associates with frontotemporal dementia. Some (15–20% of familial cases and 1–3% of sporadic cases) are due to mutations in the superoxide dismutase gene, for which a targeted gene therapy is available.

Differential Diagnosis

The spinal muscular atrophies (SMAs) are inherited syndromes caused most often by mutations of the survival motor neuron 1 (*SMN1*) gene on chromosome 5 that usually present during infancy or childhood. There are reports of juvenile SMA due to hexosaminidase deficiency. X-linked spinal and bulbar muscular atrophy (Kennedy syndrome) is associated with an expanded trinucleotide repeat sequence on the androgen receptor gene and carries a more benign prognosis than other forms of motor neuron disease. Hereditary spastic paraplegia is a diverse genetic syndrome that causes a slowly progressive myelopathy that can usually be distinguished from ALS by the presence of sensory signs and sphincter dysfunction.

Pure motor syndromes resembling motor neuron disease may also occur in association with monoclonal gammopathy or multifocal motor neuropathies with conduction block. A motor neuronopathy may also develop in Hodgkin disease and has a relatively benign prognosis. Infective anterior horn cell diseases (polio virus or West Nile virus infection) can generally be distinguished by the acute onset and monophasic course of the illness, as discussed in Chapter 37. Acute flaccid myelitis following infection with enterovirus may occur, especially in children, without sensory involvement and resembles poliomyelitis. There is no specific treatment. Compressive cervical radiculomyelopathy may cause lower motor neuron signs in the cervical myotomes with upper motor neuron signs in the legs. Benign fasciculations can be distinguished from ALS by a normal neurologic exam and electromyography.

Clinical Findings

A. Symptoms and Signs

Difficulty in swallowing, chewing, coughing, breathing, and talking (dysarthria) occurs with bulbar involvement. In progressive bulbar palsy, there is drooping of the palate; a depressed gag reflex; pooling of saliva in the pharynx; a weak cough; and a wasted, fasciculating tongue. In pseudobulbar palsy, the tongue is contracted and spastic and cannot be moved rapidly from side to side. Limb involvement is characterized by motor disturbances (weakness, stiffness, wasting, fasciculations) reflecting lower or upper motor neuron dysfunction; there are no objective changes on sensory examination, although there may be vague sensory complaints. The sphincters are generally spared. Cognitive changes or pseudobulbar affect may be present. The disorder is progressive, and ALS is usually fatal within 3–5 years; death usually results from pulmonary infections. Patients with bulbar involvement generally have the poorest prognosis, while patients with primary lateral sclerosis often have a longer survival despite profound quadriparesis and spasticity.

B. Laboratory and Other Studies

Electromyography may show signs of acute and chronic partial denervation with reinnervation. In patients with suspected ALS, the diagnosis should not be made with confidence unless such changes are found in at least three spinal regions (cervical, thoracic, lumbosacral) or two spinal regions and the bulbar musculature. Motor conduction velocity is usually normal but may be slightly reduced, and sensory conduction studies are also normal. Biopsy of a wasted muscle shows the histologic changes of denervation but is *not* necessary for diagnosis. The serum creatine kinase may be slightly elevated but never reaches the extremely high values seen in some of the muscular dystrophies. Testing for HIV, Lyme disease, and serum paraproteins can be considered. The CSF is normal. Molecular genetic testing is available when familial disorders are suspected. Reduced hexosaminidase activity is found in serum and leukocytes in patients with juvenile SMA due to hexosaminidase deficiency.

Treatment

Two medications are approved by the FDA for ALS. Riluzole, 50 mg orally twice daily, which reduces the presynaptic release of glutamate, increased short-term survival of patients with ALS in randomized trials. Edaravone, a free radical scavenger, slows disease progression in patients with mild disease. It is administered in monthly cycles as a 60 mg intravenous infusion on days 1–14 in the first month and days 1–10 in the subsequent months, or 105 mg orally once daily following the same dosing schedule. Ultra-high-dose methylcobalamin injections (50 mg intramuscularly twice weekly) slowed functional decline in a placebo-controlled randomized trial of patients within 1 year of symptom onset. Sodium phenylbutyrate/taurursodiol was approved by the FDA after promising results in a phase 2 trial, but the drug was withdrawn from the market in 2024 after a phase 3 trial failed to show any benefit.

Noninvasive ventilation at least 4 hours per day in patients with a maximal inspiratory pressure < 60 cm H_2O may prolong survival in ALS. Symptomatic and supportive measures to treat spasticity (discussed earlier in the section on spasticity), drooling, and dysphagia, prevent contractures, and preserve mobility are important. Drooling is treated with over-the-counter decongestants, anticholinergic medications (such as trihexyphenidyl, amitriptyline, or atropine), botulinum toxin injections into the salivary glands, or use of a portable suction machine. Physical and occupational therapy are helpful throughout the disease course. Combination dextromethorphan/quinidine (20 mg/10 mg, one tablet orally once or twice daily) may relieve symptoms of pseudobulbar affect. A semiliquid diet or gastrostomy tube feeding may be needed if dysphagia is severe; it is advisable to perform the procedure before the FVC falls below 50% of predicted to minimize the risk of complications. Tracheostomy is sometimes performed if respiratory muscles are severely affected; however, in the terminal stages of these disorders, realistic expectations and advance care planning should be discussed. Information on palliative care is provided in Chapter 5.

Gene therapy is approved by the FDA for patients with ALS caused by SOD1 mutations and SMA.

When to Refer

All patients (to exclude other treatable causes of symptoms and signs) should be referred.

When to Admit

Patients may need to be admitted for initiation or titration of noninvasive ventilation, or for periods of increased requirement of noninvasive ventilator support during pulmonary infections.

Oki R et al; Japan Early-Stage Trial of Ultrahigh-Dose Methylcobalamin for ALS (JETALS) Collaborators. Efficacy and safety of ultrahigh-dose methylcobalamin in early-stage amyotrophic lateral sclerosis: a randomized clinical trial. JAMA Neurol. 2022;79:575. [PMID: 35532908]

PERIPHERAL NEUROPATHIES

Peripheral neuropathies can be categorized based on the structure primarily affected. The predominant pathologic feature may be **axonal degeneration** (**axonal neuropathies**) or **demyelination** (**demyelinating neuropathies**). The distinction may be possible based on neurophysiologic findings. Motor and sensory conduction velocity can be measured in accessible segments of peripheral nerves. In axonal neuropathies, conduction velocity is normal or reduced only mildly and needle electromyography provides evidence of denervation in affected muscles. In demyelinating neuropathies, conduction may be slowed considerably in affected fibers, and in more severe cases, conduction is blocked completely, without accompanying electromyographic signs of denervation.

POLYNEUROPATHIES & MONONEURITIS MULTIPLEX

ESSENTIALS OF DIAGNOSIS

- Weakness, sensory disturbances, or both in the extremities.
- Pain is common.
- Depressed or absent tendon reflexes.
- May be family history of neuropathy.
- May be history of systemic illness or toxic exposure.

General Considerations

Diffuse **polyneuropathies** lead to a symmetric sensory, motor, or mixed deficit, often most marked distally. They include the hereditary, metabolic, and toxic disorders; idiopathic inflammatory polyneuropathy (**Guillain-Barré syndrome**); and the peripheral neuropathies that may occur as a nonmetastatic complication of malignant diseases. Involvement of motor fibers leads to flaccid weakness that is most marked distally; dysfunction of sensory fibers causes impaired sensory perception. Tendon reflexes are depressed or absent. Paresthesias, pain, and muscle tenderness may also occur. Multiple mononeuropathies (**mononeuropathy multiplex**) suggest a patchy multifocal disease process such as vasculopathy (eg, diabetes, arteritis), an infiltrative process (eg, leprosy, sarcoidosis), radiation damage, or an immunologic disorder (eg, brachial plexopathy).

Clinical Findings

The cause of polyneuropathy or mononeuritis multiplex is suggested by the history, mode of onset, and predominant clinical manifestations. Laboratory workup includes a CBC, serum protein electrophoresis with reflex to immunofixation or immunotyping, determination of plasma urea and electrolytes, liver biochemical tests, thyroid function tests, vitamin B_{12} level, tests for rheumatoid factor and antinuclear antibody, HBsAg determination, a serologic test for syphilis, fasting blood glucose level and hemoglobin A_{1c}, urinary heavy metal levels, CSF examination, and chest radiography. These tests should be ordered selectively, as guided by symptoms and signs. Measurement of nerve conduction velocity can confirm the peripheral nerve origin of symptoms and provides a means of following clinical changes, as well as indicate the likely disease process (ie, axonal or demyelinating neuropathy). Cutaneous nerve biopsy may help establish a precise diagnosis (eg, polyarteritis, amyloidosis). In about half of cases, no specific cause can be established; of these, slightly less than half are subsequently found to be familial.

Treatment

Treatment is of the underlying cause, when feasible, and is discussed below under the individual disorders. Physical therapy helps prevent contractures, and splints can maintain a weak extremity in a position of useful function. Anesthetic extremities must be protected from injury. To guard against burns, patients should check the temperature of water and hot surfaces with a portion of skin having normal sensation, measure water temperature with a thermometer, and use cold water for washing or lower the temperature setting of their hot-water heaters. Shoes should be examined frequently during the day for grit or foreign objects in order to prevent pressure lesions.

Patients with polyneuropathies or mononeuritis multiplex are subject to additional nerve injury at pressure points and should therefore avoid such behavior as leaning on elbows or sitting with crossed legs for lengthy periods.

Neuropathic, burning pain may respond to simple analgesics, such as aspirin or NSAIDs, and to gabapentin (300 mg orally three times daily, titrated up to a maximum of 1200 mg orally three times daily as necessary) or pregabalin (50–100 mg orally three times daily). Duloxetine (60 mg orally once or twice daily), venlafaxine (start 37.5 mg orally twice daily, and titrate up to 75 mg orally two to three times daily), or tricyclic antidepressants (eg, amitriptyline 10–150 mg orally at bedtime daily) may be helpful to treat pain associated with peripheral neuropathies. Medical cannabis may provide some relief, but long-term safety data are lacking. The use of a frame or cradle to reduce contact with bedclothes may be helpful. Many patients experience episodic stabbing pains, which may respond to gabapentin, pregabalin, carbamazepine (start 100 mg orally twice daily, and titrate up to 400 mg orally twice daily), or tricyclic antidepressants. Opioids may be necessary for severe hyperpathia or pain induced by minimal stimuli, but their use generally should be avoided. An implanted 10 kHz spinal cord stimulator combined with medical management reduced pain by an average of 80% in an RCT in patients with painful diabetic neuropathy, a result that was sustained for 24 months and was also associated with neurologic improvement in most patients. In a meta-analysis of RCT, scrambler therapy, which consists of transcutaneous electrical nerve stimulation at multiple simultaneous sites, appears effective for neuropathic pain. It has a favorable safety profile and is approved in the United States for treatment of chronic, acute, and post-operative pain.

Symptoms of autonomic dysfunction are occasionally troublesome. Treatment of postural hypotension is discussed earlier in this chapter. Erectile dysfunction can be treated with phosphodiesterase inhibitors; a flaccid neuropathic bladder may respond to parasympathomimetic medications such as bethanechol chloride, 10–50 mg three or four times daily.

Smith TJ et al. Cutaneous electroanalgesia for relief of chronic and neuropathic pain. N Engl J Med. 2023;389:158. [PMID: 37437145]

1. Inherited Neuropathies

A. Charcot-Marie-Tooth Disease (HMSN Type I, II)

There are several distinct varieties of Charcot-Marie-Tooth disease, usually with an autosomal dominant mode of inheritance, but occasional cases occur on a sporadic, recessive, or X-linked basis. Clinical presentation may be with foot deformities or gait disturbances in childhood or early adult life. Slow progression leads to the typical features of polyneuropathy, with distal weakness and wasting that begin in the legs, a variable amount of distal sensory loss, and depressed or absent tendon reflexes. Tremor is a conspicuous feature in some instances. **Hereditary motor and sensory neuropathy (HMSN) type I** is characterized by demyelination on electrodiagnostic studies and is usually caused by mutations in the peripheral myelin protein 22 or myelin protein zero gene. In **HMSN type II**, electrodiagnostic studies show axonal loss rather than demyelination; one-third of cases are due to mutations in the gene mitofusin 2.

A similar disorder may occur in patients with progressive distal SMAs, but there is no sensory loss; electrophysiologic investigation reveals that motor conduction velocity is normal or only slightly reduced, and nerve action potentials are normal.

B. Dejerine-Sottas Disease (HMSN Type III)

The disorder may occur on a sporadic, autosomal dominant or, less commonly, autosomal recessive basis. Onset in infancy or childhood leads to a progressive motor and sensory polyneuropathy with weakness, ataxia, sensory loss, and depressed or absent tendon reflexes.

C. Friedreich Ataxia

This disorder, the only known autosomal recessive trinucleotide repeat disease, is caused most commonly by expansion of a poly-GAA locus in the gene for frataxin on chromosome 9, leading to symptoms in childhood or early adult life. The gait becomes ataxic, the hands become clumsy, and other signs of cerebellar dysfunction develop accompanied by weakness of the legs and extensor plantar responses. Involvement of peripheral sensory fibers leads to sensory disturbances in the limbs and depressed tendon reflexes. There is bilateral pes cavus. Pathologically, there is a marked loss of cells in the posterior root ganglia and degeneration of peripheral sensory fibers. In the CNS, changes are conspicuous in the posterior and lateral columns of the cord. Electrophysiologically, conduction velocity in motor fibers is normal or only mildly reduced, but sensory action potentials are small or absent. Cardiac disease is the most common cause of death. Omaveloxolone led to functional improvement compared with placebo in a randomized trial and is approved for patients 16 years of age or older.

In the differential diagnosis for Friedreich ataxia are other spinocerebellar ataxias, a growing group of inherited disorders, each involving a different identified gene. These heterogeneous disorders, which frequently (but not exclusively) exhibit an autosomal dominant inheritance pattern and poly-CAG expansion of the affected gene, typically cause cerebellar ataxia and varying combinations of other symptoms (such as peripheral neuropathy, ophthalmoparesis, dysarthria, and pyramidal and extrapyramidal signs).

D. Refsum Disease (HMSN Type IV)

This autosomal recessive disorder is due to a disturbance in phytanic acid metabolism. Pigmentary retinal degeneration is accompanied by progressive sensorimotor polyneuropathy and cerebellar signs. Auditory dysfunction, cardiomyopathy, and cutaneous manifestations may also occur. Motor and sensory conduction velocities are reduced, often markedly, and there may be electromyographic evidence of denervation in affected muscles. Dietary restriction of phytanic acid and its precursors may be helpful therapeutically. Plasmapheresis to reduce stored phytanic acid may help at the initiation of treatment.

E. Porphyria

Peripheral nerve involvement may occur during acute attacks in both **variegate porphyria** and **acute intermittent porphyria.** Motor symptoms usually occur first, and weakness is often most marked proximally and in the upper limbs rather than the lower. Sensory symptoms and signs may be proximal or distal in distribution. Autonomic involvement is sometimes pronounced. The electrophysiologic findings are in keeping with the results of neuropathologic studies suggesting that the neuropathy is axonal in type (see Chapter 43).

F. Familial Amyloid Polyneuropathy

Sensory and autonomic symptoms are especially conspicuous, whereas distal wasting and weakness occur later. The polyneuropathy is axonal and likely results from amyloid deposition within the peripheral nerves due to mutations in the genes encoding transthyretin, apolipoprotein A1, or gelsolin. **Transthyretin amyloidosis** is the most common and is associated with cardiomyopathy, nephropathy, leptomeningeal involvement, and vitreous opacity. It is treatable with liver transplantation, the small interfering ribonucleic acids patisiran and vutrisiran, or the antisense oligonucleotides inotersen and eplontersen. Tafamidis helps transthyretin amyloid cardiomyopathy and may slow the progression of the neuropathy.

Coelho T et al. Eplontersen for hereditary transthyretin amyloidosis with polyneuropathy. JAMA. 2023;330:1448. [PMID: 37768671]

2. Neuropathies Associated with Systemic & Metabolic Disorders

A. Diabetes Mellitus

In this disorder, involvement of the peripheral nervous system may lead to symmetric sensory or mixed polyneuropathy, asymmetric motor radiculoneuropathy or plexopathy (diabetic amyotrophy), thoracoabdominal radiculopathy, autonomic neuropathy, or isolated lesions of individual nerves. These may occur singly or in any combination and are discussed in Chapter 32.

B. Uremia

Uremia may lead to a symmetric sensorimotor polyneuropathy that tends to affect the lower limbs more than the upper limbs and is more marked distally than proximally (see Chapter 25). The diagnosis can be confirmed electrophysiologically because motor and sensory conduction velocity is moderately reduced. The neuropathy improves both clinically and electrophysiologically with kidney transplantation and to a lesser extent with chronic dialysis.

C. Alcohol Use Disorder and Nutritional Deficiency

Many patients with alcohol use disorder have an axonal distal sensorimotor polyneuropathy that is frequently accompanied by painful cramps, muscle tenderness, and painful paresthesias and is often more marked in the legs than in the arms. Symptoms of autonomic dysfunction may also be conspicuous. Motor and sensory conduction velocity may be slightly reduced, even in subclinical cases, but gross slowing of conduction is uncommon. Treatment is similar to diabetic polyneuropathy but also includes abstinence from alcohol. A similar distal sensorimotor polyneuropathy is a well-recognized feature of **beriberi** (thiamine deficiency). In vitamin B_{12} deficiency, distal sensory polyneuropathy may develop but is usually overshadowed by CNS manifestations (eg, myelopathy, optic neuropathy, or intellectual changes).

D. Paraproteinemias

A symmetric sensorimotor polyneuropathy that is gradual in onset, progressive in course, and often accompanied by pain and dysesthesias in the limbs may occur in patients (especially men) with **plasma cell myeloma** (formerly multiple myeloma). The neuropathy is of the axonal type in classic lytic myeloma, but segmental demyelination (primary or secondary) and axonal loss may occur in sclerotic myeloma and lead to predominantly motor clinical manifestations. Both demyelinating and axonal neuropathies are also observed in patients with paraproteinemias without myeloma. A small fraction will develop myeloma if serially followed. The demyelinating neuropathy in these patients may be due to the monoclonal proteins reacting to a component of the nerve myelin. The neuropathy of classic plasma cell myeloma is poorly responsive to therapy. The polyneuropathy of **benign monoclonal gammopathy** may respond to immunosuppressant medications and plasmapheresis.

Polyneuropathy may also occur in association with monoclonal gammopathy of unknown significance, macroglobulinemia, and cryoglobulinemia and sometimes responds to plasmapheresis. Many patients with an IgM M-protein will have antibodies to myelin-associated glycoprotein (MAG); these patients may respond to treatment with rituximab. Entrapment neuropathy, such as carpal tunnel syndrome, is more common than polyneuropathy in patients with (nonhereditary) generalized amyloidosis.

Min YG et al. Neuropathy with anti-myelin-associated glycoprotein antibodies: update on diagnosis, pathophysiology and management. J Neurol Neurosurg Psychiatry. 2025;96:340. [PMID: 39658134]

3. Neuropathies Associated with Infectious & Inflammatory Diseases

A. Leprosy

Leprosy is an important cause of peripheral neuropathy in certain parts of the world. Sensory disturbances are mainly due to involvement of intracutaneous nerves. In tuberculoid leprosy, they develop at the same time and in the same distribution as the nerve; trunks lying beneath the lesion are also involved. In lepromatous leprosy, there is more extensive sensory loss, and this develops earlier and to a greater extent in the coolest regions of the body, such as the dorsal surfaces of the hands and feet, where the bacilli proliferate most actively. Motor deficits result from involvement of superficial nerves where their temperature is lowest, eg, the ulnar nerve in the region proximal to the olecranon groove, the median nerve as it emerges from beneath the forearm flexor muscle to run toward the carpal tunnel, the peroneal nerve at the head of the fibula, and the posterior tibial nerve in the lower part of the leg; patchy facial muscular weakness may also occur owing to involvement of the superficial branches of the seventh cranial nerve.

Motor disturbances in leprosy are suggestive of multiple mononeuropathy, whereas sensory changes resemble those of distal polyneuropathy. Examination, however, relates the distribution of sensory deficits to the temperature of the tissues; in the legs, for example, sparing frequently occurs between the toes and in the popliteal fossae, where the temperature is higher. Treatment is with antileprotic agents (see Chapter 38).

B. AIDS

A variety of neuropathies occur in patients with HIV (see Chapter 36).

C. Lyme Borreliosis

The neurologic manifestations of Lyme disease include meningitis, meningoencephalitis, polyradiculoneuropathy, mononeuropathy multiplex, and cranial neuropathy. Serologic tests establish the underlying disorder. Lyme disease and its treatment are discussed in depth in Chapter 39.

D. Sarcoidosis

Cranial nerve palsies (especially facial palsy), multiple mononeuropathy and, less commonly, symmetric polyneuropathy may all occur, the latter sometimes preferentially affecting either motor or sensory fibers. Treatment of sarcoidosis is discussed in Chapter 9.

E. Polyarteritis

Involvement of the vasa nervorum by the vasculitic process may result in infarction of the nerve. Clinically, one encounters an asymmetric sensorimotor polyneuropathy (mononeuritis multiplex) that pursues a waxing and waning course. Corticosteroids, cyclophosphamide, or rituximab helps, depending on the specific case (see Chapter 23).

F. Rheumatoid Arthritis

Compressive or entrapment neuropathies, ischemic neuropathies, mild distal sensory polyneuropathy, and severe progressive sensorimotor polyneuropathy can occur in rheumatoid arthritis (see Chapter 23).

Pacut P et al. Top 10 clinical pearls in vasculitic neuropathies. Semin Neurol. 2025;45:112. [PMID: 39348853]

4. Neuropathy Associated with Critical Illness

Patients in ICUs with sepsis and multiorgan failure sometimes develop polyneuropathies. This may be manifested initially by unexpected difficulty in weaning patients from a mechanical ventilator and in more advanced cases by wasting and weakness of the extremities and loss of tendon reflexes. Sensory abnormalities are relatively inconspicuous. The neuropathy is axonal in type. Its pathogenesis is obscure, and treatment is supportive. The prognosis is good provided that patients recover from the underlying critical illness. A myopathy may also occur.

Younger DS. Critical illness-associated weakness and related motor disorders. Handb Clin Neurol. 2023;195:707. [PMID: 37562893]

5. Toxic Neuropathies

Axonal polyneuropathy may follow exposure to industrial agents or pesticides such as acrylamide, organophosphorus compounds, hexacarbon solvents, methyl bromide, and carbon disulfide; metals such as arsenic, thallium, mercury, and lead; medications such as phenytoin, amiodarone, perhexiline, isoniazid, nitrofurantoin; and platinum or taxane chemotherapies, vincristine, and pyridoxine in high doses. Detailed occupational, environmental, and medical histories and recognition of clusters of cases are important in suggesting the diagnosis. Treatment is by preventing further exposure to the causal agent. Cryotherapy or covering the hands and feet with cold gloves and stockings before, during, and after neurotoxic chemotherapy infusion prevented neuropathy and improved quality of life in a meta-analysis of randomized trials. Isoniazid neuropathy is prevented by pyridoxine supplementation.

Diphtheritic neuropathy results from a neurotoxin released by the causative organism and is common in many areas. Palatal weakness may develop 2–4 weeks after infection of the throat, and infection of the skin may similarly be followed by focal weakness of neighboring muscles. Disturbances of accommodation may occur about 4–5 weeks after infection and distal sensorimotor demyelinating polyneuropathy after 1–3 months.

Tai HY et al. Efficacy of cryotherapy in the prevention of chemotherapy-induced peripheral neuropathy: a systematic review and meta-analysis. Support Care Cancer. 2024;32:482. [PMID: 38955817]

6. Neuropathies Associated with Malignant Diseases

A variety of neuropathies have been associated with nonmetastatic complications of malignancy. Some were discussed above in the section on paraproteinemia. A sensory neuronopathy may be observed in association with anti-Hu antibodies, especially in patients with small cell lung cancer.

Shelly S et al. Paraneoplastic neuropathies and peripheral nerve hyperexcitability disorders. Handb Clin Neurol. 2024;200:239. [PMID: 38494281]

7. Acute Idiopathic Polyneuropathy (Guillain-Barré Syndrome)

ESSENTIALS OF DIAGNOSIS

- Acute or subacute progressive polyradiculoneuropathy.
- Weakness is more severe than sensory disturbances.
- Acute dysautonomia may be life-threatening.

General Considerations

This acute or subacute polyradiculoneuropathy sometimes follows infective illness, inoculations, or surgical procedures. There is an association with preceding *Campylobacter jejuni* enteritis. Cohort studies suggest an association with adenovirus vector SARS-CoV-2 vaccines but not with mRNA vaccines. The disorder probably has an immunologic basis, but the precise mechanism is unclear.

Clinical Findings

A. Symptoms and Signs

The main complaint is of weakness that varies widely in severity in different patients and often has a proximal emphasis and symmetric distribution. It usually begins in the legs, spreading to a variable extent but frequently involving the arms and often one or both sides of the face. The muscles of respiration or deglutition may also be affected. Sensory symptoms are usually less conspicuous than motor ones, but distal paresthesias and dysesthesias are common, and neuropathic or radicular pain is present in many patients. Autonomic disturbances are also common, may be severe, and are sometimes life-threatening; they include tachycardia, cardiac irregularities, hypo- or hypertension, facial flushing, abnormalities of sweating, pulmonary dysfunction, and impaired sphincter control. The axonal subtypes of the syndrome (**acute motor axonal neuropathy** [AMAN] and **acute motor and sensory axonal neuropathy** [AMSAN]) are caused by antibodies to gangliosides on the axon membrane. The **Miller Fisher syndrome**, another subtype, is characterized by the clinical triad of ophthalmoplegia, ataxia, and areflexia, and is associated with anti-GQ1b antibodies.

B. Laboratory Findings

The CSF characteristically contains a high protein concentration with a normal cell count, but these changes may take up to 2 weeks to develop; WBC counts > 50 cells/mcL (0.05×10^9/L) should prompt consideration of alternative diagnoses. Electrophysiologic studies may reveal marked abnormalities, which do not necessarily parallel the clinical disorder in their temporal course.

Differential Diagnosis

When the diagnosis is made, the history and appropriate laboratory studies should exclude the possibility of porphyric, diphtheritic, or toxic (heavy metal, hexacarbon, organophosphate) neuropathies, and of HIV infection. The temporal course excludes other peripheral neuropathies. Poliomyelitis, botulism, and tick paralysis must also be considered as they cause weakness of acute onset. The presence of pyramidal signs, a markedly asymmetric motor deficit, a sharp sensory level, or early sphincter involvement should suggest a focal cord lesion.

Treatment

Treatment with prednisone is *ineffective* and may prolong recovery time. Plasmapheresis or IVIG (400 mg/kg/day for 5 days) is of value. Treatment is best initiated within the first few days of illness and is useful for clinically severe or rapidly progressive cases or those with ventilatory impairment. Patients should be admitted to ICU if their FVC is declining, and intubation is considered if the FVC reaches 15 mL/kg, the maximum inspiratory pressure reaches −30 mm Hg, or dyspnea becomes evident. Declining oxygen saturation is a late indicator of neuromuscular respiratory failure. Respiratory toilet and chest physical therapy help prevent atelectasis. Marked hypotension may respond to volume replacement or pressor agents. Thromboprophylaxis is important.

Prognosis

Most patients eventually make a good recovery, but this may take many months, and about 20% of patients are left with persisting disability. Approximately 3% of patients with acute idiopathic polyneuropathy have one or more clinically similar relapses, sometimes several years after the initial illness.

Censi S et al. Guillain-Barré syndrome and COVID-19 vaccination: a systematic review and meta-analysis. J Neurol. 2024;271:1063. [PMID: 38233678]

8. Chronic Inflammatory Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy, an acquired immunologically mediated disorder, has a relapsing or steadily progressive course over months or years and that autonomic dysfunction is generally less common. It may present as an exclusively motor disorder or with a mixed sensorimotor disturbance. In the relapsing form, partial recovery may occur after some relapses, but in other instances there is no recovery between exacerbations. Although remission may occur spontaneously with time, the disorder frequently follows a progressive downhill course leading to severe functional disability. Occasional acute presentations may mimic Guillain-Barré syndrome, which are frequently associated with IgG_4 antibodies to proteins expressed at the nodes of Ranvier (neurofascin-155, contactin-1, and contactin associated protein 1 [CASPR1]).

Electrodiagnostic studies show marked slowing of motor and sensory conduction, and focal conduction block. Signs of partial denervation may also be present owing to secondary axonal degeneration. Nerve biopsy may show chronic perivascular inflammatory infiltrates in the endoneurium and epineurium, without accompanying evidence of vasculitis. However, a normal nerve biopsy result or the presence of nonspecific abnormalities does *not* exclude the diagnosis.

Corticosteroids may arrest or reverse the downhill course. Treatment is usually begun with prednisone, 60–80 mg orally daily, continued for 2–3 months or until a definite response has occurred. If no response has occurred despite 3 months of treatment, a higher dose may be tried. In responsive cases, the dose is gradually tapered, but most patients become corticosteroid-dependent, often requiring prednisone, 20 mg daily on alternate days, on a long-term basis. IVIG can be used in place of, or in addition to corticosteroids, and is best used as the initial treatment in pure motor syndromes (2 g/kg over 2–5 days followed by 1 g/kg every 3 weeks); a weekly regimen of 0.2–0.4 g/kg of a 20% subcutaneous immunoglobulin solution is an effective alternative but has not been compared directly to corticosteroids or IVIG. When both IVIG and corticosteroids are ineffective, plasma exchange may be worthwhile. Weekly subcutaneous injection of efgartigimod alfa and hyaluronidase-qvfc (1008 mg/11,200 U), a neonatal Fc receptor blocker, reduced the risk of relapse in CIDP in a randomized trial and is approved in the United States. Immunosuppressant or immunomodulatory medications (such as azathioprine or rituximab) may be added when the response to other measures is unsatisfactory or to enable maintenance doses of corticosteroids to be lowered. Symptomatic treatment is also important.

Allen JA et al. Safety, tolerability, and efficacy of subcutaneous efgartigimod in patients with chronic inflammatory demyelinating polyradiculoneuropathy (ADHERE): a multicentre, randomised-withdrawal, double-blind, placebo-controlled, phase 2 trial. Lancet Neurol. 2024;23:1013. [PMID: 39304241]

Bus SR et al. Intravenous immunoglobulin for chronic inflammatory demyelinating polyradiculoneuropathy. Cochrane Database Syst Rev. 2024;2:CD001797. [PMID: 38353301]

When to Refer

- All patients with a progressive neuropathy should be referred.
- Painful neuropathy unresponsive to first-line treatment.
- Patients with disabling autonomic symptoms.

When to Admit

Patients with rapidly progressive symptoms or respiratory compromise.

MONONEUROPATHIES

ESSENTIALS OF DIAGNOSIS

- Focal motor or sensory deficit.
- Deficit is in territory of an individual peripheral nerve.

An individual nerve may be injured along its course or may be compressed, angulated, or stretched by neighboring anatomic structures, especially at a point where it passes through a narrow space (**entrapment neuropathy**). The relative contributions of mechanical factors and ischemia to the local damage are not clear. With involvement of a sensory or mixed nerve, pain is commonly felt distal to the lesion. Symptoms never develop with some entrapment neuropathies, resolve rapidly and spontaneously in others, and become progressively more disabling and distressing in yet other cases. The precise neurologic deficit depends on the nerve involved. Percussion of the nerve at the site of the lesion may lead to paresthesias in its distal distribution.

Entrapment neuropathy may be the sole manifestation of subclinical polyneuropathy, and this must be borne in mind and excluded by nerve conduction studies. Such studies are also indispensable for the localization of the focal lesion. Neuromuscular ultrasound is also increasingly useful in this context.

In patients with acute compression neuropathy such as may occur in intoxicated individuals (**Saturday night palsy**), no treatment is necessary. Complete recovery generally occurs, usually within 2 months, presumably because the underlying pathology is demyelination. However, axonal degeneration can occur in severe cases, and recovery then takes longer and may never be complete.

In chronic compressive or entrapment neuropathies, avoidance of aggravating factors and correction of any underlying systemic conditions are important. Local infiltration of the region about the nerve with corticosteroids may be of value; in addition, surgical decompression may help if there is a progressively increasing neurologic deficit or if electrodiagnostic studies show evidence of partial denervation in weak muscles.

Peripheral nerve tumors are uncommon, except in neurofibromatosis type 1, but also give rise to mononeuropathy. This may be distinguishable from entrapment neuropathy only by noting the presence of a mass along the course of the nerve and by demonstrating the precise site of the lesion with appropriate electrophysiologic studies and neuromuscular ultrasound. Treatment of symptomatic lesions is by surgical removal if possible.

1. Carpal Tunnel Syndrome

See Chapter 46.

2. Pronator Teres or Anterior Interosseous Syndrome

The median nerve gives off its motor branch, the anterior interosseous nerve, below the elbow as it descends between the two heads of the pronator teres muscle. A lesion of either nerve may occur in this region, sometimes after trauma or owing to compression from, for example, a fibrous band. With anterior interosseous nerve involvement, there is no sensory loss, and weakness is confined to the pronator quadratus, flexor pollicis longus, and the flexor digitorum profundus to the second and third digits. Weakness is more widespread and sensory changes occur in an appropriate distribution when the median nerve itself is affected. The prognosis is variable. If improvement does not occur spontaneously, decompressive surgery may be helpful.

Chang K et al. Ultrasonography in pronator teres syndrome: dynamic examination and guided hydrodissection. Pain Med. 2022;23:219. [PMID: 33876819]

3. Ulnar Nerve Lesions

Ulnar nerve lesions are likely to occur in the elbow region as the nerve runs behind the medial epicondyle and descends into the cubital tunnel. In the condylar groove, the ulnar nerve is exposed to pressure or trauma. Moreover, any increase in the carrying angle of the elbow, whether congenital, degenerative, or traumatic, may cause excessive stretching of the nerve when the elbow is flexed. Ulnar nerve lesions may also result from thickening or distortion of the anatomic structures forming the cubital tunnel, and the resulting symptoms may also be aggravated by flexion of the elbow, because the tunnel is then narrowed by tightening of its roof or inward bulging of its floor. A severe lesion at either site causes sensory changes in the fifth and medial half of the fourth digits and along the medial border of the hand. There is weakness of the ulnar-innervated muscles in the forearm and hand. With a cubital tunnel lesion, however, there may be relative sparing of the flexor carpi ulnaris muscle. Electrophysiologic evaluation using nerve stimulation techniques allows more precise localization of the lesion.

Initial treatment consists of avoiding pressure on the medial elbow (eg, avoid resting the elbows on arm rests; pad the elbow during sleep) and preventing prolonged elbow flexion, especially at night. Splints are available to keep the elbow from flexing beyond 45 to 90 degrees. If conservative measures are unsuccessful in relieving symptoms and preventing further progression, surgical treatment may be necessary. This consists of nerve transposition if the lesion is in the condylar groove, or a release procedure if it is in the cubital tunnel.

Ulnar nerve lesions may also develop at the wrist or in the palm of the hand, usually owing to repetitive trauma or to compression from ganglia or benign tumors. They can be subdivided depending on their presumed site. Compressive lesions are treated surgically. If repetitive mechanical trauma is responsible, this is avoided by occupational adjustment or job retraining.

Abourisha E et al. Surgical management of cubital tunnel syndrome: a systematic review and meta-analysis of randomised trials. J Orthop. 2024;53:41. [PMID: 38456175]

4. Radial Nerve Lesions

The radial nerve is liable to compression or injury in the axilla (eg, by crutches or by pressure when the arm hangs over the back of a chair). This leads to weakness or paralysis of all the muscles supplied by the nerve, including the triceps. Sensory changes may also occur but are often surprisingly inconspicuous, being marked only in a small area on the back of the hand between the thumb and index finger. Injuries to the radial nerve in the spiral groove occur characteristically during deep sleep, as in intoxicated individuals, and there is then sparing of the triceps muscle, which is supplied more proximally. The nerve may also be injured at or above the elbow; its purely motor posterior interosseous branch, supplying the extensors of the wrist and fingers, may be involved immediately below the elbow, but then there is sparing of the extensor carpi radialis longus, so that the wrist can still be extended. The superficial radial nerve may be compressed by handcuffs or a tight watch strap.

Chalk C. Radial neuropathy. Handb Clin Neurol. 2024;201:127. [PMID: 38697735]

5. Femoral Neuropathy

The clinical features of femoral nerve palsy consist of weakness and wasting of the quadriceps muscle, with sensory impairment over the anteromedian aspect of the thigh and sometimes also of the leg to the medial malleolus, and a depressed or absent knee jerk. Isolated femoral neuropathy may occur in patients with diabetes or from compression by retroperitoneal neoplasms or hematomas (eg, expanding aortic aneurysm). Femoral neuropathy may also result from pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position.

Chalk C et al. Femoral and obturator neuropathies. Handb Clin Neurol. 2024;201:183. [PMID: 38697739]

6. Meralgia Paresthetica

The **lateral femoral cutaneous nerve**, a sensory nerve arising from the L2 and L3 roots, may be compressed or stretched in patients with obesity or diabetes and during pregnancy. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose it. Hyperextension of the hip or increased lumbar lordosis—such as occurs during pregnancy—leads to nerve compression by the posterior fascicle of the ligament. However, entrapment of the nerve at any point along its course may cause similar symptoms, and several other anatomic variations predispose the nerve to damage when it is stretched. Pain, paresthesia, or numbness occurs about the outer aspect of the thigh, usually unilaterally, and is sometimes relieved by sitting. The pain stops at the knee, unlike the pain from lower lumbar sciatica that radiates to the foot. Examination shows no abnormalities except in severe cases when cutaneous sensation is impaired in the affected area. Symptoms are usually mild and commonly settle spontaneously. Hydrocortisone injections medial to the anterosuperior iliac spine often relieve symptoms temporarily, while ultrasound-guided hydrodissection with 5% dextrose or surgical nerve decompression may provide more lasting relief.

Xu H et al. A randomized double-blind trial of 5% dextrose versus corticosteroid hydrodissection for meralgia paresthetica. Pain Physician. 2024;27:E835. [PMID: 39621981]

7. Sciatic & Fibular (Common Peroneal) Nerve Palsies

Misplaced deep intramuscular injections are likely the most common cause of sciatic nerve palsy. Trauma to the buttock, hip, or thigh may also be responsible. The resulting clinical deficit depends on whether the whole nerve has been affected or only certain fibers. In general, the fibular fibers of the sciatic nerve are more susceptible to damage than those destined for the tibial nerve. A sciatic nerve lesion may therefore be difficult to distinguish from fibular neuropathy unless there is electromyographic evidence of involvement of the short head of the biceps femoris muscle. The fibular nerve itself may be compressed or injured in the region of the head and neck of the fibula, eg, by sitting with crossed legs or wearing high boots. There is weakness of dorsiflexion and eversion of the foot, accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and dorsum of the foot. If there is poor motor recovery, surgical treatments such as tendon transfer may improve function.

Klifto KM et al. Treatment approach to isolated common peroneal nerve palsy by mechanism of injury: systematic review and meta-analysis of individual participants' data. J Plast Reconstr Aesthet Surg. 2022;75:683. [PMID: 34801427]

8. Tarsal Tunnel Syndrome

The tibial nerve, the other branch of the sciatic, supplies several muscles in the lower extremity, gives origin to the sural nerve, and then continues as the posterior tibial nerve to supply the plantar flexors of the foot and toes. It passes through the tarsal tunnel behind and below the medial malleolus, giving off calcaneal branches and the medial and lateral plantar nerves that supply small muscles of the foot and the skin on the plantar aspect of the foot and toes. Compression of the posterior tibial nerve or its branches between the bony floor and ligamentous roof of the tarsal tunnel leads to pain, paresthesias, and numbness over the bottom of the foot, especially at night, with sparing of the heel. Muscle weakness may be hard to recognize clinically. Compressive lesions of the individual plantar nerves may also occur more distally, with clinical features similar to those of the tarsal tunnel syndrome. Treatment is surgical decompression.

Vij N et al. Clinical results following conservative management of tarsal tunnel syndrome compared with surgical treatment: a systematic review. Orthop Rev (Pavia). 2022;14:37539. [PMID: 36072502]

When to Refer

- If there is uncertainty about the diagnosis.
- Symptoms or signs are progressing despite treatment.

BELL PALSY

ESSENTIALS OF DIAGNOSIS

- Sudden onset of lower motor neuron facial palsy.
- Hyperacusis or impaired taste may occur.
- No other neurologic abnormalities.

General Considerations

Bell palsy is an *idiopathic facial paresis of lower motor neuron type* that has been attributed to an inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal. In some instances, this may be due to reactivation of herpes simplex or varicella zoster virus infection in the geniculate ganglion. The disorder is more common in pregnant persons and in persons with diabetes mellitus.

Clinical Findings

The facial paresis (Figure 27–1) generally comes on abruptly, but it may worsen over the following day or so. Pain about the ear precedes or accompanies the weakness in many cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. There may be ipsilateral restriction of eye closure and difficulty with eating and fine facial movements. A disturbance of taste is common, owing to involvement of chorda tympani fibers, and hyperacusis due to involvement of fibers to the stapedius occurs occasionally. In cases due to herpes zoster infection, vesicles may be observed in the external ear canal.

Differential Diagnosis

Lower motor neuron facial palsy can be differentiated from stroke by clinical examination. A stroke or other central lesion will not cause hyperacusis or disturbance of taste, generally spares the forehead, and is accompanied by other focal deficits. An isolated facial palsy may occur in patients with HIV seropositivity, sarcoidosis, Lyme disease (Figure 27–1; also see Chapter 39), or any process causing an inflammatory reaction in the subarachnoid space, such as meningitis. Whenever facial palsies occur bilaterally, or a facial palsy occurs in conjunction with other neurologic deficits, MRI brain imaging should be undertaken and other investigations considered.

Treatment

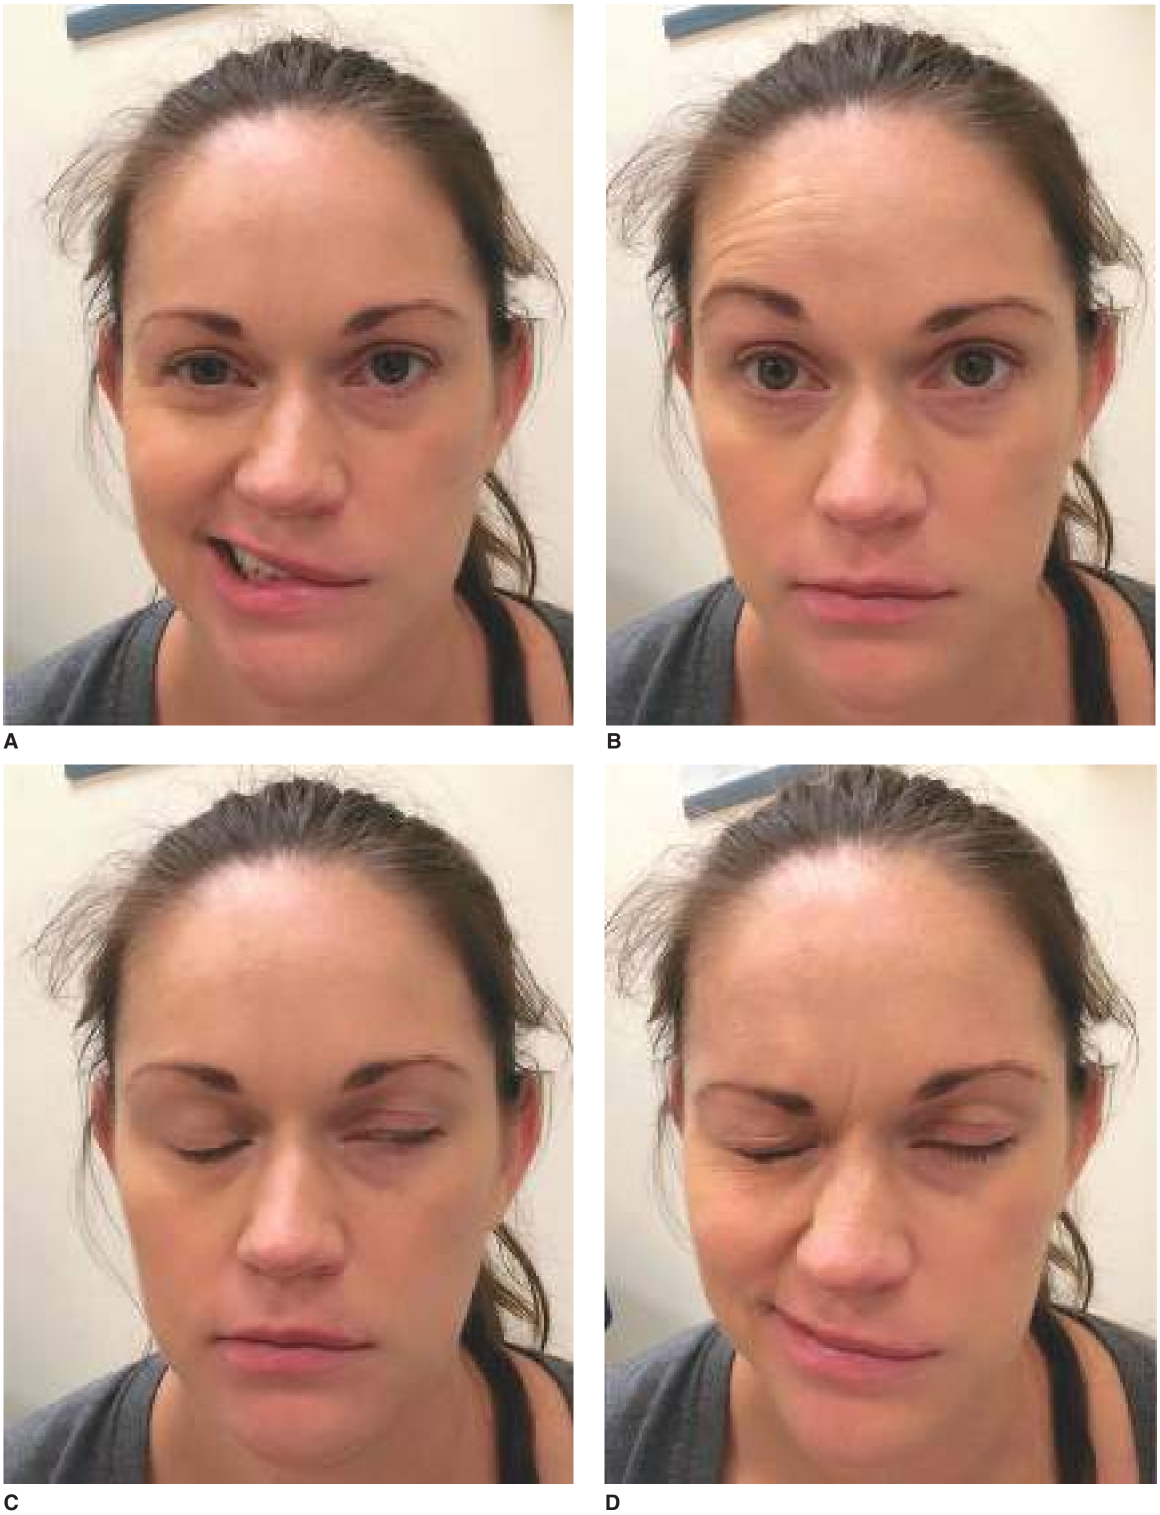
Approximately 60% of cases of Bell palsy recover completely without treatment, presumably because the lesion is so mild that it leads merely to conduction block. Treatment with corticosteroids (prednisone 60 mg orally daily for 5 days followed by a 5-day taper, or prednisolone 25 mg orally twice daily for 10 days) increases the chance of a complete recovery at 9–12 months by 12–15%. *Treatment with acyclovir or valacyclovir is only indicated when there is evidence of herpetic vesicles in the external ear canal.* It is helpful to protect the eye with lubricating drops (or lubricating ointment at night) and a patch if eye closure is not possible. There is no evidence that surgical procedures to decompress the facial nerve are of benefit. Physical therapy may improve facial function.

Varelas EA et al. Physical therapy for idiopathic facial paralysis: a systematic review. Am J Otolaryngol. 2024;46:104511. [PMID: 39647183]

DISCOGENIC NECK PAIN

ESSENTIALS OF DIAGNOSIS

- Neck pain, sometimes radiating to arms.
- Restricted neck movements.
- Motor, sensory, or reflex changes in arms with root involvement.
- Neurologic deficit in legs, gait disorder, or sphincter disturbance with cord involvement.



▲ **Figure 27–1.** Left-sided lower motor neuron pattern facial weakness (due to Bell palsy). (Reproduced with permission from Berkowitz AL. *Clinical Neurology & Neuroanatomy: A Localization-Based Approach*, 2nd ed. McGraw-Hill, 2022.)

General Considerations

A variety of congenital abnormalities may involve the cervical spine and lead to neck pain; these include hemivertebrae, fused vertebrae, basilar impression, and instability of the atlantoaxial joint. Traumatic, degenerative, infective, and neoplastic disorders may also lead to pain in the neck. When rheumatoid arthritis involves the spine, it tends to affect especially the cervical region, leading to pain, stiffness, and reduced mobility; displacement of vertebrae or atlantoaxial subluxation may lead to cord compression that can be life-threatening if not treated by fixation. Further details are given in Chapter 44 and discussion here is restricted to disk disease.

1. Acute Cervical Disk Protrusion

Acute cervical disk protrusion leads to pain in the neck and radicular pain in the arm, exacerbated by head movement. With lateral herniation of the disk, motor, sensory, or reflex changes may be found in a radicular (usually C6 or C7) distribution on the affected side (Figure 27–2); with more centrally directed herniations, the spinal cord may also be involved, leading to spastic paraparesis and sensory disturbances in the legs, sometimes accompanied by impaired sphincter function. The diagnosis is confirmed by MRI or CT myelography. In mild cases, the prognosis is good and complete recovery occurs in most patients with conservative therapy. Evidence does not support any specific intervention, and some combination of bed rest, activity restriction, immobilization of the neck in a collar for several weeks, and physical therapy is generally prescribed. If these measures are unsuccessful or the patient has a significant neurologic deficit, surgical removal of the protruding disk may be necessary.

2. Cervical Spondylosis

Cervical spondylosis results from chronic cervical disk degeneration, with herniation of disk material, secondary calcification, and associated osteophytic outgrowths. One or more of the cervical nerve roots may be compressed, stretched, or angulated; and myelopathy may also develop as a result of compression, vascular insufficiency, or recurrent minor trauma to the cord. Patients present with neck pain and restricted head movement, occipital headaches, radicular pain and other sensory disturbances in the arms, weakness of the arms or legs, or some combination of these symptoms. Examination generally reveals that lateral flexion and rotation of the neck are limited. A segmental pattern of weakness or dermatomal sensory loss (or both) may be found unilaterally or bilaterally in the upper limbs, and tendon reflexes mediated by the affected root or roots are depressed. The C5 and C6 nerve roots are most commonly involved, and examination frequently then reveals weakness of muscles supplied by these roots (eg, deltoids, supraspinatus and infraspinatus, biceps, brachioradialis), pain or sensory loss about the shoulder and outer border of the arm and forearm, and depressed biceps and brachioradialis reflexes. Spastic paraparesis may also be present if there is an associated myelopathy, sometimes accompanied by urinary urgency, incontinence, or posterior column or spinothalamic sensory deficits in the legs.

Plain radiographs of the cervical spine show osteophyte formation, narrowing of disk spaces, and encroachment on the intervertebral foramina, but such changes are common in middle-aged persons and may be unrelated to the presenting complaint. CT or MRI helps confirm the diagnosis and exclude other structural causes of the myelopathy.

Restriction of neck movements by a cervical collar may relieve pain. Local injection of anesthetics or corticosteroids by a pain management specialist may be of benefit. Operative treatment may be necessary to prevent further progression if there is a significant neurologic deficit; if there are bowel or bladder symptoms; or if root pain is severe, persistent, and unresponsive to conservative measures.

When to Refer

- Pain unresponsive to simple measures.
- Patients with neurologic deficits.
- Patients in whom surgical treatment is under consideration.

When to Admit

- Patients with progressive or significant neurologic deficit.
- Patients with sphincter involvement (from cord compression).
- Patients requiring surgical treatment.

BRACHIAL & LUMBAR PLEXUS LESIONS

1. Brachial Plexus Neuropathy

Brachial plexus neuropathy may be idiopathic, sometimes occurring in relationship to a number of different nonspecific illnesses or factors. In other instances, brachial plexus lesions follow trauma or result from congenital anomalies, neoplastic involvement, or injury by various physical agents. In rare instances, the disorder occurs on a familial basis.

Idiopathic brachial plexus neuropathy (**neuralgic amyotrophy**) characteristically begins with severe pain about the shoulder, followed within a few days by weakness, reflex changes, and sensory disturbances involving especially the C5 and C6 segments but affecting any nerve in the brachial plexus. Symptoms and signs are usually unilateral but may be bilateral. Wasting of affected muscles is sometimes profound. The disorder relates to disturbed function of cervical roots or part of the brachial plexus, but its precise cause is unknown. Recovery occurs over the ensuing months but may be incomplete. Treatment is purely symptomatic, although emerging evidence suggests that microsurgical neurolysis of hourglass-like constrictions on affected nerves identified by magnetic resonance neurography or high-resolution ultrasound improves outcome in patients who have not recovered after several months of conservative management.

2. Cervical Rib Syndrome

Compression of the C8 and T1 roots or the lower trunk of the brachial plexus by a cervical rib or band arising from the seventh cervical vertebra leads to weakness and wasting of intrinsic hand muscles, especially those in the thenar eminence, accompanied by pain and numbness in the medial two fingers and the ulnar border of the hand and forearm. Electromyography, nerve conduction studies, and somatosensory evoked potential studies may help confirm the diagnosis. MRI may be especially helpful in revealing the underlying compressive structure. Plain radiographs or CT scanning sometimes shows the cervical rib or a large transverse process of the seventh cervical vertebra, but normal findings do not exclude the possibility of a cervical band. Treatment of the disorder is by surgical excision of the rib or band.

Khoury MK et al. Systematic review of intermediate and long-term results of thoracic outlet decompression. Semin Vasc Surg. 2024;37:90. [PMID: 38704189]

3. Lumbosacral Plexus Lesions

A lumbosacral plexus lesion may develop in association with diseases such as diabetes, cancer, or bleeding disorders or in relation to injury. It occasionally occurs as an isolated phenomenon similar to idiopathic brachial plexopathy (**nondiabetic lumbosacral radiculoplexus neuropathy**), and pain and weakness then tend to be more conspicuous than sensory symptoms. The distribution of symptoms and signs depends on the level and pattern of neurologic involvement.

Pinto MV et al. Risk factors for lumbosacral radiculoplexus neuropathy. Muscle Nerve. 2022;65:593. [PMID: 34970748]

DISORDERS OF NEUROMUSCULAR TRANSMISSION

1. Myasthenia Gravis

ESSENTIALS OF DIAGNOSIS

- Fluctuating weakness of commonly used voluntary muscles, producing symptoms such as diplopia, ptosis, and difficulty in swallowing.
- Activity increases weakness of affected muscles.
- Short-acting anticholinesterases transiently improve the weakness.

General Considerations

Myasthenia gravis occurs at all ages, *sometimes in association with a thymic tumor or thyrotoxicosis*, as well as in rheumatoid arthritis and lupus erythematosus. It is most common in young women with HLA-DR3; if thymoma is associated, older men are more commonly affected. Onset is usually insidious, but the disorder is sometimes unmasked by a coincidental infection that leads to exacerbation of symptoms. Exacerbations may also occur before the menstrual period and during or shortly after pregnancy. Symptoms are due to a variable degree of block of neuromuscular transmission caused by autoantibodies binding to acetylcholine receptors; these are found in most patients with the disease and have a primary role in reducing the number of functioning acetylcholine receptors. Additionally, cellular immune activity against the receptor is found.

Clinical Findings

A. Symptoms and Signs

Patients present with ptosis, diplopia, difficulty in chewing or swallowing, respiratory difficulties, limb weakness, or some combination of these problems. Weakness may remain localized to a few muscle groups or may become generalized. The external ocular muscles and certain other cranial muscles, including the masticatory, facial, and pharyngeal muscles, are especially likely to be affected, and the respiratory and limb muscles may also be involved. Symptoms often fluctuate in intensity during the day, and this diurnal variation is superimposed on a tendency to longer-term spontaneous relapses and remissions that may last for weeks. Nevertheless, the disorder follows a slowly progressive course and may have a fatal outcome owing to respiratory complications such as aspiration pneumonia.

Clinical examination confirms the weakness and fatigability of affected muscles. In most cases, the extraocular muscles are involved, and this leads to ocular palsies and ptosis, which are commonly asymmetric. Pupillary responses are normal. The bulbar and limb muscles are often weak, but the pattern of involvement is variable. Sustained activity of affected muscles increases the weakness, which improves after a brief rest. Sensation is normal, and there are usually no reflex changes.

Life-threatening exacerbations of myasthenia (so-called **myasthenic crisis**) may lead to respiratory weakness requiring immediate admission to the ICU, where respiratory function can be monitored and ventilator support is readily available.

B. Laboratory and Other Studies

Assay of serum for elevated levels of circulating **acetylcholine receptor antibodies** is useful because it has a sensitivity of 80–90% for the diagnosis of myasthenia gravis. Certain patients without antibodies to acetylcholine receptors have serum antibodies to muscle-specific tyrosine kinase (MuSK), which should therefore be determined; these patients are more likely to have facial, respiratory, and proximal muscle weakness than those with antibodies to acetylcholine receptors. Rarely, patients with myasthenia gravis may have antibodies to the LDL receptor-related protein 4 (LRP4).

Electrophysiologic demonstration of a decrementing muscle response to repetitive 2- or 3-Hz stimulation of motor nerves indicates a disturbance of neuromuscular transmission. Such an abnormality may even be detected in clinically strong muscles with certain provocative procedures. Needle electromyography of affected muscles shows a marked variation in configuration and size of individual motor unit potentials, and single-fiber electromyography reveals an increased jitter, or variability, in the time interval between two muscle fiber action potentials from the same motor unit.

C. Imaging

A CT scan of the chest with and without contrast should be obtained to demonstrate a coexisting thymoma.

Treatment

Anticholinesterase medications provide symptomatic benefit without influencing the course of the disease. Neostigmine, pyridostigmine, or both can be used, the dose being determined on an individual basis. The usual dose of neostigmine is 7.5–30 mg (average, 15 mg) orally taken four times daily; of pyridostigmine, 30–180 mg (average, 60 mg) orally four times daily. Overmedication may temporarily increase weakness. A wide range of medications (eg, aminoglycosides) may exacerbate myasthenia gravis and should be avoided.

Thymectomy should be performed when a thymoma is present. A multicenter randomized trial demonstrated the benefit of thymectomy even in the absence of a radiologically identifiable thymoma, with improved strength, lower immunosuppression requirements, and fewer hospitalizations in the surgically treated group. Thus, *thymectomy should be considered in all patients younger than age 65 unless weakness is restricted to the extraocular muscles.* If the disease is of recent onset and only slowly progressive, operation is sometimes delayed for a year or so, in the hope that spontaneous remission will occur.

Treatment with corticosteroids is indicated for patients who have responded poorly to anticholinesterase medications. Some patients experience transient exacerbation of weakness and even develop respiratory failure within the first 1–2 weeks if corticosteroids are initiated at high doses (eg, prednisone 1 mg/kg/day). Therefore, in stable patients, corticosteroids are introduced gradually in the outpatient setting. Prednisone can be started at 20 mg orally daily and increased by 10 mg increments weekly to a target of 1 mg/kg/day (maximum daily dose 100 mg). For patients hospitalized with severe myasthenia and treated with IVIG or plasmapheresis, the higher dose can be given initially because the more rapid onset of action of the former two therapies mitigates the initial dip in strength due to corticosteroids. Corticosteroids can be prescribed as alternate-day or daily treatment, with alternate-day therapy potentially mitigating side effects. Once the patient has stabilized at the initial high dose, corticosteroids can gradually be tapered to a relatively low maintenance level (eg, 10 mg prednisone orally daily) as improvement occurs; total withdrawal is difficult, however.

Treatment with azathioprine may be effective in allowing a lower dose of corticosteroids. The usual dose is 2–3 mg/kg orally daily after a lower initial dose. Other immunosuppressive agents that are used in myasthenia gravis to reduce the corticosteroid dose include mycophenolate mofetil, rituximab, cyclosporine, methotrexate, and tacrolimus. Efgartigimod and rozanolixizumab act at the neonatal Fc receptor and reduce circulating IgG, improving motor function within weeks of administration. Both are approved by the FDA for acetylcholine antibody–positive myasthenia, and rozanolixizumab is also approved for patients with MuSK-positive myasthenia. Efgartigimod is given intravenously or subcutaneously once weekly for 4 weeks. Subsequent 4-week treatment cycles are administered based on clinical response, with start dates separated by at least 50 days. Rozanolixizumab is given subcutaneously once weekly for 6 weeks, with subsequent treatment cycles based on clinical response and separated by at least 63 days. Three complement inhibitors are approved by the FDA for patients who are acetylcholine receptor antibody positive. Zilucoplan is administered once daily by subcutaneous injection and is dosed by actual body weight. Ravulizumab is given intravenously as a weight-based loading dose followed by a maintenance dose every 8 weeks starting 2 weeks after the loading dose. Eculizumab is reserved for disease refractory to at least two alternate immunosuppressive therapies and is administered intravenously weekly for 5 weeks and then every 2 weeks. Patients must be vaccinated against meningococcus before receiving zilucoplan, ravulizumab, or eculizumab.

In patients with major disability, plasmapheresis or IVIG therapy may be beneficial and have similar efficacy. These therapies are also useful for stabilizing patients before thymectomy and for managing acute crisis.

Howard JF et al. Safety and efficacy of zilucoplan in patients with generalised myasthenia gravis (RAISE): a randomised, double-blind, placebo-controlled, phase 3 study. Lancet Neurol. 2023;22:395. [PMID: 37059508]

2. Myasthenic Syndrome (Lambert-Eaton Myasthenic Syndrome)

ESSENTIALS OF DIAGNOSIS

- Variable weakness, typically improving with activity.
- Dysautonomic symptoms may also be present.
- A history of malignant disease may be obtained.

Clinical Findings

Myasthenic syndrome *may be associated with small cell carcinoma,* sometimes developing before the tumor is diagnosed, and occasionally occurs with certain autoimmune diseases. There is defective release of acetylcholine in response to a nerve impulse, caused by P/Q-type voltage-gated calcium channel antibodies, and this leads to weakness, especially of the proximal muscles of the limbs. Unlike myasthenia gravis, however, power steadily increases with sustained contraction. The diagnosis can be confirmed electrophysiologically, because the muscle response to stimulation of its motor nerve increases remarkably after exercise or if the nerve is stimulated repetitively at high rates (50 Hz), even in muscles that are not clinically weak.

Treatment

Treatment with IVIG, plasmapheresis, and immunosuppressive medication therapy (prednisone and azathioprine) may lead to clinical and electrophysiologic improvement, in addition to therapy aimed at the tumor when present. Prednisone is usually initiated in a daily dose of 60–80 mg orally and azathioprine in a daily dose of 2 mg/kg orally. Symptomatic therapy includes the use of potassium channel antagonists; of these, amifampridine is a 3,4-diaminopyridine (15–80 mg/day orally in three divided doses) and is approved in the United States and Europe. Guanidine hydrochloride (25–50 mg/kg/day orally in divided doses) is an alternative and is occasionally helpful in patients with serious disability, but adverse effects of the medication

Table 27–11. Selected muscular dystrophies.[1]

Disorder	Inheritance	Age at Onset (years)	Distribution	Prognosis	Genetic Association
Duchenne type	X-linked recessive	1–5	Pelvic, then shoulder girdle; later, limb and respiratory muscles.	Rapid progression. Death within about 15 years after onset.	Xp21; Dystrophin (loss of functional expression).
Becker	X-linked recessive	5–25	Pelvic, then shoulder girdle.	Slow progression. May have normal life span.	Xp21; Dystrophin (reduced functional expression).
Limb-girdle (Erb)	Autosomal recessive, dominant, or sporadic	10–30	Pelvic or shoulder girdle initially, with later spread to the other.	Variable severity and rate of progression. Possible severe disability in middle life.	Multiple.
Facioscapulohumeral	Autosomal dominant	Any age	Face and shoulder girdle initially; later, pelvic girdle and legs.	Slow progression. Minor disability. Usually normal life span.	4q35.2; Double homeobox protein 4. 18p11.32; Structural maintenance of chromosome's flexible hinge domain-containing protein 1.
Emery-Dreifuss	X-linked recessive or autosomal dominant	5–10	Humeroperoneal or scapuloperoneal.	Variable.	Multiple.
Distal	Autosomal dominant or recessive	40–60	Onset distally in extremities; proximal involvement later.	Slow progression.	Multiple.
Oculopharyngeal	Autosomal dominant	Any age	Ptosis, external ophthalmoplegia, and dysphagia.	Slow progression.	14q11.2–q13; Poly (A)-binding protein-2.
Myotonic dystrophy	Autosomal dominant	Any age (usually 20–40)	Face, neck, distal limbs.	Slow progression.	19q13.32; Myotonin-protein kinase. 3q21.3; Cellular nucleic acid-binding protein.

[1] Not all possible genetic loci are shown.

include marrow suppression. The response to treatment with anticholinesterase medications such as pyridostigmine or neostigmine is usually disappointing.

Lipka AF. Lambert-Eaton myasthenic syndrome. Handb Clin Neurol. 2024;200:307. [PMID: 38494285]

3. Botulism

The toxin of *Clostridium botulinum* prevents the release of acetylcholine at neuromuscular junctions and autonomic synapses. Botulism occurs most commonly following the ingestion of contaminated home-canned food; outbreaks have also occurred among drug abusers due to wound infection after injection of contaminated heroin. The diagnosis should be suggested by the development of sudden, fluctuating, severe weakness with preserved sensation in a previously healthy person. Symptoms begin within 72 hours following ingestion of the toxin and may progress for several days. Typically, there is diplopia, ptosis, facial weakness, dysphagia, and nasal speech, followed by respiratory difficulty and finally by weakness that appears last in the limbs. Blurring of vision (with unreactive dilated pupils) is characteristic, and there may be dryness of the mouth, constipation (paralytic ileus), and postural hypotension. The tendon reflexes are not affected unless the involved muscles are weak. If the diagnosis is suspected, the local health authority should be notified and a sample of serum and contaminated food (if available) sent to be assayed for toxin. Support for the diagnosis may be obtained by electrophysiologic studies; with repetitive stimulation of motor nerves at fast rates, the muscle response increases in size progressively.

Patients should be hospitalized in case respiratory assistance becomes necessary. Treatment is with heptavalent antitoxin, in patients without known allergy to horse serum. Potassium channel antagonists may provide symptomatic relief as they do in Lambert-Eaton myasthenic syndrome. Anticholinesterase medications are of no value. Respiratory assistance and other supportive measures should be provided as necessary. Further details are provided in Chapter 38.

Raja SM. Lambert-Eaton myasthenic syndrome and botulism. Continuum (Minneap Minn). 2022;28:1596. [PMID: 36537971]

4. Disorders Associated with Use of Aminoglycosides

Aminoglycoside antibiotics, eg, gentamicin, may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings, but symptoms subside rapidly as the responsible medication is eliminated from the body. These antibiotics are dangerous in patients with preexisting disturbances of neuromuscular transmission and are therefore best avoided in patients with myasthenia gravis.

When to Refer

All patients should be referred.

When to Admit

- Patients with suspected botulism, acute exacerbation of myasthenia gravis, or respiratory involvement.
- Patients requiring plasmapheresis.
- For thymectomy.

MYOPATHIC DISORDERS

ESSENTIALS OF DIAGNOSIS

- Muscle weakness without sensory loss, often in a characteristic distribution.
- Serum creatine kinase elevated in most cases.
- Age at onset, time course, and inheritance pattern may suggest underlying disorder.

General Considerations

Myopathies can be inherited or acquired. Acquired myopathies often present acutely or subacutely while inherited myopathies are typically insidious in onset. Patients typically describe *weakness affecting proximal muscles*, such as difficulty climbing stairs, arising from a chair, or reaching overhead, or of head drop. Sensory symptoms are absent. A detailed family history is required.

Examination shows weakness of proximal muscles. In some cases, there is a more specific pattern of weakness (eg, quadriceps and finger flexor weakness in inclusion body myositis). Extraocular muscle involvement is rarely seen, except in certain mitochondrial disorders, oculopharyngeal muscular dystrophy, and hyperthyroidism; when present, it should suggest the possibility of a neuromuscular junction disorder. Reflexes are normal or diminished in proportion to the degree of weakness. Sensation is normal.

Initial testing should include serum creatine kinase determination. Consider testing TSH, cortisol, vitamin D, and calcium. Antibodies specific to certain inflammatory myopathies and connective tissue disease can be checked when these conditions are suspected and may obviate the need for muscle biopsy (see Chapter 23). Electromyography will reveal small motor units and early recruitment; it is helpful in confirming the localization of weakness to the muscle and suggesting a suitable site for biopsy, as does MRI. The electromyographic findings may be normal in corticosteroid and mitochondrial myopathies. Muscle biopsy establishes the diagnosis when inflammatory, mitochondrial, metabolic, or certain inherited myopathies are suspected. In cases where the family history or pattern of weakness suggests a specific genetic disorder, genetic testing can be pursued directly and biopsy may not be needed. Selected common and treatable myopathies are discussed below.

1. Muscular Dystrophies

These inherited myopathic disorders are subdivided by mode of inheritance, age at onset, and clinical features, as shown in Table 27–11. In the **Duchenne type**, pseudohypertrophy of muscles frequently occurs at some stage; intellectual disability is common; and there may be skeletal deformities, muscle contractures, and cardiac involvement. A genetic defect on the short arm of the X chromosome has been identified in Duchenne dystrophy. The affected gene codes for the protein dystrophin, which is markedly reduced or absent from the muscle of patients with the disease. Dystrophin levels are generally normal in the **Becker** variety, but the protein is qualitatively altered. The diagnosis is usually made with genetic testing; muscle biopsy is needed occasionally. Duchenne muscular dystrophy can be recognized early in pregnancy in about 95% of women by genetic studies; in late pregnancy, DNA probes can be used on fetal tissue obtained for this purpose by amniocentesis.

Four antisense oligonucleotides are approved by the FDA for treatment of Duchenne muscular dystrophy. Patients treated with these antisense oligonucleotides had more functional dystrophin on muscle biopsy than controls and a slower rate of disease progression than matched historical controls. A viral vector transgene encoding a microdystrophin protein, delandistrogene moxeparvovec, increases microdystrophin production with an unknown effect on clinical outcomes and is approved by the FDA. Prednisone (0.75 mg/kg orally daily or 10 mg/kg orally given weekly over 2 days) or deflazacort (0.9 mg/kg orally daily) improves muscle strength and function in boys with Duchenne dystrophy, but side effects need to be monitored. Although both corticosteroid preparations cause similar side effects, weight gain at 1 year is less with deflazacort. Vamorolone (6 mg/kg once daily; maximum daily dose 300 mg) is a novel oral corticosteroid approved for patients ≥ 2 years of age. It is as effective as prednisone but with fewer adverse effects. Givinostat (22.2 to 53.2 mg twice daily based on body weight) is an oral histone deacetylase inhibitor approved for patients > 6 years of age. In an RCT, it slowed decline over 72 weeks compared with placebo. Prolonged bed rest must be avoided, as inactivity often leads to worsening of the underlying muscle disease. Physical therapy and orthopedic procedures may help counteract deformities or contractures.

Dang UJ et al. Efficacy and safety of vamorolone over 48 weeks in boys with Duchenne muscular dystrophy: a randomized controlled trial. Neurology. 2024;102:e208112. [PMID: 38335499]

Mercuri E et al. Safety and efficacy of givinostat in boys with Duchenne muscular dystrophy (EPIDYS): a multicentre, randomised, double-blind, placebo-controlled, phase 3 trial. Lancet Neurol. 2024;23:393. [PMID: 38508835]

2. Myotonic Dystrophy

Myotonic dystrophy, a slowly progressive, dominantly inherited disorder, usually manifests itself in the third or fourth decade but occasionally appears early in childhood. Two types, with a different genetic basis, have been recognized. Myotonia leads to complaints of muscle stiffness and is evidenced by the marked delay that occurs before affected muscles can relax after a contraction. This can often be demonstrated clinically by delayed relaxation of the hand after sustained grip or by percussion of the belly of a muscle. In addition, there is weakness and wasting of the facial, sternocleidomastoid, and distal limb muscles. Associated clinical features include cataracts, frontal baldness, testicular atrophy, diabetes mellitus, cardiac abnormalities, and intellectual changes. Electromyographic sampling of affected muscles reveals myotonic discharges in addition to changes suggestive of myopathy.

It is difficult to determine whether medication therapy for myotonia is safe or effective. When myotonia is disabling, treatment with a sodium channel blocker—such as phenytoin (100 mg orally three times daily), procainamide (0.5–1 g orally four times daily), or mexiletine (150–200 mg orally three times daily)—may be helpful, but the associated side effects, particularly for antiarrhythmic medications, are often limiting. Neither the weakness nor the course of the disorder is influenced by treatment. Cardiac function should be monitored, and pacemaker placement may be considered if there is evidence of heart block.

Hamel JI. Myotonic dystrophy. Continuum (Minneap Minn). 2022;28:1715. [PMID: 36537977]

3. Myotonia Congenita

Myotonia congenita is commonly inherited as a dominant trait. Generalized myotonia without weakness is usually present from birth, but symptoms may not appear until early childhood. Patients report muscle stiffness that is enhanced by cold and inactivity and relieved by exercise. Muscle hypertrophy, at times pronounced, is also a feature. A recessive form with later onset is associated with slight weakness and atrophy of distal muscles. Treatment with procainamide, tocainide, mexiletine, or phenytoin may help the myotonia, as in myotonic dystrophy.

Suetterlin K et al. Inherited myotonias. Handb Clin Neurol. 2024;203:25. [PMID: 39174252]

4. Mitochondrial Myopathies

The mitochondrial myopathies are a clinically diverse group of disorders that on pathologic examination of skeletal muscle with the modified Gomori stain show characteristic “ragged red fibers” containing accumulations of abnormal mitochondria. Patients may present with progressive external ophthalmoplegia or with limb weakness that is exacerbated or induced by activity. Other patients present with central neurologic dysfunction, eg, myoclonic epilepsy (**myoclonic epilepsy**, **ragged red fiber syndrome**, or **MERRF**), or the combination of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (**MELAS**). Migraine is a common symptom. Systemic features include but are not limited to diabetes mellitus, hearing loss, retinopathy, cardiomyopathy, gastric dysmotility, and short stature. The serum creatine kinase is usually normal. Mitochondrial myopathies result from separate abnormalities of mitochondrial DNA. There are no approved treatments for these disorders, but coenzyme Q10, creatine, and levocarnitine are often prescribed; arginine is also given to patients with MELAS because it reduced frequency and severity of stroke-like episodes in an open-label trial.

Stefanetti RJ et al. l-Arginine in mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes: a systematic review. Neurology. 2022;98:e2318. [PMID: 35428733]

5. Acid Maltase Deficiency (Pompe Disease)

This is a glycogen storage disease due to mutations in the gene encoding acid α-1,4-glucosidase. Age at presentation ranges from infancy to the late fifties and depends on the degree of residual enzyme activity. The juvenile and adult-onset forms present with slowly progressive proximal weakness that includes respiratory failure. Cardiomyopathy is less common in the adult form. Serum creatine kinase is mildly elevated. Muscle biopsy shows glycogen containing lysosomal vacuoles, but the diagnosis is suggested by detecting reduced acid-1,4-α-glucosidase activity on a dried blood spot and then confirmed by genetic testing. Enzyme replacement with recombinant α-glucosidase stabilizes disease progression and results in improvement in respiratory function. Patients who weigh 40 kg or more and are not improving on initial enzyme replacement therapy are eligible for treatment with the combination of cipaglucosidase alfa-atga and miglustat, which demonstrated similar efficacy to alglucosidase alfa in a randomized trial.

Schoser B et al. 104-week efficacy and safety of cipaglucosidase alfa plus miglustat in adults with late-onset Pompe disease: a phase III open-label extension study (ATB200-07). J Neurol. 2024;271:2810. [PMID: 38418563]

6. Dermatomyositis, Anti-Synthetase Syndromes, Immune-Mediated Necrotizing Myopathies, & Polymyositis

See Chapter 23.

7. Inclusion Body Myositis

This disorder, of unknown cause, begins insidiously, usually after middle age, with progressive proximal weakness of first the lower and then the upper extremities, and affecting facial and pharyngeal muscles. Weakness often begins in the quadriceps femoris in the lower limbs and the forearm flexors in the upper limbs. Distal weakness is usually mild. Serum creatine kinase levels may be normal or increased. The diagnosis is confirmed by muscle biopsy. Anticytosolic 5'-nucleotidase 1A antibodies are detected in one-third of cases and may be associated with a more severe phenotype. Corticosteroid and immunosuppressive therapies are sometimes offered but is usually ineffective, and IVIG therapy is not recommended.

Goyal NA. Inclusion body myositis. Continuum (Minneap Minn). 2022;28:1663. [PMID: 36537974]

8. Endocrine Myopathies

Myopathy is observed with hypo- and hyperthyroidism, Cushing syndrome and disease, Addison disease, vitamin D deficiency, and both hyper- and hypoparathyroidism (the latter mediated by calcium derangements). In hypothyroidism, there may be associated entrapment neuropathies, and examination may show delayed relaxation of tendon reflexes, muscle enlargement, or myoedema. Hyperthyroidism can cause both distal and proximal weakness and rarely a bulbar myopathy. Serum creatine kinase is normal except in hypothyroid myopathy, which can also be painful. Treatment is of the underlying endocrinopathy.

9. Critical Illness Myopathy

Myopathy may occur in association with critical illness, typically in patients who received neuromuscular blocking agents and corticosteroids. It is frequently discovered when patients unexpectedly require prolonged ventilatory support. There can be an associated sensorimotor polyneuropathy. Serum creatine kinase may be elevated initially but has frequently returned to normal or is below normal by the time the condition is suspected. Treatment is supportive.

Younger DS. Critical illness-associated weakness and related motor disorders. Handb Clin Neurol. 2023;195:707. [PMID: 37562893]

10. Toxic Myopathies

Myopathy can occur in patients taking aminocaproic acid, amiodarone, chloroquine, colchicine, corticosteroids, cyclosporine, daptomycin, emetine, fibrates, gemcitabine, nucleoside reverse transcriptase inhibitors, or statin medications. Myopathy also occurs with chronic alcohol use disorder, whereas acute reversible muscle necrosis may occur shortly after acute alcohol, cocaine, or methamphetamine intoxication, and with propofol infusion. Inflammatory myopathy may occur in patients taking penicillamine and can be induced by programmed death-1 inhibitors; myotonia may be induced by clofibrate, and preexisting myotonia may be exacerbated or unmasked by depolarizing muscle relaxants (eg, suxamethonium), β-blockers (eg, propranolol), fenoterol and, possibly, certain diuretics. Valproic acid can precipitate or worsen myopathy in patients with mitochondrial disorders or carnitine palmitoyltransferase II deficiency.

Le Quang M et al. Clinical and pathological aspects of toxic myopathies. J Neurol. 2024;271:5722. [PMID: 38907023]

When to Refer

All patients should be referred to establish the diagnosis and underlying cause.

When to Admit

- For respiratory assistance.
- For rhabdomyolysis.

PERIODIC PARALYSIS SYNDROMES

Periodic paralysis may have a familial (dominant inheritance) basis. The syndromes to be described are *channelopathies* that manifest as abnormal, often potassium-sensitive, muscle-membrane excitability and lead clinically to episodes of flaccid weakness or paralysis, sometimes in association with abnormalities of the plasma potassium level. Strength is initially normal between attacks, but progressive myopathic weakness may develop in up to one-third of patients as they age. **Hypokalemic periodic paralysis** is characterized by attacks that tend to occur on awakening, after exercise, or after a heavy meal and may last for several days. An ongoing attack may be aborted by potassium chloride given orally or by intravenous drip, provided the ECG can be monitored and kidney function is satisfactory. A low-carbohydrate and low-salt diet may help prevent attacks, as may potassium supplementation, carbonic anhydrase inhibitors, and potassium sparing diuretics. It can occur in the setting of hyperthyroidism (**thyrotoxic periodic paralysis**) with or without an underlying genetic polymorphism; treatment of the endocrine disorder prevents recurrences. A nonselective β-adrenergic blocker may prevent attacks until the endocrine abnormality has been treated. In **hyperkalemic periodic paralysis,** attacks also tend to occur after exercise but usually last for < 1 hour. They may also be triggered by potassium-rich foods and cold. They may be terminated by intravenous calcium gluconate (1–2 g), intravenous diuretics (furosemide, 20–40 mg), glucose, glucose and insulin, or inhaled β agonists (albuterol 1–2 puffs of a

90 mcg/actuation metered dose inhaler). Thiazide diuretics or carbonic anhydrase inhibitors are used to prevent attacks. **Normokalemic periodic paralysis** is similar clinically to the hyperkalemic variety, but the plasma potassium level remains normal during attacks. Several randomized trials support the use of dichlorphenamide (50–100 mg orally twice daily) for prevention of attacks in both hyper- and hypokalemic periodic paralysis; acetazolamide (250–750 mg orally daily) is also effective. Chlorothiazide may also be used to prevent attacks in hyperkalemic periodic paralysis.

When to Refer

All patients should be referred.

When to Admit

Patients with prolonged attacks or attacks involving respiration or deglutition requiring intravenous therapy.

Cannon SC. Periodic paralysis. Handb Clin Neurol. 2024;203:39. [PMID: 39174253]

Psychiatric Disorders

Kristin S. Raj, MD
Nolan R. Williams, MD
Charles DeBattista, DMH, MD

The American Psychiatric Association's *DSM-5* is the common language that clinicians use for psychiatric conditions. It utilizes specific criteria with which to objectively assess symptoms for use in clinical diagnosis and communication.

COMMON PSYCHIATRIC DISORDERS

ADJUSTMENT DISORDERS

ESSENTIALS OF DIAGNOSIS

- Anxiety or depression in reaction to an identifiable stress, though out of proportion to the stressor severity.
- Symptoms not as severe as a major depressive episode or do not have the chronicity of generalized anxiety disorder (GAD).

General Considerations

An individual experiences stress when adaptive capacity is overwhelmed by events. The event may be an insignificant one and even favorable changes (eg, promotion and transfer) can produce stress. Stress is subjectively defined, and the response to stress is a function of each person's personality and physiologic endowment.

Clinical Findings

An individual may react to stress by becoming anxious or depressed, by developing a physical symptom, by running away, drinking alcohol, overeating, starting an affair, or in limitless other ways. Common subjective responses are anxiety, sadness, fear, rage, guilt, and shame. Acute and reactivated stress may be manifested by restlessness, irritability, fatigue, increased startle reaction, and a feeling of tension. Inability to concentrate, sleep disturbances (insomnia, bad dreams), and somatic preoccupations sometimes lead to self-medication, most commonly with alcohol or other CNS depressants. Emotional and behavioral distressing symptomatology in response to stress is called **adjustment disorder**, with the major symptom specified (eg, adjustment disorder with depressed mood, with anxiety, with mixed anxiety and depressed mood, with disturbance of conduct, with mixed disturbance of emotions and conduct, and unspecified). Even with an identifiable stressor, if the patient meets criteria for another disorder such as major depression, the convention is to diagnose a major depression and not an adjustment disorder with depressed mood. Risk factors for developing an adjustment disorder include female gender, younger age, unemployed status, stress, physical illness and injury, low social support, and a history of mental health disorders.

Differential Diagnosis

Adjustment disorders are distinguished from anxiety disorders, mood disorders, bereavement, other stress disorders such as PTSD, personality disorders exacerbated by stress, and from somatic disorders with psychic overlay. Unlike many other psychiatric disorders, adjustment disorders are *wholly situational* and usually resolve when the stressor resolves or the individual effectively adapts to the situation. Adjustment disorders may have symptoms that overlap with other disorders, such as anxiety symptoms, but they occur in reaction to an identifiable life stressor. An adjustment disorder that persists and worsens can potentially evolve into another psychiatric disorder such as major depression or GAD. However, that is not the case for most patients. By definition, an adjustment disorder occurs within 3 months of the onset of an identifiable stressor.

Treatment

A. Behavioral

Stress reduction techniques include immediate symptom reduction (eg, progressive muscle relaxation or slowed exhalations) or early recognition and removal from a stress source before full-blown symptoms appear. It is often helpful to keep a daily log of stress precipitators, responses, and alleviators. Relaxation, mindfulness-based stress reduction, and exercise techniques are helpful in improving the reaction to stressful events.

B. Social

The stress reactions of life problems are a function of psychosocial upheaval. It is important for the clinician to establish the framework of the problem, since the patient's denial system may obscure the issues. Clarifying the problem in the patient's psychosocial context facilitates the difficult decisions the patient eventually must make (eg, change of job).

C. Psychological

Prolonged psychotherapy is seldom necessary in cases of isolated stress response or adjustment disorder. Supportive psychotherapy with an emphasis on strengthening of existing coping mechanisms is helpful as the patient's own resiliency restores the previous level of function. In addition, cognitive behavioral therapy is helpful to treat acute stress and facilitate recovery. Computerized interventions, including virtual reality, have shown some efficacy in improving symptoms.

D. Pharmacologic

Judicious use of sedatives (eg, lorazepam, 0.5–1 mg two or three times daily orally) for a limited time can provide relief from acute anxiety symptoms. Short-term use of SSRIs targeting dysphoria and anxiety may be useful.

Prognosis

Return to satisfactory function after a short period is expected with this syndrome. Resolution may be delayed if others' responses to the patient's difficulties are harmful or if the secondary gains outweigh the advantages of recovery. The longer the symptoms persist, the worse the prognosis.

TRAUMA & STRESSOR-RELATED DISORDERS

ESSENTIALS OF DIAGNOSIS

- Exposure to a traumatic or life-threatening event.
- Flashbacks, intrusive images, and nightmares, often represent reexperiencing the event.
- Avoidance symptoms, including numbing, social withdrawal, and avoidance of stimuli associated with the event.
- Increased vigilance, such as startle reactions and difficulty falling asleep.
- Symptoms impair functioning.

General Considerations

Post-traumatic stress disorder (PTSD) has been reclassified from an anxiety disorder to a trauma and stressor-related disorder in the *DSM-5*. PTSD is a syndrome characterized by "reexperiencing" a traumatic event (eg, sexual assault, severe burns, military combat) and decreased responsiveness and avoidance of current events associated with the trauma. The lifetime prevalence of PTSD among adult Americans has been estimated to be 6.8% with a point prevalence of 3.6% and with women having rates twice as high as men. Many individuals with PTSD (20–40%) have experienced other associated problems, including divorce, parenting problems, difficulties with the law, and substance abuse.

Clinical Findings

The key to establishing the diagnosis of PTSD lies in the history of exposure to a perceived or actual life-threatening event, serious injury, serious medical illness, or sexual violence. The symptoms of PTSD include intrusive thoughts (eg, flashbacks, nightmares), avoidance (eg, withdrawal), negative thoughts and feelings, and increased reactivity. Patients with PTSD can experience physiologic hyperarousal, including startle reactions, illusions, overgeneralized associations, sleep problems, nightmares, dreams about the precipitating event, impulsivity, difficulties in concentration, and hyper-alertness. The symptoms may be precipitated or exacerbated by events that are a reminder of the original traumatic event. Symptoms frequently arise after a long latency period (eg, child abuse can result in later-onset PTSD). *DSM-5* includes the requirement that the symptoms persist for at least 1 month. In some individuals, the symptoms fade over months or years, and in others they may persist for a lifetime. Those with comorbid chronic pain tend to have heightened PTSD symptoms compared with those without chronic pain.

Differential Diagnosis

In 75% of cases, PTSD occurs with comorbid depression or panic disorder, and there is considerable overlap in the symptom complexes of all three conditions. Acute stress disorder has many of the same symptoms as PTSD, but symptoms persist for < 1 month after the trauma. Another major comorbidity is alcohol and substance abuse. The **Primary Care-PTSD Screen** (https://www.ptsd.va.gov/professional/assessment/documents/pc-ptsd5-screen.pdf) and the **PTSD Checklist** (https://www.ptsd.va.gov/professional/assessment/adult-sr/ptsd-checklist.asp) are two useful screening instruments in primary care clinics or community settings with populations at risk for trauma exposure.

Treatment

A. Psychotherapy

Cognitive processing therapy, cognitive behavioral therapy, Eye Movement Desensitization and Restructuring (EMDR), and prolonged exposure therapy have demonstrated improvement in symptoms of PTSD. In these approaches, the individual confronts the traumatic situation and over time learns to view and experience it with less hyperarousal. PTSD responds to interventions that help patients integrate the event in an adaptive way with some sense of mastery in having survived the trauma. Because partner relationship problems may be an area of concern, couples counseling may be indicated.

Treatment of comorbid substance abuse is an essential part of the recovery process for patients with PTSD. There are better outcomes when substance abuse treatment is delivered alongside trauma-focused psychotherapy. Support groups and 12-step programs such as Alcoholics Anonymous are often helpful.

B. Pharmacotherapy

SSRIs are helpful in ameliorating depression, panic attacks, sleep disruption, and startle responses. SSRIs are the only medications approved for the treatment of PTSD and considered the pharmacotherapy of choice. Early treatment of anxious arousal with β-blockers (eg, propranolol, 80–160 mg orally daily) may lessen the peripheral symptoms of anxiety (eg, tremors, palpitations) but has not been shown to prevent development of PTSD. Similarly, noradrenergic agents such as clonidine (titrated from 0.1 mg orally at bedtime to 0.2 mg three times a day) may help with the hyperarousal symptoms of PTSD. The α-blocking agent prazosin (2–10 mg orally at bedtime) has mixed evidence for decreasing nightmares and improving quality of sleep in PTSD. Benzodiazepines, such as clonazepam, are generally thought to be *contraindicated* in the treatment of PTSD. The risks of benzodiazepines, including addiction and potential increase of intrusive and dissociative symptoms, are thought to outweigh the short-term anxiolytic and sleep benefits. Trazodone (25–100 mg orally at bedtime) is commonly prescribed as a non–habit forming hypnotic agent. Second-generation antipsychotics have not demonstrated utility in the treatment of PTSD, but agents such as quetiapine 50–300 mg/day may have a limited role in treating irritability and sleep disturbance in PTSD patients. Phase 2 and 3 studies of methylenedioxymethamphetamine (MDMA) have shown large effect sizes and higher remission rates than prior studies of SSRIs. However, independent reviews of these studies commissioned by the FDA found numerous problems with the studies that may have introduced bias into the findings. As a result, in 2024 the FDA declined to approve MDMA for the treatment of PTSD, pending additional studies.

Prognosis

Half of patients with PTSD experience chronic symptoms. Prognosis is best in those with good premorbid psychiatric functioning. A study comparing sertraline and prolonged exposure therapy for patients with PTSD demonstrated that patients who received their preferred treatment were more likely to be adherent, respond to treatment, and have lower self-reported PTSD, depression, and anxiety symptoms.

ANXIETY DISORDERS

ESSENTIALS OF DIAGNOSIS

- Persistent excessive anxiety or chronic fear and associated behavioral disturbances.
- Physical symptoms such as muscle tension, restlessness, and becoming easily fatigued.
- Not limited to an adjustment disorder.
- Not a result of physical disorders, other psychiatric conditions (eg, schizophrenia), or drug abuse (eg, cocaine).

General Considerations

Stress, fear, and anxiety may interact. The principal components of anxiety are **psychological** (tension, fears, difficulty in concentration, apprehension) and **somatic** (tachycardia, hyperventilation, shortness of breath, palpitations, tremor, sweating). Sympathomimetic symptoms of anxiety are both a response to a CNS state and a reinforcement of further anxiety. Anxiety can become self-generating, since the symptoms reinforce the reaction, causing it to spiral. Additionally, avoidance of triggers of anxiety reinforces the anxiety. The person continues to associate the trigger with anxiety and never relearns through experience that the trigger need not always result in fear, or that anxiety will improve with prolonged exposure to an objectively neutral stressor.

Clinical Findings

A. Generalized Anxiety Disorder

Anxiety disorders are the most prevalent psychiatric disorders. About 7% of women and 4% of men will meet criteria for GAD over a lifetime. GAD becomes chronic in many patients and lasts longer than 2 years in over half of patients. Anxiety disorder in older adults is twice as common as dementia and four to six times more common than major depression; it is associated with poorer quality of life and contributes to the onset of disability. The anxiety symptoms of apprehension, worry, and difficulty controlling the worry are present more days than not for at least 6 months. Further manifestations can include restlessness, muscle tension, difficulty concentrating, sleep disturbance, and irritability.

B. Panic Disorder

Panic attacks are recurrent, unpredictable episodes of intense surges of anxiety accompanied by marked physiologic manifestations. Symptoms and signs such as dyspnea, tachycardia, palpitations, dizziness, paresthesia, choking, smothering feelings, and nausea are associated with feelings of impending doom (alarm response). These symptoms overlap with some of the complaints found in the somatic symptom disorders; however, the key to the diagnosis of panic disorder is the psychic pain and suffering the individual expresses. **Panic disorder** is diagnosed when panic attacks are accompanied by a chronic fear of the recurrence of an attack or a maladaptive change in behavior to try to avoid potential triggers of the panic attack. Recurrent **sleep panic attacks** (not nightmares) occur in about 30% of panic disorders. Persistent worry about future panic attacks develops in patients with panic disorder and further constricts their daily lives. Panic disorder tends to be familial, with onset usually under age 25; it affects 3–5% of the population, and the female-to-male ratio is 2:1. The premenstrual period is one of heightened vulnerability. Patients frequently undergo evaluations for emergent medical conditions (eg, heart attack or hypoglycemia), which are then ruled out before the correct diagnosis is made. GI symptoms (eg, stomach pain, heartburn, diarrhea, constipation, nausea, and vomiting) are common, occurring in about one-third of cases. MI, pheochromocytoma, hyperthyroidism, and various recreational drug reactions can mimic panic disorder. Patients who have panic disorder can become demoralized, hypochondriacal, agoraphobic, and depressed. These individuals are at increased risk for major depression and suicide. Alcohol abuse (in about 20%) may result from self-treatment and is frequently combined with dependence on sedatives. About 25% of patients with panic disorders also have obsessive-compulsive disorder (OCD).

C. Phobic Disorders

Simple phobias are fears of a specific object or situation (eg, spiders, height) that are out of proportion to the danger posed, which tend to be chronic. **Social phobias** are global or specific; in the former, all social situations are poorly tolerated, while the latter group includes **performance anxiety** (eg, fear of public speaking). Agoraphobia is frequently associated with panic attacks; it often develops in early adult life, potentially making activities of daily living difficult. Patients with agoraphobia experience intense fear about common situations, such as being in open spaces (eg, marketplaces), being in enclosed spaces (eg, theaters), standing in line, or being alone outside of their homes.

Treatment

In all cases, underlying medical disorders must be ruled out (eg, cardiovascular, endocrine, respiratory, and neurologic disorders and substance-related syndromes).

A. Pharmacologic

1. Generalized anxiety disorder—Antidepressants including the SSRIs and SNRIs are the first-line pharmacotherapies in the long-term management of GAD. They are as effective as benzodiazepines without the risks of tolerance or dependence. Because benzodiazepines take effect more quickly, they can be beneficial in brief acute management (Table 28–1).

Table 28–1. Commonly used antianxiety and hypnotic agents (listed in alphabetical order within classes).

Medication	Usual Daily Oral Doses	Usual Daily Maximum Doses
Benzodiazepines (used for anxiety)		
Alprazolam (Xanax)[1]	0.5 mg	4 mg
Chlordiazepoxide (Librium)[2]	10–20 mg	100 mg
Clonazepam (Klonopin)[2]	1–2 mg	10 mg
Clorazepate (Tranxene)[2]	15–30 mg	60 mg
Diazepam (Valium)[2]	5–15 mg	30 mg
Lorazepam (Ativan)[1]	2–4 mg	4 mg
Oxazepam (Serax)[1]	10–30 mg	60 mg
Benzodiazepines (used for sleep)		
Estazolam (Prosom)[1]	1 mg	2 mg
Flurazepam (Dalmane)[2]	15 mg	30 mg
Quazepam (Doral)[2]	7.5 mg	15 mg
Temazepam (Restoril)[1]	15 mg	30 mg
Triazolam (Halcion)[4]	0.125 mg	0.25 mg
Miscellaneous (used for anxiety)		
Buspirone (Buspar)[1]	10–30 mg	60 mg
Phenobarbital[2]	15–30 mg	90 mg
Miscellaneous (used for sleep)		
Eszopiclone (Lunesta)[3]	2–3 mg	3 mg
Hydroxyzine (Vistaril)[1]	50 mg	100 mg
Lemborexant (Dayvigo)	5 mg	10 mg
Ramelteon (Rozerem)	8 mg	8 mg
Suvorexant (Belsomra)	5–10 mg	20 mg
Zaleplon (Sonata)[4]	5–10 mg	10 mg
Zolpidem (Ambien)[3]	5–10 mg	10 mg

[1] Intermediate physical half-life (10–20 hours).
[2] Long physical half-life (> 20 hours).
[3] Short physical half-life (1–6 hours).
[4] Short physical half-life (about 1 hour).

Antidepressants can themselves be anxiogenic when first started—thus, at the initiation of treatment, patient education and at times concomitant short-term treatment with a benzodiazepine are indicated. Some SSRIs are specifically FDA-approved, and all are generally accepted as effective treatment. The SNRIs venlafaxine and duloxetine are approved for the treatment of GAD in usual antidepressant doses. Initial daily dosing should start low (37.5–75 mg for venlafaxine and 30 mg for duloxetine) and be titrated upward as needed. Buspirone (30–60 mg daily in divided doses) is also effective for generalized anxiety. Higher doses are sometimes associated with side effects of GI symptoms and dizziness. Patients should be advised that there is a 2- to 4-week delay before antidepressants and buspirone take full effect. Sleep is sometimes negatively affected. Bupropion may be the most anxiogenic antidepressant and does not have evidence in treatment of anxiety disorders. Gabapentin (titrated to doses of 900–1800 mg orally daily, with larger doses at night) and pregabalin appear effective but do not have FDA-approval for anxiety. Alcohol is the most frequently self-administered drug and should be strongly discouraged.

2. Panic disorder—Antidepressants are the first-line pharmacotherapy for panic disorder. Several SSRIs, including fluoxetine, paroxetine, and sertraline, are approved for treatment. The SNRI venlafaxine also is FDA-approved for treatment.

While panic disorder often responds to high-potency benzodiazepines such as clonazepam and alprazolam, these agents are best prescribed early in the course of treatment concurrently with an antidepressant. Once the antidepressant has begun fully working (after 4 or more weeks), the benzodiazepine may be tapered. Because panic disorder, like GAD, is often a chronic condition, long-term use of benzodiazepines can result in tolerance or dependance.

The longer-acting benzodiazepines are used for the treatment of anxiety symptoms and alcohol withdrawal; the intermediate medications are useful as sedatives for insomnia (eg, lorazepam), while short-acting agents (eg, midazolam) are used for medical procedures such as endoscopy. In psychiatric disorders, the benzodiazepines are usually given orally. Because lorazepam does not produce active metabolites and has a half-life of 10–20 hours, it is useful in treating older adult patients or those with liver dysfunction. Ultra–short-acting agents, such as triazolam, have half-lives of 1–3 hours and may lead to rebound withdrawal anxiety. Longer-acting benzodiazepines, such as flurazepam, diazepam, and clonazepam, produce active metabolites, have half-lives of 20–120 hours, and should be avoided in older adults; however, some clinicians prefer clonazepam because of its long half-life and thus ease of dosing to once or twice a day. Medication dosage must be individualized as patients vary widely in their response and effects can be long-lasting. An adequate and scheduled dose early in the course of symptom development will obviate the need for "pill popping," which can contribute to dependency problems.

The side effects of all the benzodiazepine antianxiety agents are patient- and dose-dependent. As the dosage exceeds the levels necessary for sedation, the side effects include disinhibition, ataxia, dysarthria, nystagmus, and delirium.

Paradoxical agitation, anxiety, psychosis, confusion, mood lability, and anterograde amnesia have been reported, particularly with the shorter-acting benzodiazepines. These agents produce cumulative clinical effects with repeated dosage (especially if the patient has not had time to metabolize the previous dose), additive effects when given with other classes of sedatives or alcohol, and residual effects after termination of treatment (particularly in the case of medications that undergo slow biotransformation).

Overdosage results in respiratory depression, hypotension, shock syndrome, coma, and death. Flumazenil, a benzodiazepine antagonist, is effective in overdosage. Overdosage (see Chapter 43) and withdrawal states are medical emergencies. Serious side effects of chronic excessive dosage are development of tolerance, resulting in increasing dose requirements, and physiologic dependence, resulting in withdrawal symptoms similar in appearance to alcohol and barbiturate withdrawal (withdrawal effects must be distinguished from reemergent anxiety). Abrupt withdrawal of sedative medications may cause serious and even fatal convulsive seizures. Psychosis, delirium, and autonomic dysfunction have also been described. Both duration of action and duration of exposure are major factors related to likelihood of withdrawal.

Common withdrawal symptoms after low to moderate daily use of benzodiazepines are classified as somatic (disturbed sleep, tremor, nausea, muscle aches), psychological (anxiety, poor concentration, irritability, mild depression), or perceptual (poor coordination, mild paranoia, mild confusion). The presentation of symptoms will vary depending on the half-life of the medication. The potential for interactions with benzodiazepines and other medications must be considered.

β-Blockers have been used in conjunction with antidepressants in resistant cases, although there are limited data to support their use. They block symptoms mediated by sympathetic stimulation (eg, palpitations, tremulousness) but not nonadrenergic symptoms (eg, diarrhea, muscle tension). Propranolol (40–160 mg/day orally) can mute the peripheral symptoms of anxiety without significantly affecting motor and cognitive performance.

3. Phobic disorders—Social phobias and agoraphobia may be treated with SSRIs, such as paroxetine, sertraline, and fluvoxamine. In addition, phobic disorders often respond to SNRIs such as venlafaxine. Gabapentin in a dosage of 300–3600 mg/day is an alternative to antidepressants. Benzodiazepines have a potential role in specific phobias such as those with flight anxiety. They may also respond to behavioral therapies such as systematic desensitization.

B. Behavioral

Behavioral approaches are widely used in various anxiety disorders, often in conjunction with medication. Relaxation techniques can sometimes be helpful in reducing anxiety. Desensitization, by exposing the patient to graded doses of a phobic object or situation, is an effective technique. Emotive imagery, wherein the patient imagines the anxiety-provoking situation while at the same time learning to relax, helps decrease the anxiety when the patient faces the real-life situation. Physiologic symptoms in panic attacks respond well to relaxation training. Both GAD and panic disorder respond as well to cognitive behavioral therapy as medications. Exercise, both aerobic and resistance training, reduces anxiety symptoms across many anxiety disorders.

C. Psychological

Cognitive behavioral therapy is the first-line psychotherapy in treatment of anxiety disorders. It includes a cognitive component of examining the thoughts associated with the fear and a behavioral technique of exposing the individual to the feared object or situation. The combination of medication and cognitive behavioral therapy is more effective than either alone. **Mindfulness meditation** can be effective in decreasing symptoms of anxiety. **Group therapy** is the treatment of choice when the anxiety is clearly a function of the patient's difficulties in dealing with social settings. **Acceptance and commitment therapy** have been used with some success in anxiety disorders. It encourages individuals to keep focused on life goals while they "accept" the presence of anxiety in their lives. **Virtual reality therapy** has similar efficacy to the other established therapies.

D. Social

Peer support groups for panic disorder and agoraphobia have been helpful. Measures such as family counseling can aid acceptance of the patient's symptoms and avoid counterproductive behavior in behavioral training. Any help in maintaining the social structure is anxiety-alleviating, and work, school, and social activities should be maintained. School and vocational counseling may be provided by professionals, who often are needed to help the clinician in defining the patient's limitations.

Prognosis

Anxiety disorders are usually long-standing and may be difficult to treat. All can be relieved to varying degrees with medications and behavioral techniques. The prognosis is better if the commonly observed anxiety-panic-phobia-depression cycle can be broken with a combination of the therapeutic interventions discussed above.

OBSESSIVE-COMPULSIVE DISORDER & RELATED DISORDERS

ESSENTIALS OF DIAGNOSIS

- Preoccupations or rituals (repetitive psychologically triggered behaviors) that are distressing to the individual.
- Symptoms are excessive or persistent beyond potentially developmentally normal periods.

General Considerations

Obsessive-compulsive disorder (OCD) is part of a separate category of Obsessive-Compulsive Disorder and Related Disorders in *DSM-5*. In OCD, the irrational idea or impulse repeatedly and unwantedly intrudes into awareness. **Obsessions** (recurring distressing thoughts, such as fears of exposure to germs) and **compulsions** (repetitive actions such as washing one's hands many times or cognitions such as counting rituals) are recognized by the individual as unwanted or unwarranted and are resisted, but anxiety often is alleviated only by ritualistic performance of the compulsion or by deliberate contemplation of the intruding idea or emotion. Some patients experience only obsessions, while some experience both obsessions and compulsions. Many patients do not volunteer the symptoms and must be asked about them. There is an overlapping of OCD with some features in other disorders ("**OCD spectrum**"), including tics, trichotillomania (hair pulling), excoriation disorder (skin picking), hoarding, and body dysmorphic disorder. The incidence of OCD in the general population is 2–3% and there is a high comorbidity with major depression: major depression will develop in two-thirds of OCD patients during their lifetime. Male-to-female ratios are similar, with the highest rates occurring in the young, divorced, separated, and unemployed. Neurologic abnormalities of fine motor coordination and involuntary movements are common. Under extreme stress, these patients sometimes exhibit paranoid and delusional thoughts, often associated with depression, that can mimic schizophrenia.

Treatment

A. Pharmacologic

OCD responds to serotonergic antidepressants including SSRIs and clomipramine in 60% of cases but usually has a longer time to response than depression (up to 12 weeks). Fluoxetine has been widely used but in doses higher than those used in depression (up to 60–80 mg orally daily). Other SSRI medications are used with comparable efficacy. Clomipramine is effective in doses equivalent to those used for depression. Plasma levels of clomipramine and its metabolite should be checked 2–3 weeks after a dosing of 50 mg/day has been achieved, with levels kept under 500 ng/mL to avoid toxicity. There is some evidence that antipsychotics, topiramate, memantine, riluzole, *N*-acetylcysteine, lamotrigine, ondansetron, and anti-inflammatory medication (minocycline, celecoxib) may be helpful as adjuncts to the SSRIs in treatment-resistant cases.

B. Behavioral

OCD may respond to a variety of behavioral techniques. One common strategy is **exposure and response prevention.** As in the treatment of simple phobias, exposure and response prevention involves gradually exposing the OCD spectrum patient to situations that the patient fears, such as perceived germs. Patients work through a list of their obsessions and compulsions with their therapist by first exposing themselves to the trigger, then working to prevent the habitual thought or compulsion that accompanies it. By gradually exposing patients to increasingly stressful situations and helping them manage their anxiety without performing the unwanted behavior, OCD spectrum patients are often able to develop some mastery over the behaviors.

C. Psychological

In addition to behavioral techniques, OCD may respond to psychological therapies including cognitive behavioral therapy in which the patient learns to identify maladaptive cognitions associated with obsessive thoughts and challenge those cognitions. These cognitions can be identified and gradually replaced with more rational thoughts. There is evidence that both cognitive behavioral therapy and exposure and response prevention and medications combined can be more effective than a single intervention alone. There is growing evidence for the use of acceptance and commitment therapy, another behavioral therapy, in reducing OCD symptoms.

D. Social

OCD can have devastating effects on the ability of a patient to lead a normal life. Educating both the patient and family about the course of illness and treatment options is extremely useful in setting appropriate expectations. Severe OCD is commonly associated with vocational disability, and the clinician may sometimes need to facilitate a leave of absence from work or encourage vocational rehabilitation to get the patient back to work.

E. Procedures

Transcranial magnetic stimulation is an effective FDA-approved therapy for treatment-resistant OCD. Psychosurgery has a limited place in selected cases of severe unremitting OCD. Experimental work suggests a role for deep brain stimulation in OCD, and it is FDA-approved on a humanitarian device exemption basis for refractory OCD patients.

Prognosis

OCD is usually a chronic disorder with a waxing and waning course. As many as 40% of patients in whom OCD problems develop in childhood will experience remission as adults. However, it is less common for OCD to remit without treatment when it develops during adulthood.

SOMATIC SYMPTOM DISORDERS (Abnormal Illness Behaviors)

ESSENTIALS OF DIAGNOSIS

- Prominent physical symptoms may involve one or more organ systems and are associated with distress, impairment, or both.
- Sometimes able to correlate symptom development with psychosocial stresses.
- Combination of biogenetic and developmental patterns.

General Considerations

Any organ system can be affected in somatic symptom disorders. In *DSM-5*, somatic symptom disorders encompass somatic disorders, including conversion disorder, hypochondriasis, somatization disorder, and pain disorder secondary to psychological factors. Vulnerability in one or more organ systems and exposure to family members with somatization problems plays a major role in the development of particular symptoms, and the "functional" versus "organic" dichotomy is a hindrance to good treatment. Clinicians should suspect psychiatric disorders in a number of somatic conditions. For example, 45% of patients describing palpitations had lifetime psychiatric diagnoses including generalized anxiety, depression, panic, and somatic symptom disorders. Similarly, 33–44% of patients who undergo coronary angiography for chest pain but have negative results have been found to have panic disorder.

In any patient presenting with a condition judged to be somatic symptom disorder, depression must be considered in the diagnosis.

Clinical Findings

A. Functional Neurologic Disorder/ Conversion Disorder

"Conversion" of psychic conflict into physical neurologic symptoms in parts of the body innervated by the sensorimotor system (eg, paralysis, aphonic) is a disorder that can occur concomitantly with panic disorder or depression. The two most common types of functional neurological disorder (FND) are motor (often, weakness) or seizure-type symptoms. The somatic manifestation that takes the place of anxiety is often paralysis, and in some instances, the dysfunction may have symbolic meaning (eg, arm paralysis in marked anger so the individual cannot use the arm to strike someone). Psychogenic nonepileptic seizures can be difficult to differentiate from intoxication states or panic attacks and can occur in patients who also have epileptic seizures. Lack of postictal confusion, closed eyes during the seizure, ictal crying, and a fluctuating course can suggest nonepileptic seizures; some symptoms such as asynchronous movements or pelvic thrusting can occur in both nonepileptic seizures and frontal lobe seizures (see also Chapter 27). La belle indifférence (an unconcerned affect) is not a significant identifying characteristic, as commonly believed, since individuals even with genuine medical illness may exhibit a high level of denial. It is important to identify physical disorders with unusual presentations (eg, multiple sclerosis, SLE).

B. Somatic Symptom Disorder

Somatic symptom disorder is characterized by one or more somatic symptoms that are associated with significant distress or disability. The somatic symptoms are associated with disproportionate and persistent thoughts about the seriousness of the symptoms, a high level of anxiety about health, or excessive time and energy devoted to these symptoms. The patient's focus on somatic symptoms is usually chronic. Panic, anxiety, and depression are often present, and major depression is an important consideration in the differential diagnosis. There is a significant relationship (20%) to a lifetime history of panic-agoraphobia-depression. It usually occurs before age 30 and is 10 times more common in women. Preoccupation with medical and surgical therapy becomes a lifestyle that may exclude other activities. Patients most often first present to primary care physicians and experience reassurance regarding their physical condition as only briefly helpful or dismissive. Patients' complaints of symptoms should always be first carefully medically evaluated.

C. Factitious Disorders

In these disorders, symptom production is *intentional*. Therefore they are not somatic symptom conditions, in contrast to the unconscious process of the other somatic symptom disorders. They are characterized by self-induced or described symptoms or false physical and laboratory findings for the purpose of deceiving clinicians or other health care personnel. The deceptions may involve self-mutilation, fever, hemorrhage, hypoglycemia, seizures, and an almost endless variety of manifestations—often presented in an exaggerated and dramatic fashion **(Munchausen syndrome). Factitious disorder imposed on another**, previously termed **Munchausen by proxy**, is diagnosed when someone (often a parent) creates an illness in another person (often a child) for perceived psychological benefit of the first person, such as sympathy or a relationship with clinicians. The duplicity may be either simple or extremely complex and difficult to recognize. The patients are frequently connected in some way with the health professions and there is no apparent external motivation other than achieving the patient role. A poor clinician-patient relationship and "doctor shopping" tend to exacerbate the problem.

Complications

Sedative and analgesic dependency is the most common iatrogenic complication. Patients may pursue medical or surgical treatments that induce iatrogenic problems. Thus, identifying patients with a potential somatic symptom disorder and attempting to limit tests, procedures, and medications that may lead to harm are quite important.

Treatment

A. Medical

Medical support with careful attention to *building a therapeutic clinician-patient relationship is the mainstay of treatment*. It must be accepted that the patient's distress is real. *Every problem not found to have an organic basis is not necessarily a mental disease*. Regular, frequent, short appointments that are not symptom-contingent may be helpful. Medications should *not* be prescribed to replace appointments. One person should be the primary clinician, and consultants should be used mainly for evaluation. An empathic, realistic, optimistic approach must be maintained in the face of the expected ups and downs. Ongoing reevaluation is necessary since somatization can coexist with a concurrent physical illness.

B. Psychological

The primary clinician can use psychological approaches when the patient is ready to make some changes in lifestyle in order to achieve symptomatic relief. This is often best approached with orientation toward pragmatic current changes rather than an exploration of early experiences that the patient frequently fails to relate to current distress. Cognitive behavioral therapy has been shown to be an effective treatment for somatoform disorders by reducing physical symptoms, psychological distress, and disability. Group therapy with other individuals who have similar problems is sometimes of value to improve coping, allow ventilation, and focus on interpersonal adjustment. There is recent evidence for the efficacy of intensive psychodynamic therapy administered in the ER to reduce somatic symptoms and reduce ER usage. Hypnosis used early can be helpful in resolving conversion disorders. If the primary clinician has been working with the patient on psychological problems related to the physical illness, the groundwork is often laid for successful psychiatric referral.

For patients who have been identified as having a factitious disorder, early psychiatric consultation is indicated. There are two main treatment strategies for these patients. One consists of a conjoint confrontation of the patient by both the primary clinician and the psychiatrist. The patient's disorder is portrayed as a cry for help, and psychiatric treatment is recommended. The second approach avoids direct confrontation and attempts to provide a face-saving way to relinquish the symptom without overt disclosure of the disorder's origin. Techniques such as biofeedback and self-hypnosis may foster recovery using this strategy.

C. Behavioral

Behavioral therapy is probably best exemplified by **biofeedback** techniques. In biofeedback, the abnormality (eg, increased peristalsis) must be recognized and monitored by the patient and therapist (eg, by an electronic stethoscope to amplify the sounds). This is immediate feedback, and after learning to recognize it, the patient can then learn to identify any change thus produced (eg, a decrease in bowel sounds) and so become a conscious originator of the feedback instead of a passive recipient. Relief of the symptom operantly conditions the patient to utilize the maneuver that relieves symptoms (eg, relaxation causing a decrease in bowel sounds). With emphasis on this type of learning, the patient is able to identify symptoms early and initiate the counter-maneuvers, thus decreasing the symptomatic problem. Migraine and tension headaches have been responsive to biofeedback methods.

Physical-based therapies such as speech/occupational/physical also have strong evidence for improving symptoms in those living with a functional neurologic disorder.

D. Social

Social endeavors include family, work, and other interpersonal activity. Family members should come for some appointments with the patient so they can learn how best to live with the patient. This is important in treatment of somatic and pain disorders. Peer support groups provide a climate for encouraging the patient to accept and live with the problem. Ongoing communication with the employer may be necessary to encourage long-term continued interest in the employee. Employers can become just as discouraged as clinicians in dealing with employees who have chronic problems.

Prognosis

The prognosis is better if the primary clinician intervenes early before the situation has deteriorated. After the problem has crystallized into chronicity, it is more difficult to effect change.

CHRONIC PAIN DISORDERS

ESSENTIALS OF DIAGNOSIS

- Chronic complaints of pain.
- Symptoms frequently exceed signs.
- Minimal relief with standard treatment.
- History of having seen many clinicians.
- Frequent use of several nonspecific medications.

General Considerations

Most clinicians are adept at dealing with acute pain problems but face greater challenges in treating chronic pain disorders. Patients with chronic pain frequently take many medications, stay in bed a great deal, have seen many clinicians, and experience little joy in work or play. Relationships suffer and life becomes a constant search for relief.

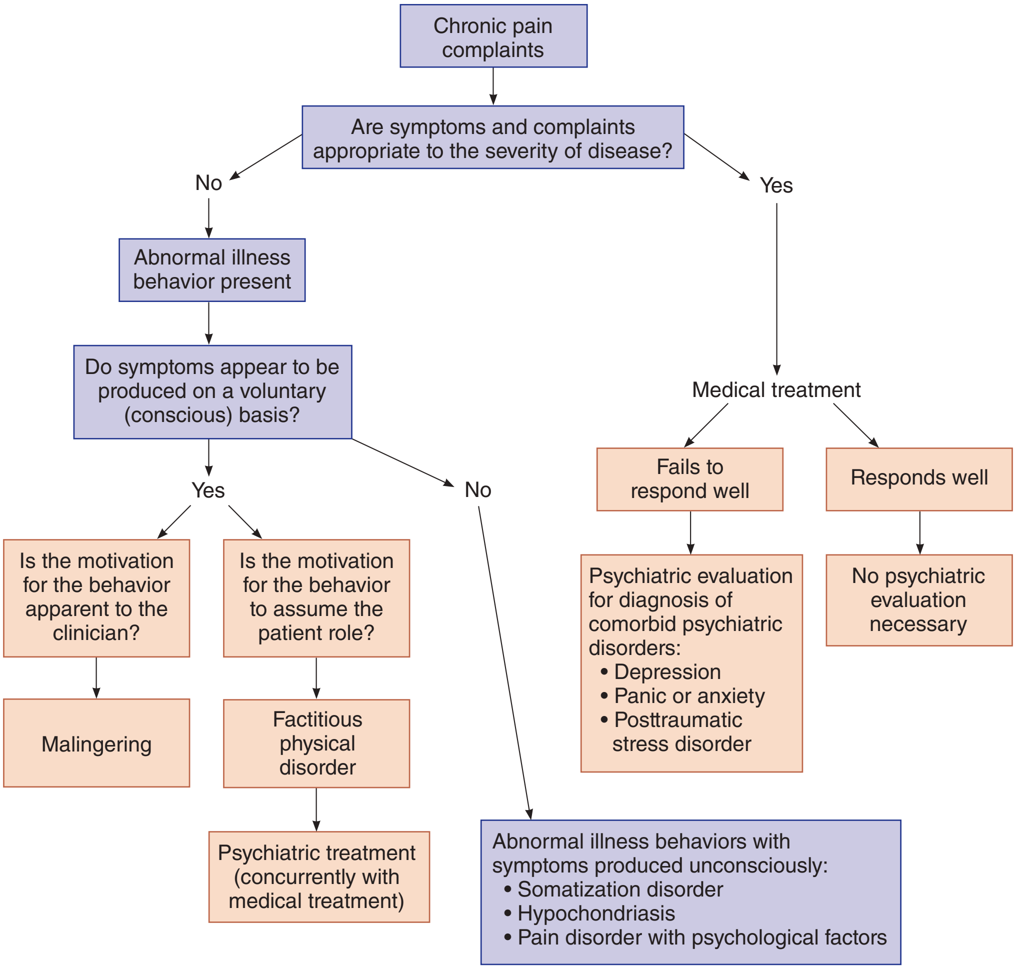
The search results in complex clinician-patient relationships. It is counterproductive to speculate about whether the pain is "real." It is real to the patient, and acceptance of the problem must precede a mutual endeavor of the patient and clinician to alleviate it. Clinicians unwittingly reinforce the sick role because of the very nature of the practice of medicine, which is to respond to complaints of illness. Helpful suggestions from the clinician are often met with responses like, "Yes, but…." Treatment therefore includes many medication trials, and failures can provoke angry responses or depression, exacerbating the pain syndrome. As medications become the principal approach to treatment, drug dependency problems may develop. The pressure on the clinician becomes wearing and often leads to covert rejection of the patient, such as not being available or making referrals to other clinicians. This is perceived by the patient, who then intensifies the effort to find help, and the typical cycle is repeated.

Clinical Findings

Components of the chronic pain syndrome consist of anatomic changes, chronic anxiety and depression, anger, and changed lifestyle. Usually, the anatomic problem is irreversible and already subjected to many interventions with increasingly unsatisfactory results. An algorithm for assessing chronic pain and differentiating it from other psychiatric conditions is illustrated in Figure 28–1.

Chronic anxiety and depression produce heightened irritability and overreaction to stimuli. A marked decrease in pain threshold is apparent. This pattern develops into a preoccupation with the body and a constant need for reassurance. Patients may start avoiding usual behaviors when they first develop the pain, and chronic avoidance of usual physical functioning can lead to the development of chronic pain.

Changes in lifestyle involve various pain behaviors. There frequently is a family script in which the patient



Chronic pain complaints
Are symptoms and complaints appropriate to the severity of disease?
No
Yes
Abnormal illness behavior present
Do symptoms appear to be produced on a voluntary (conscious) basis?
Yes
No
Is the motivation for the behavior apparent to the clinician?
Is the motivation for the behavior to assume the patient role?
Malingering
Factitious physical disorder
Psychiatric treatment (concurrently with medical treatment)
Abnormal illness behaviors with symptoms produced unconsciously:
• Somatization disorder
• Hypochondriasis
• Pain disorder with psychological factors
Medical treatment
Fails to respond well
Responds well
Psychiatric evaluation for diagnosis of comorbid psychiatric disorders:
• Depression
• Panic or anxiety
• Posttraumatic stress disorder
No psychiatric evaluation necessary

Figure 28–1. Algorithm for assessing psychiatric component of chronic pain. (Reproduced with permission from Eisendrath SJ. Psychiatric aspects of chronic pain. Neurology. 1995;45:S26–S36.)

accepts the role of being sick. This role becomes the focus of family interactions and important in maintaining the family, so that neither the patient nor the family wants the patient's role to change. Cultural factors may play a role in the behavior of the patient and how significant people around the patient cope with the problem. For example, some cultures encourage demonstrative behavior, while others value the stoic role.

Another secondary gain that can maintain the patient in the sick role is financial compensation or other benefits. Systems may be structured so that they reinforce the maintenance of sickness and discourage any attempts to give up the role.

Treatment

A. Behavioral

The cornerstone of a unified approach to chronic pain syndromes is a **comprehensive behavioral program.** This is necessary to identify and eliminate pain reinforcers, decrease medication use, and effectively use positive reinforcers that shift the focus from the pain. It is critical that the patient be made a partner in the effort to manage and function better in the setting of ongoing pain symptoms. The clinician must shift from the idea of biomedical cure to ongoing care of the patient. The patient should agree to discuss the pain only with the clinician and not with family members; this tends to stabilize the patient's personal life, since the family is usually tired of the subject.

At the beginning of treatment, the patient should be assigned self-help tasks graded up to maximal activity as a means of positive reinforcement. Avoid positive reinforcers for pain such as marked sympathy and attention to pain. Emphasize a positive response to productive activities which remove the focus of attention from the pain. Activity is desensitizing as the patient learns to tolerate increasing activity levels. The patient can keep a self-rating chart to log accomplishments and measure progress. By recording degrees of pain in relation to various situations and mental attitudes. similar circumstances can be avoided or modified.

Biofeedback techniques (see Somatic Symptom Disorders, above) and hypnosis have been successful in ameliorating some pain syndromes. Hypnosis is most effective in patients with a high level of denial, who are more responsive to suggestion. Hypnosis can be used to lessen anxiety, alter perception of the length of time that pain is experienced, and encourage relaxation. Mindfulness-based stress reduction programs may also be useful.

B. Medical

A single clinician in charge of the comprehensive treatment approach is the highest priority. Consultations as indicated and technical procedures done by others are appropriate, but the care of the patient should remain in the hands of the primary clinician. Referrals should not be allowed to raise the patient's hopes unrealistically or to become a way for the clinician to reject the case. The attitude of the clinician should be one of honesty, interest, and hopefulness—not for a cure but for control of pain and improved function. If the patient manifests opioid addiction, detoxification may be an early treatment goal.

Medical management of chronic pain is addressed in Chapter 5. The harms of opioids generally outweigh the benefits in chronic pain management. A fixed schedule lessens the conditioning effects of these medications. SNRIs (eg, venlafaxine, milnacipran, and duloxetine) and TCAs (eg, nortriptyline) in doses up to those used in depression may be helpful, particularly in neuropathic pain syndromes. Both duloxetine and milnacipran are approved for the treatment of fibromyalgia; duloxetine is also indicated in chronic pain conditions. In general, the SNRIs tend to be safer in overdose than the TCAs; suicidality is an important consideration in treating patients with chronic pain syndromes. Gabapentin and pregabalin, anticonvulsants with possible applications in the treatment of anxiety disorders, have been shown to be useful in neuropathic pain and fibromyalgia.

In addition to medications, a variety of nonpharmacologic strategies may be offered, including physical therapy and acupuncture.

C. Social

Involvement of family members and other significant persons in the patient's life should be an early priority. The best efforts of both patient and therapists can be unwittingly sabotaged by other persons who may feel that they are "helping" the patient. They frequently tend to reinforce the negative aspects of the chronic pain disorder. The patient becomes more dependent and less active, and the pain syndrome becomes an immutable way of life. The more destructive pain behaviors described by many experts in chronic pain disorders are the results of well-meaning but misguided efforts of family members. Ongoing therapy with the family can be helpful in the early identification and elimination of these behavior patterns.

D. Psychological

Cognitive behavioral therapy, acceptance and commitment therapy, and mindfulness-based therapies have evidence in treatment of chronic pain. Therapy can be used in individual or group settings. A major goal is to gain patient involvement. A group can be a powerful instrument for achieving this goal, with the development of group loyalties and cooperation. People will frequently make efforts with group encouragement that they would never make alone. Individual therapy should be directed toward strengthening existing coping mechanisms and improving self-esteem. Teaching patients to challenge expectations induced by chronic pain may lead to improved functioning. As an illustration, many chronic pain patients incorrectly believe they will damage themselves by attempting to function. The rapport between patient and clinician, as in all psychotherapeutic efforts, is a major factor in therapeutic success.

PSYCHOSEXUAL DISORDERS

The stages of sexual activity include **excitement** (arousal), **orgasm**, and **resolution**. The precipitating excitement or arousal is psychologically determined.

In a well-adjusted person, arousal stimuli lead to vasocongestive and orgasmic responses. These can be considered as separate stages that can produce different syndromes responding to different treatment procedures.

Clinical Findings

There are three major groups of sexual disorders.

A. Paraphilias

In these conditions, the excitement stage of sexual activity is associated with sexual objects or orientations different from those usually associated with adult sexual stimulation. The stimulus may be a woman's shoe, a child, animals, instruments of torture, or incidents of aggression. The pattern of sexual stimulation is usually one that has early psychological roots. When paraphilias are associated with distress, impairment, or risk of harm, they become paraphilic disorders. Some paraphilias or paraphilic disorders include exhibitionism, transvestism, voyeurism, pedophilia, incest, sexual sadism, and sexual masochism.

B. Gender Dysphoria

Gender dysphoria is distress associated with the incongruence between a person's experienced or expressed gender and a person's biological sex. As a disorder, it is defined by significant distress or impairment; those experiencing this incongruence but without the distress would *not* meet criteria for having gender dysphoria. Screening should be done for conditions related to the oppression and stigmatization that transgender people face, including a high risk of suicide.

C. Sexual Dysfunctions

This category includes a large group of vasocongestive and orgasmic disorders. Often, they involve problems of sexual adaptation, education, and technique that are often initially discussed with, diagnosed by, and treated by the primary care provider.

There are two conditions common in men: erectile dysfunction and ejaculation disturbances.

Erectile dysfunction is inability to achieve or maintain an erection firm enough for satisfactory intercourse; patients sometimes use the term incorrectly to mean premature ejaculation. Decreased nocturnal penile tumescence occurs in some depressed patients. Psychological erectile dysfunction is caused by interpersonal or intrapsychic factors (eg, partner disharmony, depression). Organic factors are discussed in Chapter 26.

Ejaculation disturbances include premature ejaculation, inability to ejaculate, and retrograde ejaculation. (Ejaculation is possible in patients with erectile dysfunction.) Ejaculation is usually connected with orgasm, and ejaculatory control is an acquired behavior that is minimal in adolescence and increases with experience. Pathogenic factors are those that interfere with learning control, most frequently sexual ignorance. Intrapsychic factors (anxiety, guilt, depression) and interpersonal maladaptation (partner problems, unresponsiveness of mate, power struggles) are also common. Organic causes include interference with sympathetic nerve distribution (often due to surgery or radiation) and the effects of pharmacologic agents (eg, SSRIs or sympatholytics).

In women, the most common forms of sexual dysfunction are orgasmic disorder and hypoactive sexual desire disorder.

Orgasmic disorder is a complex condition in which there is a general lack of sexual responsiveness. The woman has difficulty in experiencing erotic sensation and does not have the vasocongestive response. Sexual activity varies from active avoidance of sex to an occasional orgasm. **Orgasmic dysfunction**—in which a woman has a vasocongestive response but varying degrees of difficulty in reaching orgasm—is sometimes differentiated from **anorgasmia.** Causes for the dysfunctions include poor sexual techniques, early traumatic sexual experiences, interpersonal disharmony (partner struggles, use of sex as a means of control), and intrapsychic problems (anxiety, fear, guilt). Organic causes include any conditions that might cause pain in intercourse, pelvic pathology, mechanical obstruction, and neurologic deficits.

Hypoactive sexual desire disorder consists of diminished or absent libido in either sex and may be a function of organic or psychological difficulties (eg, anxiety, phobic avoidance). Any chronic illness can reduce desire as can aging. Hormonal disorders, including hypogonadism or use of antiandrogen compounds such as cyproterone acetate, and CKD contribute to deterioration in sexual desire. Alcohol, sedatives, opioids, marijuana, and some medications may affect sexual drive and performance. Menopause may lead to diminution of sexual desire in some women, and testosterone therapy is sometimes warranted as treatment.

Treatment

A. Paraphilias

1. Psychological—Paraphilias, particularly those of a more superficial nature (eg, voyeurism) and those of recent onset, are responsive to psychotherapy in some cases. The prognosis is much better if the motivation comes from the individual rather than the legal system; unfortunately, judicial intervention is frequently the only stimulus to treatment because the condition persists and is reinforced until conflict with the law occurs. Therapies frequently focus on barriers to normal arousal response; the expectation is that the variant behavior will decrease as normal behavior increases. Cognitive behavioral therapy may reduce behaviors such as compulsive pornography use.

2. Behavioral—In some cases, paraphilic disorders improve with modeling, role-playing, and conditioning procedures.

3. Social—Although they do not produce a change in sexual arousal patterns or gender role, self-help groups have facilitated adjustment to an often hostile society. Attention to the family is important in helping people in such groups to accept their situation and alleviate their guilt about the role they think they had in creating the problem.

4. Pharmacologic—Medroxyprogesterone acetate, a suppressor of libidinal drive, can be used to mute disruptive sexual behavior in men. Onset of action is usually within 3 weeks, and the effects are generally reversible. Fluoxetine or other SSRIs at depression doses may reduce some of the compulsive sexual behaviors including the paraphilias. A focus of study in the treatment of severe paraphilia has been agonists of luteinizing hormone–releasing hormone (LHRH). Case reports and open label studies suggest that LHRH-agonists may play a role in preventing relapse in some patients with paraphilia.

B. Gender Dysphoria

The Standards of Care for the Health of Transsexual, Transgender, and Gender Nonconforming People is a publication of the World Professional Association for Transgender Health (WPATH), with the goal to provide clinical guidance for health professionals to assist transsexual, transgender, and gender nonconforming people with a path to maximize their health, psychological well-being, and self-fulfillment. The standards of care are based on the best available science and expert professional consensus.

1. Psychological—Individuals with gender dysphoria often find benefit from psychotherapy, providing them with a safe place to explore and understand their thoughts and feelings, and to identify their own specific needs and desires and adjust to a changing life.

2. Social—Peer support groups, parent psychoeducation and support, and community empowerment are important social components of treatment.

3. Medical—Some individuals with gender dysphoria choose to pursue surgery or hormone therapy or both. Medical care can also include gynecologic and urologic care, reproductive options, and voice and communication therapy. Most recommendations prior to surgery include that the individual spends significant time prior living as their desired gender. Rates of suicide fall significantly after surgery but still remain much higher than the general population.

C. Sexual Dysfunction

1. Psychological—The use of psychotherapy by itself is best suited for those cases in which interpersonal difficulties or intrapsychic problems predominate. Anxiety and guilt about parental injunctions against sex may contribute to sexual dysfunction. Even in these cases, however, a combined behavioral-psychological approach usually produces results most quickly. Mindfulness may be beneficial.

2. Behavioral—Syndromes resulting from conditioned responses have been treated by conditioning techniques, with excellent results. Masters and Johnson have used behavioral approaches in all sexual dysfunctions, with concomitant supportive psychotherapy and with improvement of the communication patterns of the couple.

3. Social—The proximity of other people (eg, a mother-in-law) in a household is frequently an inhibiting factor in sexual relationships. In such cases, some social engineering may alleviate the problem.

4. Medical—Even if the condition is not reversible, identification of the specific cause helps the patient to accept the condition. Partner disharmony, with its exacerbating effects, may thus be avoided. Sildenafil, tadalafil, and vardenafil are phosphodiesterase type 5 inhibitors that are effective oral agents for the treatment of penile erectile dysfunction (eg, sildenafil 25–100 mg orally 1 hour prior to intercourse). These agents are effective for SSRI-induced erectile dysfunction in men and in some cases for SSRI-associated sexual dysfunction in women. Use of the medications in conjunction with any nitrates can have significant hypotensive effects leading to death in rare cases. Because of their common effect in delaying ejaculation, the SSRIs have been effective in premature ejaculation.

Flibanserin is a 5-HT_{1A}-agonist/5-HT_2-antagonist that is FDA-approved for the treatment of female hypoactive sexual desire disorder. Women treated with flibanserin have a marginally higher number of sexual events. Patients should be advised that flibanserin interacts with alcohol, causing hypotensive events. Flibanserin is taken 100 mg orally at bedtime to circumvent the side effects of dizziness, sleepiness, and nausea. An intranasal form that may have better bioavailability is being studied.

Bremelanotide is FDA-approved medication for the treatment of hypoactive sexual desire disorder in premenopausal women; however, the mechanism of action is unclear and subjective improvement is low. Bremelanotide is self-administered by injection to the thigh or abdomen about 45 minutes before anticipated sexual activity. Both flibanserin and bremelanotide have potentially intolerable side effects, and their usage remains low.

PERSONALITY DISORDERS

ESSENTIALS OF DIAGNOSIS

- Long history dating back to childhood.
- Recurrent maladaptive behavior.
- Difficulties with interpersonal relationships or society.
- Depression with anxiety when maladaptive behavior fails.

General Considerations

An individual's personality structure, or character, is an integral part of self-image. It reflects genetics, interpersonal influences, and recurring patterns of behavior adopted to cope with the environment. The classification of subtypes of personality disorders depends on the predominant symptoms and their severity.

Classification & Clinical Findings

See Table 28–2.

Differential Diagnosis

Patients with personality disorders tend to experience anxiety and depression when pathologic coping mechanisms fail and may first seek treatment when this occurs. Occasionally, the more severe cases may decompensate into psychosis under stress and mimic other psychotic disorders.

Treatment

Hospitalization is indicated in the case of serious suicidal or homicidal danger. In most cases, treatment can be accomplished in the day treatment center or self-help community.

Table 28–2. Personality disorders: Classification and clinical findings (listed in alphabetical order).

Personality Disorder	Clinical Findings
Antisocial	Selfish, callous, promiscuous, impulsive, unable to learn from experience, often has legal problems.
Avoidant	Fears rejection, hyperreacts to rejection and failure, with poor social endeavors and low self-esteem.
Borderline	Impulsive; has unstable and intense interpersonal relationships; is suffused with anger, fear, and guilt; lacks self-control and self-fulfillment; has identity problems and affective instability; is suicidal (a serious problem—up to 80% of hospitalized borderline patients make an attempt at some time during treatment, and the incidence of death by suicide is as high as 5%); aggressive behavior, feelings of emptiness, and occasional psychotic decompensation.
Dependent	Passive, overaccepting, unable to make decisions, lacks confidence, with poor self-esteem.
Histrionic (hysterical)	Dependent, immature, seductive, egocentric, vain, emotionally labile.
Narcissistic	Exhibitionist, grandiose, preoccupied with power, lacks interest in others, with excessive demands for attention.
Obsessive-compulsive	Perfectionist, egocentric, indecisive, with rigid thought patterns and need for control.
Paranoid	Defensive, oversensitive, secretive, suspicious, hyperalert, with limited emotional response.
Schizoid	Shy, introverted, withdrawn, avoids close relationships.
Schizotypal	Superstitious, socially isolated, suspicious, with limited interpersonal ability, eccentric behaviors, and odd speech.

A. Social

Social and therapeutic environments such as day hospitals, halfway houses, and self-help communities utilize peer “pressure” to modify the self-destructive behavior. The patient with a personality disorder often has failed to profit from experience, and difficulties with authority can impair the learning experience. The use of peer relationships and the repetition possible in a structured setting of a helpful community enhance the behavioral treatment opportunities and increase learning. When problems are detected early, both the school and the home can serve as foci of intensified social pressure to change the behavior, particularly with the use of behavioral techniques.

B. Behavioral

Dialectical behavioral therapy is a program of individual and group therapy specifically designed for patients with chronic suicidality and borderline personality disorder. It blends mindfulness and a cognitive behavioral model to address self-awareness, interpersonal functioning, affective lability, and reactions to stress.

C. Psychological

Psychological interventions can be conducted in group and individual settings. Group therapy is helpful when specific interpersonal behavior needs to be improved. This mode of treatment also has a place with so-called “acting-out” patients, ie, those who frequently act in an impulsive and inappropriate way. The group also quickly identifies the patient’s types of behavior and helps improve the validity of the patient’s self-assessment, so that the antecedents of the unacceptable behavior can be effectively handled, thus decreasing its frequency. Individual therapy should initially be supportive, ie, helping the patient to restabilize and mobilize coping mechanisms. If the individual has the ability to observe his or her own behavior, a longer-term and more introspective therapy may be warranted. Psychodynamic psychotherapy also can be an effective treatment, as can other specific forms of therapy, including transference-focused psychotherapy, mentalization-based therapy, and schema-focused therapy. The therapist must be able to handle countertransference feelings (which are frequently negative), maintain appropriate boundaries in the relationship, and refrain from premature confrontations and interpretations.

D. Pharmacologic

Pharmacotherapy can be directed to specific symptom clusters, but there is limited evidence for its efficacy in personality disorders. Antidepressants have improved anxiety, depression, and sensitivity to rejection in some patients with borderline personality disorder. SSRIs also have a role in reducing aggressive behavior in impulsive aggressive patients (eg, fluoxetine 20–60 mg orally daily or sertraline 50–200 mg orally daily). Antipsychotics may be helpful in targeting hostility, agitation, and as adjuncts to antidepressant therapy (eg, olanzapine [2.5–10 mg/day orally], risperidone [0.5–2 mg/day orally], or haloperidol [0.5–2 mg/day orally, split into two doses]). In some cases, medications are required only for several days and can be discontinued after the patient has regained a previously established level of adjustment; they can also provide ongoing support. Anticonvulsants, including carbamazepine, 400–800 mg orally daily in divided doses, lamotrigine, 50–200 mg/day, and valproate, 500–2000 mg/day, have been shown to decrease the severity of behavioral dyscontrol in some personality disorder patients. Patients with a schizotypal personality often improve with antipsychotics, while those with avoidant personality may benefit from strategies that reduce anxiety, including the use of SSRIs and benzodiazepines.

E. Neuromodulation

There is a growing body of evidence for noninvasive brain stimulation techniques, such as transcranial magnetic stimulation for treatment of some symptoms of borderline personality disorder, including mood dysregulation and impulsivity.

Prognosis

Antisocial and narcissistic categories generally have a guarded prognosis as engagement in therapy often is limited. Those patients with a history of parental abuse and a family history of mood disorder tend to have the most challenging treatments. Continued assessment of personality disorders is needed for targeting of treatments to symptoms.

SCHIZOPHRENIA SPECTRUM DISORDERS

ESSENTIALS OF DIAGNOSIS

- Social withdrawal, usually slowly progressive, with decrease in emotional expression or motivation or both.
- Deterioration in personal care with disorganized behaviors or decreased reactivity to the environment or both.
- Disorganized thinking, often inferred from speech that switches topics oddly or is incoherent.
- Auditory hallucinations, often of a derogatory nature.
- Delusions, fixed false beliefs despite conflicting evidence, frequently of a persecutory nature.

General Considerations

Schizophrenia is manifested by a massive disruption of thinking, mood, and overall behavior as well as poor filtering of stimuli. The cause of schizophrenia is believed to be multifactorial, with genetic, environmental, and neurotransmitter pathophysiologic components. There is no laboratory method for confirming the diagnosis of schizophrenia. There may or may not be a history of a major disruption in the individual's life (failure, loss, physical illness) before gross psychotic deterioration is evident.

Other psychotic disorders on this spectrum are similar to schizophrenia in their acute symptoms but have a less pervasive influence over the long term. The patient usually attains higher levels of functioning. The acute psychotic episodes tend to be less disruptive of the person's lifestyle, with a quick return to previous levels of functioning.

Classification

A. Schizophrenia

Schizophrenia is the most common of the psychotic disorders that are characterized by a loss of contact with reality. The term *psychosis* is broad and refers to having one or more of the following: paranoia, auditory hallucinations, and delusions. One percent of the population suffers from schizophrenia. Schizophrenia is a chronic disorder that is characterized by increasing social and vocational disability that begins in late adolescence or early adulthood and tends to continue through life. The average age of onset for men is 18 years and for women is 25 years. **Positive symptoms** include hallucinations, delusions, and disorganized speech, which are related to increased dopaminergic (D_2) activity in the mesolimbic region; all patients have at least one or two of these symptoms to meet criteria for diagnosis. There is often a component of paranoia and disorganized behavior. **Negative symptoms** include diminished sociability, restricted affect, and poverty of speech; these symptoms are related to decreased D_2 activity in the mesocortical system. A marked decline in the level of functioning must be present for at least 6 months from before the onset of symptoms.

B. Delusional Disorder

Delusional disorders are psychoses in which the predominant symptoms are persistent beliefs that are false (delusions) yet remain fixed despite being shown evidence that they are unfounded. Although there is minimal impairment of daily functioning and intellectual and occupational activities, social and partner functioning tends to be markedly impacted. Hallucinations are not usually present. The person may have paranoid delusions, commonly persecution, of one's partner being unfaithful, or of being related to or loved by a well-known person.

C. Schizoaffective Disorder

Schizoaffective disorders are cases that do not clearly fit either the schizophrenia or affective categories. These patients usually have affective symptoms (either a major depressive episode, manic episode, or hypomanic episode) that precede or develop concurrently with psychotic manifestations. The psychotic symptoms may linger for some time after resolution of the mood episode but do not remain permanently. Because of this, the long-term prognosis is better than for schizophrenia.

D. Schizophreniform Disorders

Schizophreniform disorders are similar in their symptoms to schizophrenic disorders except that the duration of prodromal, acute, and residual symptoms is > 1 month but < 6 months.

E. Brief Psychotic Disorders

Brief psychotic disorders are defined as psychotic symptoms lasting < 1 month. They are the result of psychological stress. The shorter duration is significant and correlates with a more acute onset and resolution as well as a much better prognosis.

Clinical Findings

A. Symptoms and Signs

The symptoms and signs of schizophrenia vary markedly among individuals as well as in the same person at different times. The patient's appearance may be bizarre, although the usual finding is mildly to moderately unkempt. Motor activity is generally reduced, although extremes ranging from catatonic stupor to frenzied excitement occur. Social behavior is characterized by marked withdrawal coupled with disturbed interpersonal relationships and a reduced ability to experience pleasure. Dependency and a poor self-image are common. Verbal utterances are variable, the language being concrete yet symbolic, with unassociated rambling statements (at times interspersed with mutism) during an acute episode. Neologisms (made-up words or phrases), echolalia (repetition of words spoken by others), and verbigeration (repetition of senseless words or phrases) are occasionally present. Affect is usually flattened, with occasional inappropriateness. Depression is present in many cases but may be less apparent during the acute psychotic episode and more obvious during recovery. Depression is sometimes confused with akinetic side effects of antipsychotic medications. Work is generally unavailable and time unfilled, providing opportunities for counterproductive activities such as drug abuse, withdrawal, and increased psychotic symptoms.

Thought content may vary from a paucity of ideas to a rich complex of delusional fantasy with archaic thinking. One frequently notes after a period of conversation that little if any information has been conveyed. Incoming stimuli produce varied responses. In some cases, a simple question may trigger explosive outbursts, whereas at other times there may be no overt response whatsoever (catatonia). When paranoid ideation is present, the patient is often irritable and less cooperative. Delusions (false beliefs) are characteristic of paranoid thinking and usually take the form of a preoccupation with the supposedly threatening behavior exhibited by other individuals. This ideation may cause the patient to adopt active countermeasures such as locking doors and windows, taking up weapons, covering the ceiling with aluminum foil to counteract radar waves, and other unusual efforts. Somatic delusions can revolve around issues of bodily decay or infestation. Perceptual distortions usually include auditory hallucinations—visual hallucinations are more commonly associated with organic mental states—and may include illusions (distortions of reality) such as figures changing in size or lights varying in intensity. Lack of humor, feelings of dread, depersonalization (a feeling of being apart from the self), and fears of annihilation may be present. Any of the above symptoms generate higher anxiety levels, with heightened arousal and occasional panic and suicidal ideation, as the individual fails to cope.

The development of the acute episode in schizophrenia frequently is the end product of a gradual decompensation. Frustration and anxiety appear early, followed by depression and alienation, along with progressive ineffectiveness in day-to-day coping. This often leads to feelings of panic and increasing disorganization, with loss of the ability to test and evaluate the reality of perceptions. The stage of so-called **psychotic resolution** includes delusions, autistic preoccupations, and psychotic insight, with acceptance of the decompensated state. The process can be complicated by using caffeine, alcohol, and other recreational drugs. Patients with schizophrenia have a shorter life expectancy than the general population and often have associated comorbid conditions such as the metabolic syndrome, which may be induced or exacerbated by the atypical antipsychotic agents.

B. Imaging

A full medical evaluation and CT scan or MRI of the brain should be considered in first episodes of psychosis to rule out organic brain conditions.

Differential Diagnosis

The diagnosis of schizophrenia is best made over time because repeated observations increase the reliability of the diagnosis. When the clinical course has been atypical, the diagnosis of schizophrenia should be reconsidered; cases initially diagnosed as schizophrenia later may be rediagnosed as bipolar disorder, which may respond to mood stabilizers rather than antipsychotics. Some manic episodes can have symptoms that overlap with schizophrenia, including thought disorder, auditory hallucinations, and delusions. However, schizophrenia is less likely to be associated with the decreased need for sleep, increase in goal-directed activity, and overconfidence, all of which are typical symptoms of mania.

Psychotic depressions, brief reactive psychosis, delusional disorder, and any illness with psychotic ideation tend to be confused with schizophrenia, partly because of the incorrect tendency to use the terms interchangeably.

In the early stages of illness, medical disorders such as thyroid dysfunction, adrenal and pituitary disorders, reactions to toxic materials (eg, mercury, PCBs), and other organic mental disorders must be ruled out. Postpartum psychosis is discussed under Mood Disorders. Complex partial seizures, especially when psychosensory phenomena are present, are an important differential consideration. Toxic drug states arising from prescription and over-the-counter medications, street drugs, and herbal products may mimic the psychotic disorders. The chronic use of amphetamines, cocaine, and other stimulants frequently produces a psychosis that is almost identical to the acute paranoid schizophrenic episode. Drug-induced psychoses can have all the positive symptoms of schizophrenia but less commonly the negative symptoms. The presence of formication (sensation of insects crawling on or under the skin) and stereotypy suggests the possibility of stimulant abuse. Phencyclidine, a common street drug, may cause a reaction that is difficult to distinguish from other psychotic disorders. Cerebellar signs, excessive salivation, dilated pupils, and increased deep tendon reflexes should alert the clinician to the possibility of a toxic psychosis. Industrial chemical toxicity (both organic and metallic), degenerative disorders, and metabolic deficiencies must be considered in the differential diagnosis.

Catatonia, a psychomotor disturbance that may involve decreased motor activity, decreased interaction, or excessive and odd motor activity, is frequently assumed to exist solely as a component of schizophrenic disorders. However, it can actually be the end product of a number of illnesses, including a number of organic conditions as well as other psychiatric disorders such as bipolar disorder. Neoplasms, viral and bacterial encephalopathies, CNS hemorrhage, metabolic derangements such as diabetic ketoacidosis, sedative withdrawal, and liver and kidney malfunction have all been implicated. It is important to realize that drug toxicity (eg, overdoses of antipsychotic medications such as fluphenazine or haloperidol) can cause catatonic syndrome, which may be misdiagnosed as a catatonic schizophrenia and inappropriately treated with more antipsychotic medication. Catatonia is also seen in other major psychiatric disorders, including bipolar disorder and major depression.

Treatment

A. Pharmacologic

Antipsychotic medications are the treatment of choice. The relapse rate can be reduced by 50% with proper maintenance therapy. Long-acting, injectable antipsychotics are used in patients who are not adherent to medication recommendations or who do not respond to oral medication, or patients who choose the ease of not taking a daily pill. Side effects are discussed below.

Antipsychotic medications include the **"typical or first-generation"** antipsychotics (haloperidol, chlorpromazine, loxapine, perphenazine, fluphenazine and dopamine [D_2]-receptor antagonists) and the **"atypical or second-generation"** antipsychotics (clozapine, risperidone, olanzapine, quetiapine, aripiprazole, ziprasidone, paliperidone, asenapine, iloperidone, lurasidone, cariprazine, and lumateperone) (Tables 28–3 and 28–4). Generally, increasing

Table 28–3. Commonly used antipsychotic medications (listed in alphabetical order).

Medication	Usual Daily Oral Dose	Usual Daily Maximum Dose[1]
Aripiprazole (Abilify)	10–15 mg	30 mg
Asenapine (Saphris)	10–20 mg	20 mg
Cariprazine (Vraylar)	1.5–6 mg	6 mg
Chlorpromazine (Thorazine; others)	100–400 mg	1 g
Clozapine (Clozaril)	300–450 mg	900 mg
Fluphenazine (Permitil, Prolixin)[2]	2–10 mg	60 mg
Haloperidol (Haldol)	2–5 mg	60 mg
Iloperidone (Fanapt)	12–24 mg	24 mg
Loxapine (Loxitane)	20–60 mg	200 mg
Lumateperone (Caplyta)	42 mg	42 mg
Lurasidone (Latuda)	40–80 mg	80 mg
Olanzapine (Zyprexa)	5–10 mg	20 mg
Olanzapine/samidorphan (Lybalvi)	5/10 mg	20/10 mg
Paliperidone (Invega)	6–12 mg	12 mg
Perphenazine (Trilafon)[2]	16–32 mg	64 mg
Pimavanserin (Nuplazid)	34 mg	34 mg
Quetiapine (Seroquel)	200–400 mg	800 mg
Risperidone (Risperdal)[3]	2–6 mg	10 mg
Thiothixene (Navane)[2]	5–10 mg	80 mg
Trifluoperazine (Stelazine)	5–15 mg	60 mg
Xanomeline/trospium (Cobenfy)	100/20 mg twice daily	125/30 mg twice daily
Ziprasidone (Geodon)	40–160 mg	160 mg

[1] Can be higher in some cases.

[2] Indicates piperazine structure.

[3] For risperidone, daily doses above 6 mg increase the risk of extrapyramidal syndrome. Risperidone 6 mg is approximately equivalent to haloperidol 20 mg.

Table 28–4. Relative potency and side effects of antipsychotic medications (listed in alphabetical order).

Medication	Chlorpromazine:Drug Potency Ratio	Anticholinergic Effects[1]	Extrapyramidal Effect[1]
Aripiprazole	1:20	1	1
Chlorpromazine	1:1	4	1
Clozapine	1:1	4	—
Fluphenazine	1:50	1	4
Haloperidol	1:50	1	4
Iloperidone	1:25	1	1
Loxapine	1:10	2	3
Lurasidone	1:5	1	2
Olanzapine	1:20	1	1
Perphenazine	1:10	2	3
Quetiapine	1:1	1	1
Risperidone	1:50	1	3
Thiothixene	1:20	1	4
Trifluoperazine	1:20	1	4
Ziprasidone	1:1	1	1

[1] 1, weak effect; 4, strong effect.

milligram potency of the typical antipsychotics is associated with decreasing anticholinergic and adrenergic side effects and increasing extrapyramidal symptoms. There appears to be similar antipsychotic efficacy for first- and second-generation antipsychotics but second-generation antipsychotics may be better tolerated with fewer extrapyramidal side effects, leading to enhanced compliance.

Clozapine, the first “atypical” (novel) antipsychotic medication developed, has dopamine (D_4) receptor–blocking activity as well as central serotonergic, histaminergic, and α-blocking activity. It is effective in the treatment of about 30% of psychoses resistant to other antipsychotic medications and may have specific efficacy in decreasing suicidality in patients with schizophrenia. Risperidone is an antipsychotic that blocks some serotonin receptors ($5\text{-}HT_2$) and D_2 receptors. Risperidone causes fewer extrapyramidal side effects than the typical antipsychotics at doses < 6 mg. It appears to be as effective as haloperidol and possibly as effective as clozapine in treatment-resistant patients without necessitating weekly white cell counts, as required with clozapine therapy. Risperidone-induced hyperprolactinemia, even on low doses, has been reported and more commonly than with other atypical antipsychotics. Risperidone is available in a long-acting injectable preparation.

Olanzapine is a potent blocker of $5\text{-}HT_2$ and dopamine D_1, D_2, and D_4 receptors. High doses of olanzapine (10–20 mg daily) appear to be more effective than lower doses. The medication is somewhat more effective than haloperidol in the treatment of negative symptoms, such as withdrawal, psychomotor retardation, and poor interpersonal relationships. It is available in an orally disintegrating form for patients who are unable to tolerate standard oral dosing and in an injectable form for the management of acute agitation associated with schizophrenia and bipolar disorder.

Quetiapine is an antipsychotic with greater $5\text{-}HT_2$ relative to D_2 receptor blockade as well as a relatively high affinity for α-1 and α-2 receptors. It appears to be as efficacious as haloperidol in treating positive and negative symptoms of schizophrenia, with fewer extrapyramidal side effects even at high doses.

Ziprasidone has both anti-dopamine receptor and anti-serotonin receptor effects, with good efficacy for both positive and negative symptoms of schizophrenia. Aripiprazole is a partial agonist at the dopamine D_2 and serotonin $5\text{-}HT_1$ receptors and an antagonist at $5\text{-}HT_2$ receptors, and it is effective against positive and negative symptoms of schizophrenia. It functions as an antagonist or agonist, depending on the dopaminergic activity at the dopamine receptors, which may decrease side effects. Aripiprazole is available as an acute injectable preparation as well as a long-term injectable preparation that is given once monthly in patients who are unable to adhere to daily oral dosing. Asenapine, approved for the treatment of schizophrenia and bipolar disorder (mixed or manic state), appears to be helpful in treating negative symptoms of schizophrenia. It is available in a transdermal form, which may reduce some side effects associated with the sublingual form. Paliperidone, the active metabolite of risperidone, is available as a capsule and a monthly injection. Lurasidone has been shown to be effective in treating acute decompensation in patients with chronic schizophrenia. Cariprazine is a partial agonist of the D_2 and D_3 receptor and is approved by the FDA for the treatment of schizophrenia and bipolar disorder. Akathisia and insomnia are among its more commonly reported side effects. Because cariprazine is not a potent D_2-antagonist, it is less likely to increase prolactin levels than most antipsychotics. Cariprazine demonstrates greater efficacy in reducing negative symptoms of schizophrenia. Lumateperone, another second-generation antipsychotic, appears to have a favorable metabolic profile and appears to act on glutamate as well as D_2 and 5-HT_2 receptors. Unlike other antipsychotics, it does not require dose titration; the starting dose of 42 mg/day is the therapeutic dose. It does not have appreciable antimuscarinic or antihistaminic properties, which reduces side effects associated with other antipsychotics such as sedation or weight gain.

In 2024, the first-in-class muscarinic M1/M4 agonist xanomeline/trospium was approved for the treatment of schizophrenia. In contrast to all other antipsychotics, it is the first agent that does not act as a dopamine or 5-HT_2 antagonist. Consequently, xanomeline/trospium does not carry many of the side effects associated with traditional antipsychotics, including extrapyramidal symptoms and metabolic complications. A muscarinic agonist, it has other possible side effects, including nausea, vomiting, constipation, abdominal pain, diarrhea, and gastroesophageal reflux. For treatment of schizophrenia, xanomeline/trospium is at least comparable to other antipsychotics in terms of both positive and negative symptoms. It may prove to be a valuable alternative for patients unable to tolerate previous antipsychotic treatments.

Beyond antipsychotics, there is mixed evidence that cannabidiol (CBD) may improve psychotic symptoms in schizophrenia.

1. Clinical indications—The antipsychotics are used to treat all forms of the schizophrenias as well as drug-induced psychoses, psychotic depression, augmentation of unipolar depression, acute mania, and the prevention of mood cycles in bipolar disorder. They are also effective in Tourette syndrome and behavioral dyscontrol in autistic patients. While frequently used to treat agitation in dementia patients, no antipsychotic has been shown to be reliably effective in this population and may increase the risk of early mortality in older adult patients with dementia. The improvement rate for treating positive symptoms with antipsychotics is about 80%. Patients whose behavioral symptoms worsen with use of antipsychotic medications may have an undiagnosed organic condition such as anticholinergic toxicity.

Symptoms that are ameliorated by these medications include hyperactivity, hostility, aggression, delusions, hallucinations, irritability, and poor sleep. Individuals with acute psychosis and good premorbid function respond quite well. The most common cause of failure in the treatment of acute psychosis is inadequate dosage, and the most common cause of relapse is noncompliance.

Although first-generation antipsychotics are efficacious in the treatment of positive symptoms of schizophrenia, such as hallucinations and delusions, second-generation antipsychotics are thought to have efficacy in reducing positive symptoms and some efficacy in treating negative symptoms. Antidepressant medications may be used in conjunction with antipsychotics if significant depression is present. Resistant cases may require concomitant use of lithium, carbamazepine, or valproic acid. The addition of a benzodiazepine medication to the antipsychotic regimen may prove helpful in treating the agitated or catatonic psychotic patient who has not responded to antipsychotics alone—lorazepam, 1–2 mg orally, can produce a rapid resolution of catatonic symptoms and may allow maintenance with a lower antipsychotic dose.

2. Dosage forms and patterns—The dosage range is quite broad (Table 28–3). For example, risperidone can be effective for some patients with psychotic features at 0.25–1 mg orally at bedtime, whereas up to 6 mg/day may be used in a young patient with acute schizophrenia. In an acutely distressed, psychotic patient one might use haloperidol, 10 mg intramuscularly, which is absorbed rapidly and achieves an initial tenfold plasma level advantage over equal oral doses. Psychomotor agitation, racing thoughts, and general arousal are quickly reduced. The dose can be repeated every 3–4 hours; when the patient is less symptomatic, oral doses can replace parenteral administration in most cases. In older adults, both atypical (eg, risperidone 0.25–0.5 mg daily or olanzapine 1.25 mg daily) and typical (eg, haloperidol 0.5 mg daily or perphenazine 2 mg daily) antipsychotics often are used effectively for behavioral control but have been linked to premature death in some cases.

After a maintenance dose has been established, most patients can then be maintained on a single daily dose, usually at bedtime. This is appropriate when the sedative effect of the medication is desired for nighttime sleep and undesirable daytime sedative effects can be avoided. For patients who experienced their first psychotic episode, medications should be tapered off after 6 months of stability and then carefully monitored; the rate of relapse is lower for first-episode patients than that of multiple-episode patients.

Psychiatric patients—particularly patients who have paranoia—often neglect to take their medication. In these patients and those who do not respond to oral medication, long-acting fluphenazine enanthate or decanoate (the latter has fewer extrapyramidal side effects) or haloperidol decanoate may be given by deep subcutaneous injection or intramuscularly in the clinician's office with efficacy lasting 7–28 days. The usual dose of the fluphenazine long-acting preparations is 25 mg every 2 weeks, but dosage varies widely from 0.5 mg monthly to 100 mg weekly. Use the smallest effective amount as infrequently as possible.

Intravenous haloperidol, the antipsychotic most commonly used by this route, is often used in critical care units in the management of agitation and delirium. Intravenous haloperidol should be given no faster than 1 mg/min to reduce cardiovascular side effects, such as torsades de pointes. ECG monitoring should be used whenever haloperidol is administered intravenously.

Several long-acting formulations of atypical antipsychotic medications also are available, including risperidone (25–50 mg intramuscularly every 2 weeks), paliperidone, aripiprazole, and olanzapine. Concomitant use of a benzodiazepine (eg, lorazepam, 2 mg orally twice daily) may permit reduction of the required dosage of oral or parenteral antipsychotic medication.

Some antipsychotic agents are available for intranasal administration, which may be less traumatic to patients than injectable forms. The intranasal form of loxapine has a more rapid onset of action for the treatment of agitation (about 10 minutes) than either intramuscular or oral antipsychotic agents. However, intranasal loxapine requires the cooperation of the patient and is more expensive than generic antipsychotic injectable preparations. Asenapine is available in a transdermal formulation.

3. Side effects—For both typical and atypical antipsychotic agents, a range of side effects are reported. The most common anticholinergic side effects include **dry mouth** (which can lead to ingestion of caloric liquids and weight gain or hyponatremia), **blurred near vision, urinary retention** (particularly in older adult men with enlarged prostates), **delayed gastric emptying, esophageal reflux, ileus, delirium**, and precipitation of **acute glaucoma** in patients with narrow anterior chamber angles. Other autonomic effects include **orthostatic hypotension** and **sexual dysfunction**—problems in achieving erection, ejaculation (including retrograde ejaculation), and orgasm in men (approximately 50% of cases) and women (approximately 30%). Delay in achieving orgasm is often a factor in medication noncompliance. **Electrocardiographic changes** occur frequently, but clinically significant arrhythmias are less common. Older adult patients and those with preexisting cardiac disease are at greater risk. The most frequently seen changes include diminution of the T wave amplitude, appearance of prominent U waves, depression of the ST segment, and prolongation of the QT interval (Table 28–5). Ziprasidone can produce QTc prolongation. A pretreatment ECG is indicated for patients at risk for cardiac sequelae (including patients taking other medications that might prolong the QTc interval). In critical care patients, torsades de pointes has been associated with the use of high-dose intravenous haloperidol (usually > 30 mg/24 hours).

Many atypical antipsychotics are associated with new-onset **diabetes, hyperlipidemia**, and **weight gain** (Table 28–5). The risk of diabetes mellitus is increased in patients taking clozapine and olanzapine. Monitoring of weight, fasting blood sugar, and lipids prior to initiation of treatment and at regular intervals thereafter is an important part of medication monitoring. The addition of metformin to olanzapine may improve drug-induced weight gain in patients with drug-naïve, first-episode schizophrenia. **Lactation and menstrual irregularities** are common. Both antipsychotic and antidepressant medications can **inhibit sperm motility. Bone marrow depression** and **cholestatic jaundice** occur rarely; these are hypersensitivity reactions, and they usually appear in the first 2 months of treatment. They subside on discontinuance of the medication. There is cross-sensitivity among all of the phenothiazines, and a medication from a different group should be used when allergic reactions occur.

Clozapine is associated with a 1.6% risk of **agranulocytosis** (higher in persons of Ashkenazi Jewish ancestry); hence, monitoring is required with weekly blood counts during the first 6 months of treatment and every other week thereafter. Before initiating clozapine, genetic testing may be considered for the *HLADQB1* allele that is associated with a 2.5 times higher risk of agranulocytosis. Clozapine has been associated with fatal myocarditis and is contraindicated in patients with severe heart disease. In addition, it lowers the seizure threshold and has many side effects, including sedation, severe constipation, hypotension, increased liver biochemical levels, hypersalivation, respiratory arrest, weight gain, and changes in both the ECG and the electroencephalogram. Adynamic ileus is a rare side effect of clozapine that can be fatal; patients should be closely monitored for constipation and treated quickly.

Photosensitivity, retinopathy, and **hyperpigmentation** are associated with use of high dosages of chlorpromazine. Patients on long-term medication should have periodic eye examinations.

The **neuroleptic malignant syndrome (NMS)** is a catatonia-like state manifested by extrapyramidal signs, blood pressure changes, altered consciousness, and hyperpyrexia; it is an uncommon but serious complication of

Table 28–5. Adverse factors associated with atypical antipsychotic medications (listed in alphabetical order).

Medication	Weight Gain	Hyperlipidemia	New-Onset Diabetes Mellitus	QTc Prolongation[1]

[1] QTc prolongation is a side effect of many medications and suggests a possible risk for arrhythmia. Prescriber's Letter 2011;18(12):271207.

antipsychotic treatment. Muscle rigidity, involuntary movements, confusion, dysarthria, and dysphagia are accompanied by pallor, cardiovascular instability, fever, pulmonary congestion, and diaphoresis and may result in stupor, coma, and death. The cause may be related to a number of factors, including poor antipsychotic medication dosage control, affective illness, decreased serum iron, dehydration, and increased sensitivity of dopamine receptor sites. Lithium in combination with an antipsychotic medication may increase vulnerability, which is already increased in patients with an affective disorder. In most cases, the symptoms develop within the first 2 weeks of antipsychotic drug treatment. The syndrome may occur with small doses of the medications. Intramuscular administration is a risk factor. Elevated creatine kinase and leukocytosis with a shift to the left are present early in about half of cases. Treatment includes controlling the fever and providing fluid support. Dopamine agonists such as bromocriptine, 2.5–10 mg orally three times a day, and amantadine, 100–200 mg orally twice a day, have also been useful. Dantrolene, 50 mg intravenously as needed, is used to alleviate rigidity (do not exceed 10 mg/kg/day due to hepatotoxicity risk). There is ongoing controversy about the efficacy of these three agents as well as the use of calcium channel blockers and benzodiazepines. ECT has been used effectively in resistant cases. Clozapine has been used with relative safety and fair success as an antipsychotic medication for patients who have had NMS.

Akathisia is the most common (about 20%) extrapyramidal symptom. It usually occurs early in treatment (but may persist after antipsychotics are discontinued) and is frequently mistaken for anxiety or exacerbation of psychosis. It is characterized by a subjective desire to be in constant motion followed by an inability to sit or stand still and consequent pacing. It may induce suicidality or feelings of fright, rage, terror, or sexual torment. Insomnia is often present. It is crucial to educate patients in advance about these potential side effects so that the patients do not misinterpret them as signs of increased illness. In all cases, reevaluate the dosage requirement or the type of antipsychotic medication. One should inquire also about cigarette smoking, which in women has been associated with an increased incidence of akathisia. Antiparkinsonism medications (such as trihexyphenidyl, 2–5 mg orally three times daily) may be helpful, but first-line treatment often includes a benzodiazepine (such as clonazepam, 0.5–1 mg orally three times daily). In resistant cases, symptoms may be alleviated by propranolol, 30–80 mg/day orally, diazepam, 5 mg orally three times daily, or amantadine, 100 mg orally three times daily.

Acute dystonias usually occur early, although a late (**tardive**) occurrence is reported in patients (mostly men after several years of therapy) who previously had early severe dystonic reactions and a mood disorder. Younger patients are at higher risk for acute dystonias. The most common signs are bizarre muscle spasms of the head, neck, and tongue. Frequently present are torticollis, oculogyric crises, swallowing or chewing difficulties, and masseter spasms. Laryngospasm is particularly dangerous. Back, arm, or leg muscle spasms are occasionally reported. Diphenhydramine, 50 mg intramuscularly, is effective for the acute crisis; one should then give benztropine mesylate, 2 mg orally twice daily, for several weeks, and then discontinue gradually. Few of the extrapyramidal symptoms require long-term use of antiparkinsonism medications.

Drug-induced parkinsonism is indistinguishable from idiopathic parkinsonism, but it is reversible, occurs later in treatment than the preceding extrapyramidal symptoms, and in some cases appears after antipsychotic withdrawal. The condition includes the typical signs of apathy and reduction of facial and arm movements (akinesia, which can mimic depression), festinating gait, rigidity, loss of postural reflexes, and pill-rolling tremor. Patients with AIDS are particularly vulnerable to extrapyramidal side effects. High-potency antipsychotics often require antiparkinsonism medications, which can provide immediate relief in the same dosages as above. The dosage of the antipsychotic drug should also be reduced. After 4–6 weeks, antiparkinsonism medications can often be discontinued with no recurrent symptoms. In any of the extrapyramidal symptoms, amantadine, 100–400 mg orally daily, may be used instead of the antiparkinsonism medications. Antipsychotic-induced catatonia is similar to catatonic stupor with rigidity, drooling, urinary incontinence, and cogwheeling. It usually responds slowly to withdrawal of the offending medication and use of antiparkinsonism agents.

Tardive dyskinesia is a syndrome of abnormal involuntary stereotyped movements of the face, mouth, tongue, trunk, and limbs that may occur after months or (usually) years of treatment with antipsychotic agents. The syndrome affects 20–35% of patients who have undergone long-term antipsychotic therapy. Predisposing factors include older age, many years of treatment, cigarette smoking, and diabetes mellitus. There are no clear-cut differences among the antipsychotic medications in the development of tardive dyskinesia. (Although the atypical antipsychotics appear to offer a lower risk of tardive dyskinesia, long-term effects have not been investigated.) However, clozapine is unique in that it has been found to treat antipsychotic-induced tardive dyskinesia. Early manifestations of tardive dyskinesia include fine worm-like movements of the tongue at rest, difficulty in sticking out the tongue, facial tics, increased blink frequency, or jaw movements of recent onset. Later manifestations may include bucco-linguo-masticatory movements, lip smacking, chewing motions, mouth opening and closing, disturbed gag reflex, puffing of the cheeks, disrupted speech, respiratory distress, or choreoathetoid movements of the extremities (the last being more prevalent in younger patients). The symptoms do not necessarily worsen even though antipsychotic medications are continued. The dyskinesias do not occur during sleep and can be voluntarily suppressed for short periods. Stress and movements in other parts of the body will often aggravate the condition.

Early signs of dyskinesia must be differentiated from similar symptoms produced by ill-fitting dentures or reversible side-effects of nonantipsychotic medications such as levodopa, TCAs, antiparkinsonism agents, anticonvulsants, and antihistamines. Other neurologic conditions such as Huntington chorea can be differentiated by history and examination.

The emphasis should be on prevention of side effects. Use the least amount of antipsychotic medication necessary to improve the psychotic symptoms. If early manifestations of dyskinesias occur, gradually discontinue antipsychotic medications, if clinically feasible. Keep the patient off the medications until reemergent psychotic symptoms dictate their resumption, at which point restart in low doses and gradually increase until there is clinical improvement. Clozapine and olanzapine appear to offer less risk of recurrence. The use of adjunctive agents such as benzodiazepines or lithium may help directly or indirectly by allowing control of psychotic symptoms with a low dosage of antipsychotics. If the dyskinesia syndrome recurs and it is necessary to continue antipsychotic medications to control psychotic symptoms, informed consent should be obtained. Vesicular monoamine transporter 2 (VMAT2) inhibitors, such as valbenazine and deutetrabenazine, amantadine, vitamin B_6, vitamin E, and propranolol all have had some usefulness in treating the dyskinetic side effects. The VMAT2 inhibitors are considered the treatment of choice for tardive dyskinesia and are the only medications FDA-approved for its treatment but are expensive and not covered by many insurance plans.

B. Social

Some individuals with a chronic psychiatric illness may have a history of repeated hospitalizations, a continued low level of functioning, and symptoms that never completely remit. Family rejection and work failure are common. In these cases, board and care homes staffed by personnel experienced in caring for psychiatric patients are most important. There is frequently an inverse relationship between stability of the living situation and the amounts of required antipsychotic medications, since the most salutary environment is one that reduces stimuli. Nonresidential self-help groups such as Recovery, Inc., should be utilized whenever possible. They provide a setting for sharing, learning, and mutual support and are frequently the only social involvement with which this type of patient is comfortable. Vocational rehabilitation and work agencies (eg, Goodwill Industries, Inc.) provide assessment, training, and job opportunities at a level commensurate with the person's clinical condition.

C. Psychological

Cognitive behavioral therapy is an efficacious augmentation strategy in the treatment of schizophrenia. It involves helping the individual challenge psychotic thinking and alters response to hallucinations. Similarly, a form of psychotherapy called acceptance and commitment therapy has shown value in helping prevent hospitalizations in schizophrenia. Cognitive remediation therapy is another approach to treatment that may help patients with schizophrenia become better able to focus their disorganized thinking. Family therapy may also help alleviate the patient's stress and to assist relatives in coping with the patient. Metacognitive training, social skills training, psychoeducation, family interventions, physical exercise, lifestyle interventions, and supported employment are all additional effective strategies. Overall, it is best to employ both medication and psychosocial services early when symptoms begin.

D. Behavioral

Hospitalization is sometimes necessary, particularly when the patient's behavior shows gross disorganization. The presence of competent family members or social support lessens the need for hospitalization, and each case should be judged individually. The major considerations are to prevent self-inflicted harm or harm to others and to provide for the patient's basic needs.

Behavioral techniques (see above) are most frequently used in therapeutic settings such as day treatment centers, but they can also be incorporated into family situations or any therapeutic setting.

E. Neuromodulation

Electroconvulsive therapy (ECT) has been effective in treating catatonia and in treating schizophrenia when used in combination with medications. There is emerging evidence for the use of transcranial magnetic stimulation for psychosis, which has limited side effects.

▶ Prognosis

For most patients with any psychosis, the prognosis is good for alleviation of positive symptoms such as hallucinations or delusions treated with medication. Negative symptoms such as diminished affect and sociability are much more difficult to treat but appear mildly responsive to atypical antipsychotics. Cognitive deficits, such as the executive dysfunction that is common to schizophrenia, also do not appear as responsive to antipsychotics as do positive symptoms. Unfortunately, both negative symptoms and cognitive deficits appear to contribute more to long-term disability than do positive symptoms. Unavailability of structured work situations and lack of family therapy or access to other social support are two other reasons why the prognosis is so guarded in such a large percentage of patients.

MOOD DISORDERS (Depression & Mania)

ESSENTIALS OF DIAGNOSIS

Present in most depressions

- Mood varies from mild sadness to intense despondency and feelings of guilt, worthlessness, and hopelessness.
- Difficulty in thinking, including inability to concentrate, ruminations, and lack of decisiveness.
- Loss of interest, with diminished involvement in work and recreation.
- Somatic complaints such as disrupted, lessened, or excessive sleep; loss of energy; change in appetite; decreased sexual drive.

Present in some severe depressions

- Psychomotor retardation or agitation.
- Delusions of a somatic or persecutory nature.
- Withdrawal from activities.
- Physical symptoms of major severity, eg, anorexia, insomnia, reduced sexual drive, weight loss, and various somatic complaints.
- Suicidal ideation.

Possible symptoms in mania

- Mood ranging from euphoria to irritability.
- Sleep disruption.
- Hyperactivity.
- Racing thoughts.
- Grandiosity or extreme overconfidence.
- Variable psychotic symptoms.

General Considerations

Depression is extremely common, with up to 30% of primary care patients having depressive symptoms. Depression may be the final expression of (1) genetic factors, (2) developmental problems (negative childhood events), or (3) psychosocial stresses (divorce, unemployment).

Mania or hypomania are hallmarks of bipolar disorder. They may occur alone or together with depression either in a mixed episode or in cyclical fashion.

Clinical Findings

There are four major types of depression, with similar symptoms in each group.

A. Adjustment Disorder with Depressed Mood

Depressed mood may occur in reaction to some identifiable stressor or adverse life situation, usually loss of a person by death (grief reaction), divorce, etc; financial reversal (crisis); or loss of an established role, such as being needed. Although sadness and grief are normal responses to loss, depression is not. The symptoms range from mild sadness, anxiety, irritability, worry, and lack of concentration, discouragement, and somatic complaints to the more severe symptoms of frank depression. When the full criteria for major depressive disorder are present, that diagnosis should be made and treatment instituted, even when there is a known stressor. One should not neglect treatment for major depression simply because it appears to be an understandable reaction to a particular stress or difficulty.

B. Depressive Disorders

The subclassifications include major depressive disorder and dysthymia.

1. Major depressive disorder—A major depressive disorder consists of a syndrome of mood, physical, and cognitive symptoms that occurs at any time of life. Complaints vary widely but frequently include a loss of interest and pleasure (**anhedonia**), withdrawal from activities, and feelings of guilt. Also included are inability to concentrate, some cognitive dysfunction, anxiety, chronic fatigue, feelings of worthlessness, somatic complaints (unexplained somatic complaints frequently indicate depression), loss of sexual drive, and thoughts of death. Unemployment has been associated with increase in depression risk. Diurnal variation with improvement as the day progresses is common. Vegetative signs that frequently occur are insomnia, anorexia with weight loss, and constipation. Occasionally, severe agitation and psychotic ideation are present. **Psychotic major depression** occurs in up to 14% of all patients with major depression and 25% of patients who are hospitalized with depression. Psychotic symptoms (delusions, paranoia) are more common in depressed persons who are older than 50 years. Paranoid symptoms may range from general suspiciousness to ideas of reference with delusions. The somatic delusions frequently revolve around feelings of impending annihilation or somatic concerns (eg, that the body is rotting away with cancer). Hallucinations are less common than unusual beliefs and tend not to occur independent of delusions.

In addition to psychotic major depression, other subcategories include **major depression with atypical features** that is characterized by hypersomnia, overeating, lethargy, and mood reactivity in which the mood brightens in response to positive events or news. **Melancholic major depression** is characterized by a lack of mood reactivity seen in atypical depression, the presence of a prominent anhedonia, and more severe vegetative symptoms. **Major depression with a seasonal onset (seasonal affective disorder)** is a dysfunction of circadian rhythms that occurs more commonly in the fall and winter months and is believed to be due to decreased exposure to full-spectrum light. Common symptoms include carbohydrate craving, lethargy, hyperphagia, and hypersomnia. **Major depression with peripartum onset** occurs during pregnancy or starts up to 4 weeks after delivery.

Half of depressions associated with the peripartum period start during pregnancy. Most women (up to 80%) experience some mild letdown of mood in the postpartum period. For some of these (10–15%), the symptoms are more severe and similar to those usually seen in serious depression, with a potential emphasis on concerns related to the baby (obsessive thoughts about harming it or inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Postpartum psychosis is much less common (< 2%), often occurs within the first 2 weeks, and requires early and aggressive management. Biologic vulnerability with hormonal changes and psychosocial stressors all play a role. The chances of a second episode are about 25% and may be reduced with prophylactic treatment.

2. Persistent depressive disorder (dysthymia)—Dysthymia is a chronic depressive disturbance. Sadness, loss of interest, and withdrawal from activities over a period of 2 or more years with a relatively persistent course are necessary for this diagnosis. Generally, the symptoms are milder but longer-lasting than those in a major depressive episode.

3. Premenstrual dysphoric disorder—Depressive symptoms occur during the late luteal phase (last 2 weeks) of the menstrual cycle. (See also Chapter 21.)

C. Bipolar Disorder

Bipolar spectrum illnesses consist of episodic mood shifts into mania, major depression, hypomania, and mixed mood states. The initial diagnosis of bipolar disorder can be difficult due to its ability to mimic aspects of many other coincident major mental health disorders and a high comorbidity with substance abuse. **Bipolar I** is diagnosed when an individual has manic episodes. For individuals who experience hypomanic episodes without frank mania as well as depressive episodes, the diagnosis is **bipolar II**.

1. Mania—A manic episode is a mood state characterized by elation or intense irritability with hyperactivity, overinvolvement in life activities, flight of ideas, easy distractibility, and little need for sleep. The overenthusiastic quality of the mood and the expansive behavior initially attract others, but the irritability, mood lability with swings into depression, aggressive behavior, and grandiosity usually lead to marked interpersonal difficulties. Activities may occur that are later regretted, eg, excessive spending, resignation from a job, a hasty marriage, sexual acting-out, and exhibitionistic behavior, with alienation of friends and family. Atypical manic episodes can include gross delusions, paranoid ideation of severe proportions, and auditory hallucinations usually related to some grandiose perception. The episodes begin abruptly (sometimes precipitated by life stresses) and may last from several days to months. Generally, the manic episodes are of shorter duration than the depressive episodes. In almost all cases, the manic episode is part of a broader bipolar disorder. Patients with four or more discrete episodes of a mood disturbance in 1 year have "**rapid cycling**." Substance abuse, particularly cocaine, can mimic rapid cycling.

2. Cyclothymic disorder—This is a chronic mood disturbance with episodes of subsyndromal depression and hypomania. The symptoms must have at least a 2-year duration and are milder than those that occur in depressive or manic episodes. Occasionally, the symptoms will escalate into a full-blown manic or depressive episode, in which case reclassification as bipolar I or II would be warranted.

D. Mood Disorders Secondary to Illness and Medications

Any illness, severe or mild, can cause significant depression. Conditions such as rheumatoid arthritis, multiple sclerosis, stroke, and chronic heart disease are likely to be associated with depression, as are other chronic illnesses. Depression is common in cancer, as well, with a particularly high degree of comorbidity in pancreatic cancer. Hormonal variations clearly play a role in some depressions. Varying degrees of depression occur at various times in schizophrenic disorders, CNS disease, and organic mental states. Alcohol dependency frequently coexists with serious depression.

Drug-induced depression has occurred with a number of medications. Corticosteroids are commonly associated with mood changes such as depression and hypomania or psychosis. Medications associated with development of depressive symptoms include digitalis, antiparkinsonian medications, retinoids, interferon, disulfiram, anticholinesterase agents, and clonidine. Stimulant use results in a depressive syndrome when the drug is withdrawn. Alcohol, sedatives, and opioids are depressants but, paradoxically, are often used by patients in self-treatment of depression.

Differential Diagnosis

Since depression may be a part of any illness—either reactively or as a secondary symptom—careful attention must be given to personal life adjustment problems and the role of medications. Schizophrenia, partial complex seizures, organic brain syndromes, panic disorders, and anxiety disorders must be differentiated. Thyroid dysfunction and other endocrinopathies should be ruled out. Malignancies are sometimes associated with depressive symptoms and may antecede the diagnosis of tumor. Strokes, particularly dominant hemisphere lesions, can occasionally present with a syndrome that looks like major depression.

Complications

The most important complication is **suicide**, which often includes elements of aggression. Suicide rates in the general population vary from 9 per 100,000 in Spain to 15 per 100,000 in the United States to 31 per 100,000 in Russia. Men over the age of 50 are more likely to die by suicide because of their tendency to use more violent means, particularly guns. Women make more attempts but are less likely to die by suicide. The suicide rate in the younger population, aged 15–35, continues to rise. Suicide rates are higher in patients with previous suicide attempts, a family history of suicide, psychiatric illness (eg, panic disorder, anxiety, severe depression), and severe medical illness.

Suicide is 10 times more prevalent in patients with schizophrenia than in the general population. Contemplation of violent methods, a humiliating social stressor, and drug use (including long-term sedative or alcohol use) contribute to impulsiveness or mood swings. Patients with cancer, respiratory illnesses, AIDS, and those being maintained on hemodialysis have higher suicide rates.

Patients confronted with acute situational problems may make suicide attempts. These situations include a recent breakup in a relationship, a major disappointment, or a stressful situation with a component of public humiliation (eg, person who has experienced cyberbullying). A suicide attempt in such cases may be an impulsive or aggressive act not associated with significant depression. Alcohol use is a significant factor in many suicide attempts.

The immediate goal of psychiatric evaluation is to assess the current suicidal risk and determine the need for hospitalization versus outpatient management. A useful question is to ask the person whether they have thoughts of no longer wanting to be around. Assessing the risk further by inquiring about intent, plans, means, and suicide-inhibiting factors (eg, strong ties to children or the church) is essential. Alcohol, hopelessness, delusional thoughts, and complete or nearly complete loss of interest in life or ability to experience pleasure are all correlated with increased risk of suicide attempts. In a patient with depression, an apparent dramatic improvement may be due to the patient's decision to die by suicide. Other high-risk individuals are those with psychotic illness who tend not to verbalize their concerns. An attempt is less likely to be suicidal if very small amounts of poison or medication were ingested or scratching of wrists was superficial, if the act was performed near others or with early notification of others, or if the attempt was arranged so that early detection would be anticipated.

The patient's current mood status is best evaluated by direct evaluation of plans and concerns about the future, personal reactions to the attempt, and thoughts about the reactions of others. The patient's immediate resources should also be assessed—people who can be significantly involved, family support, job situation, financial resources, etc. Measurement of mood is often facilitated by using a standardized instrument such as the **Hamilton** or **Montgomery-Asberg** clinician-administered rating scales or the self-administered **Quick Inventory of Depressive Symptomatology (QIDS-SR 16).** Scales allow for initial assessment as well as ongoing treatment tracking. Suicide risk can be specifically assessed using an instrument such as the **Columbia-Suicide Severity Risk Scale** (https://cssrs.columbia.edu/wp-content/uploads/C-SSRS_Pediatric-SLC_11.14.16.pdf).

If hospitalization is not indicated after a suicide attempt, the clinician must formulate and institute a treatment plan or make an adequate referral. (The National Suicide Prevention Lifeline, 1-800-273-8255, may be of assistance.) Medication should be dispensed in small amounts to at-risk patients. Although TCAs and SSRIs are associated with an equal incidence of suicide attempts, the risk of death by suicide is much higher with TCA overdose. Guns and medications should be removed from the patient's household. Driving should be cautioned against until the patient improves.

Treatment of Depression

A. Medical

Milder forms of depression usually do not require medication therapy and can be managed by psychotherapy and the passage of time. Hospitalization is necessary if suicide is a major consideration or if complex treatment modalities are required. In severe cases—particularly when vegetative signs are significant and symptoms have persisted for more than a few weeks—antidepressant medication therapy is often effective. Medication therapy is also suggested by a family history of major depression in first-degree relatives or a past history of prior episodes.

The antidepressant medications may be classified into four groups: (1) the newer antidepressants, including the SSRIs, SNRIs, and bupropion, vilazodone, vortioxetine, and mirtazapine, (2) the TCAs and clinically similar medications, (3) the MAO inhibitors (Table 28–6), and (4) stimulants. ECT and repetitive transcranial magnetic stimulation are procedural treatments for depression. These modalities are described in greater detail below.

Medication selection is influenced by the history of previous response or lack thereof if that information is available. A positive family history of response to a particular medication may suggest that the patient will respond similarly. If no background information is available, a medication such as sertraline, 25 mg orally daily and increasing gradually up to 200 mg, depending on response and side effects, or venlafaxine at 37.5 mg/day and titrated gradually, as necessary, to a maximum dose of 225 mg/day can be selected and a full trial instituted. During the medication trial, patients should be monitored for worsening mood or suicidal ideation every 1–2 weeks until week 6. The STAR*D trial suggests that if there is no response to the first medication, the best alternatives are to switch to a second agent that may be from the same or different class of antidepressant; if there is partial response to the first agent, another approach is to try augmenting it with a second agent, such as bupropion (150–450 mg/day), lithium (eg, 300–900 mg/day orally), thyroid medication (eg, liothyronine, 25–50 mcg/day orally), or a second-generation antipsychotic (eg, aripiprazole [5–15 mg/day]). The Agency for Health Care Policy and Research has produced clinical practice guidelines that outline one algorithm of treatment decisions (Figure 28–2).

Cognitive issues such as concentration and memory problems are common to depression; the evidence shows that these issues sometimes persist even after depression has remitted, with a higher risk in those individuals who have had more depressive episodes.

Psychotic depression should be treated with a combination of an antipsychotic and an antidepressant such as an SSRI at their usual doses. Mifepristone may have specific and early activity against psychotic depression. ECT is generally regarded as the single most effective treatment for psychotic depression, with remission rates between 60% and 90%.

Table 28–6. Commonly used antidepressant medications (listed in alphabetical order within classes).

Medication	Usual Daily Oral Dose (mg)	Usual Daily Maximum Dose (mg)	Sedative Effects[1]	Anticholinergic Effects[1]
SSRIs				
Citalopram (Celexa)	20	40	< 1	1
Escitalopram (Lexapro)	10	20	< 1	1
Fluoxetine (Prozac, Sarafem)	5–40	80	< 1	< 1

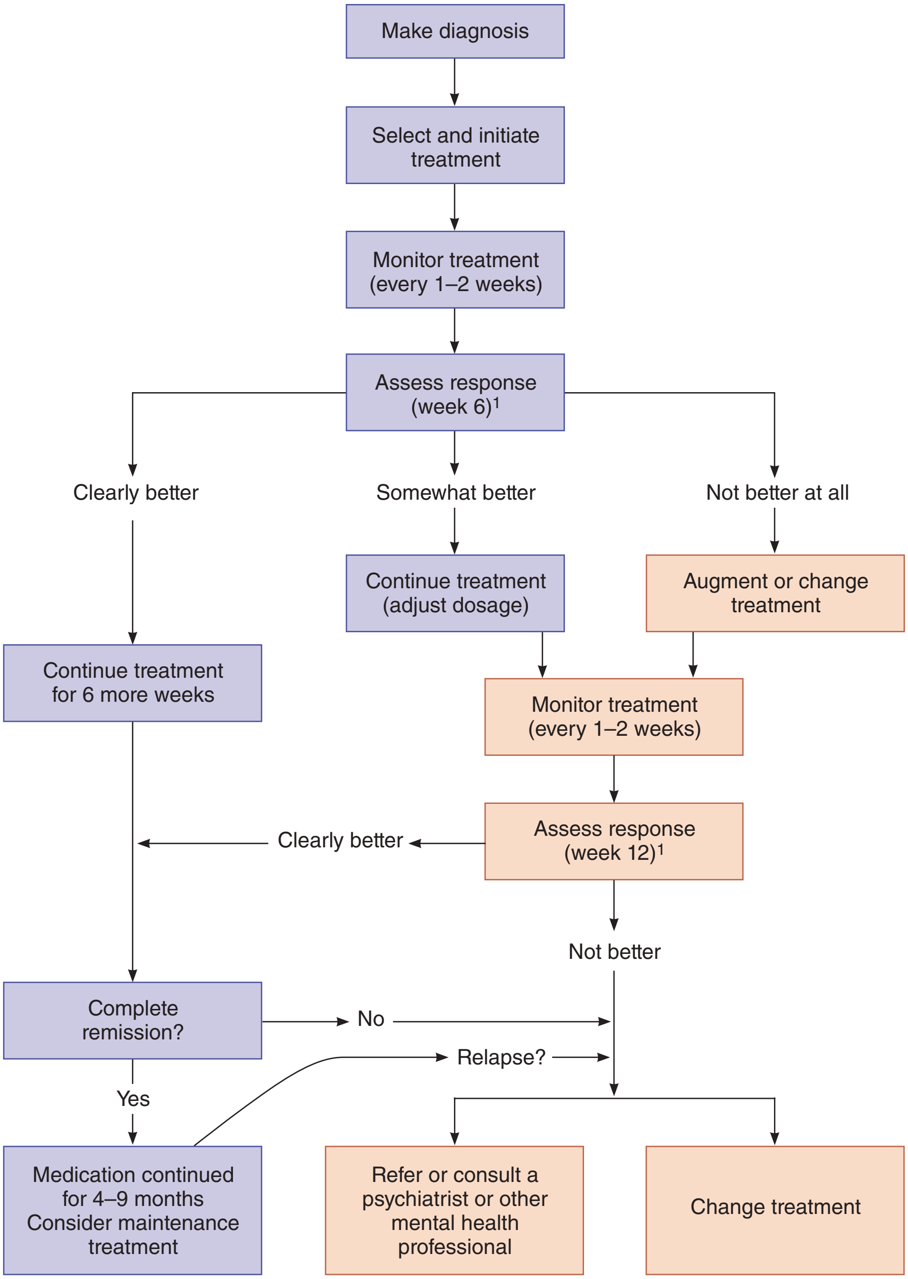
Tranylcypromine (Parnate)	20–30	50	. . .	. . .
Other Compounds				
Bupropion SR (Wellbutrin SR)	300	400[2]	< 1	< 1
Bupropion XL (Wellbutrin XL)	300[4]	450[3]	< 1	< 1
Mirtazapine (Remeron)	15–45	45	4	2
Nefazodone (Serzone)	150–600	600	3	1
Trazodone (Desyrel)	100–300	400	4	< 1
Vilazodone (Viibryd)	10–40	40	1	1
Vortioxetine (Brintellix)	10	20	< 1	< 1

[1] 1, weak effect; 4, strong effect.

[2] 200 mg twice daily.

[3] Wellbutrin XL is a once-daily form of bupropion. Bupropion is still available as immediate release, and, if used, no single dose should exceed 150 mg.



Make diagnosis
Select and initiate treatment
Monitor treatment (every 1–2 weeks)
Assess response (week 6)¹
Clearly better
Somewhat better
Not better at all
Continue treatment (adjust dosage)
Augment or change treatment
Continue treatment for 6 more weeks
Monitor treatment (every 1–2 weeks)
Clearly better
Assess response (week 12)¹
Not better
Complete remission?
No
Relapse?
Yes
Medication continued for 4–9 months Consider maintenance treatment
Refer or consult a psychiatrist or other mental health professional
Change treatment

[1] Times of assessment (weeks 6 and 12) rest on very modest data. It may be necessary to revise the treatment plan earlier for patients not responding at all.

▲ **Figure 28–2.** Overview of treatment for depression. (Reproduced from Agency for Health Care Policy and Research: Depression in Primary Care. Vol. 2: Treatment of Major Depression. United States Department of Health and Human Services, 1993.)

Major depression with atypical features or seasonal onset can be treated with bupropion or an SSRI with good results. MAO inhibitors appear more effective than TCAs, and an MAO inhibitor may be used if more benign antidepressant strategies prove unsuccessful.

Melancholic depression may respond to ECT, TCAs, and SNRIs, which are preferable to SSRIs. However, SSRIs are often used in the treatment of melancholic depression and are effective in many cases.

Depressed patients often have suicidal thoughts, and the amount of medication dispensed should be appropriately controlled particularly if prescribing an MAO inhibitor, TCA, and to a lesser extent, venlafaxine. At the same time, adults with untreated depression are at higher risk for suicide than those who are treated sufficiently to reduce symptoms. It has been thought that in children and adolescent populations, antidepressants may be associated with slightly increased risk of suicidality. One meta-analysis indicates that suicidality persists even after symptoms of depression are treated, suggesting other causes such as increased impulsivity among younger patients. After age 25, antidepressants may have neutral or possibly protective effects until age 65 years or older. The older TCAs have a narrow therapeutic index. One advantage of the newer medications is their wider margin of safety. Nonetheless, even with newer agents, because of the possibility of suicidality early in antidepressant treatment, close follow-up is indicated. In all cases of pharmacologic management of depressed states, caution is indicated until the risk of suicide is considered minimal.

1. SSRIs, SNRIs, and atypical antidepressants—SSRIs include fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram and its enantiomer escitalopram (Table 28–6). The chief advantages of these agents are that they are generally well tolerated, the starting dose is typically a therapeutic dose for most patients, and they have much lower lethality in overdose compared to TCAs or MAO inhibitors. (Citalopram carries a warning regarding QT prolongation in doses above 40 mg, and 20 mg is considered the maximum dose for patients older than 60 years. There is no similar FDA warning for escitalopram.) The SNRIs include venlafaxine, desvenlafaxine, duloxetine, milnacipran, and levomilnacipran. In addition to possessing the strong serotonin reuptake blocking properties of the SSRIs, the SNRIs are also norepinephrine reuptake blockers. The atypical antidepressants are bupropion, nefazodone, trazodone, vilazodone, vortioxetine, and mirtazapine (Table 28–6). All these antidepressants are effective in the treatment of depression, both typical and atypical. The SSRI medications have been effective in the treatment of panic disorder, bulimia, GAD, OCD, and PTSD.

Most of the medications in this group tend to be activating and are given in the morning so as not to interfere with sleep. Some patients, however, may have sedation, requiring that the medication be given at bedtime. The SSRIs can be given in once-daily dosage. Nefazodone and trazodone are usually given twice daily. Bupropion and venlafaxine are available in extended-release formulations and can be given once daily. Venlafaxine appears to be more effective with doses > 200 mg/day orally, although some individuals respond to doses as low as 75 mg/day. There may be some delay in response with medications in this group; fluoxetine, for example, requires 2–6 weeks to act in depression. The starting dose of fluoxetine (10 mg) is given for 1 week before increasing to the average daily oral dose of 20 mg for depression. Some patients, particularly older adults, may tolerate and benefit from as little as 10 mg/day or every other day. Newer medications such as intranasal esketamine and oral bupropion combined with dextromethorphan work more rapidly. Intravenous brexanolone and oral zuranolone also have more rapid efficacy than traditional antidepressants and specific efficacy for postpartum depression.

The side effects common to these medications are headache, nausea, tinnitus, insomnia, and nervousness. Akathisia has been common with the SSRIs; other extrapyramidal symptoms (eg, dystonias) have occurred infrequently but particularly in withdrawal states. Because SSRIs affect platelet serotonin levels, abnormal bleeding can occur. Sertraline and citalopram appear to be the safest agents in this class when used with warfarin. Sexual side effects of erectile dysfunction, retrograde ejaculation, and anorgasmia are very common with the SSRIs. Oral phosphodiesterase-5 inhibitors (such as sildenafil, 25–50 mg; tadalafil, 5–20 mg; or vardenafil, 10–20 mg taken 1 hour prior to sexual activity) can improve erectile dysfunction in some patients and have been shown to improve other SSRI-induced sexual dysfunction in both men and women. Adjunctive bupropion (75–150 mg orally daily) may also enhance sexual arousal. Taking a "drug holiday," ie, skipping a day of medication periodically when sexual activity is anticipated, can also decrease sexual side effects. The SSRIs are strong serotonin uptake blockers and may in high dosage or in combination with MAO inhibitors cause a **"serotonin syndrome."** This syndrome is manifested by rigidity, hyperthermia, autonomic instability, myoclonus, confusion, delirium, and coma. This syndrome can be troublesome in older adults. SSRIs are safer agents than TCAs in patients with cardiac disease.

Withdrawal symptoms, including dizziness, paresthesias, dysphoric mood, agitation, and a flu-like state, have been reported for the shorter-acting SSRIs and SNRIs but may occur with other classes including the TCAs and MAO inhibitors. These medications should be discontinued gradually over a period of weeks or months to reduce the risk of withdrawal phenomena.

Venlafaxine lacks significant anticholinergic side effects. Nausea, nervousness, and profuse sweating appear to be the major side effects. Venlafaxine appears to have few drug-drug interactions. It does require monitoring of blood pressure because dose-related hypertension may develop in some individuals. Desvenlafaxine, a newer form of the medication, is started at its target dose of 50 mg/day orally and does not require upward titration although higher doses have been well studied and some patients benefit from 100 mg/day. Duloxetine may also result in small increases in blood pressure. Common side effects include dry mouth, dizziness, and fatigue. Milnacipran, approved for the treatment of fibromyalgia, and levomilnacipran, approved for the treatment of major depression, carry many of the side effects common to other SNRIs including a mild tachycardia, hypertension, sexual side effects, mydriasis, urinary constriction, and occasional abnormal bleeding. Levomilnacipran is started at 20 mg/day orally then increased to 40 mg/day after 2–3 days. The target dose is 40–120 mg given once daily. Milnacipran is typically started at 12.5 mg/day orally, titrated to 12.5 mg twice daily after 2 days, and then to 25 mg twice daily after 7 days. The target dose is typically 100–200 mg/day given in in two divided doses. While not approved for the treatment of major depression, the evidence suggests that milnacipran, like levomilnacipran, is an effective antidepressant agent.

Nefazodone appears to lack the anticholinergic effects of the TCAs and the agitation sometimes induced by SSRIs. Because nefazodone inhibits the liver's cytochrome P450 3A4 isoenzymes, concurrent use of these medications can lead to serious QT prolongation, ventricular tachycardia, or death. Nefazodone carries an FDA warning given its association with liver failure in rare cases. Pretreatment and ongoing monitoring of liver biochemical enzymes is indicated.

Mirtazapine is thought to enhance central noradrenergic and serotonergic activity with minimal sexual side effects compared with the SSRIs. Its action as a potent antagonist of histaminergic receptors may make it a useful agent for patients with depression and insomnia. It is also an effective antiemetic due to its antagonism of the 5-HT_3 receptor. Its most common adverse side effects include somnolence, increased appetite, weight gain, lipid abnormalities, and dizziness. There is a modest association of agranulocytosis (2 of 2796 patients) or a clinically significant neutropenia. It is given in a single oral dose at bedtime starting at 15 mg and titrated up to 45 mg, although 30 mg may be optimal for most people.

Vortioxetine is an antidepressant that blocks serotonin reuptake, is a partial agonist of the 5-HT_{1A} receptor, and affects a variety of other serotonin receptor sites. The side effects attributed to its serotonergic effects include GI upset and sexual dysfunction. Vortioxetine has demonstrated efficacy in improving some cognitive symptoms of depression and received regulatory approval for this indication in Europe and the United States. Vortioxetine is typically dosed at 10 mg/day orally and may be increased to 20 mg/day.

2. Tricyclic antidepressants (TCAs) and clinically similar medications—TCAs were the mainstay of medication therapy for depression for many years. They have also been effective in panic disorder, pain syndromes, and anxiety states. Specific ones have been studied and found to be effective in OCD (clomipramine), enuresis (imipramine), psychotic depression (amoxapine), and reduction of craving in cocaine withdrawal (desipramine).

TCAs are characterized more by their similarities than by their differences. They tend to affect both serotonin and norepinephrine reuptake; some medications act mainly on the former and others principally on the latter neurotransmitter system. Individuals receiving the same dosages vary markedly in therapeutic drug levels achieved (older adult patients require smaller doses), and determination of plasma drug levels is helpful when clinical response has been disappointing. Nortriptyline is usually effective when plasma levels are between 50 and 150 ng/mL; imipramine at plasma levels of 200–250 ng/mL; and desipramine at plasma levels of 100–250 ng/mL. High blood levels are not more effective than moderate levels and may be counterproductive (eg, delirium, seizures). Patients with GI side effects benefit from plasma level monitoring to assess absorption of the drug. Most TCAs can be given in a single dose at bedtime, starting at low doses (eg, nortriptyline 25 mg orally) and increasing by 25 mg every several days as tolerated until the therapeutic response is achieved (eg, nortriptyline, 100–150 mg) or to maximum dose if necessary (eg, nortriptyline, 150 mg). The most common cause of treatment failure is an inadequate trial. A full trial consists of giving a therapeutic daily dosage for at least 6 weeks. Because of marked anticholinergic and sedating side effects, clomipramine is started at a low dose (25 mg/day orally) and increased slowly in divided doses up to 100 mg/day, held at that level for several days, and then gradually increased as necessary up to 250 mg/day. The TCAs have anticholinergic side effects to varying degrees (amitriptyline 100 mg is equivalent to atropine 5 mg). One must be particularly wary of the effect in older adult men with prostatic hyperplasia. The anticholinergic effects also predispose to other medical problems such as constipation, confusion, heat stroke, or dental problems from xerostomia. Orthostatic hypotension is common, is not dose-dependent, and may not remit with time on medication; this may predispose to falls and hip fractures in older adults.

Cardiac effects of the TCAs are functions of the anticholinergic effect, direct myocardial depression, quinidine-like effect, and interference with adrenergic neurons. These factors may produce altered rate, rhythm, and contractility, particularly in patients with preexisting cardiac disease, such as bundle-branch or bifascicular block. Even relatively small overdoses (eg, 1500 mg of imipramine) have resulted in lethal arrhythmias. Electrocardiographic changes range from benign ST segment and T wave changes and sinus tachycardia to a variety of complex and serious arrhythmias requiring a change in medication. Because TCAs have class I antiarrhythmic effects, they should be used with caution in patients with ischemic heart disease, arrhythmias, or conduction disturbances. SSRIs or the atypical antidepressants are better initial choices for this population.

TCAs lower the seizure threshold, which is of particular concern in patients with risk for seizures. Loss of libido and erectile, ejaculatory, and orgasmic dysfunction are common and can compromise compliance. Trazodone rarely causes priapism (1 in 9000), but when it occurs, it requires treatment within 12 hours (epinephrine 1:1000 injected into the corpus cavernosum). Delirium, agitation, and mania are infrequent complications of the TCAs but can occur. Sudden discontinuation of some of these medications can produce "cholinergic rebound," manifested by headaches and nausea with abdominal cramps. Overdoses of TCAs are often serious because of the narrow therapeutic index and quinidine-like effects (see Chapter 43).

3. Monoamine oxidase inhibitors—The MAO inhibitors are generally used as third-line medications for depression (after a failure of SSRIs, SNRIs, TCAs, or the atypical antidepressants) because of the dietary and other restrictions required (Table 28–7). They should be considered third-line medications for refractory panic disorder as well as depression. MAO inhibitor skin patches (selegiline) bypass the GI tract, obviating the need for dietary restrictions at the lowest dosage strength (6 mg/24 hours).

The MAO inhibitors commonly cause symptoms of orthostatic hypotension (which may persist) and

Table 28–7. Principal dietary restrictions in MAO inhibitor use.

1. Cheese, except cream cheese and cottage cheese and fresh yogurt
2. Fermented or aged meats such as bologna, salami
3. Broad bean pods such as Chinese bean pods
4. Liver of all types
5. Meat and yeast extracts
6. Red wine, sherry, vermouth, cognac, beer, ale
7. Soy sauce, shrimp paste, sauerkraut

sympathomimetic effects of tachycardia, sweating, and tremor. Nausea, insomnia (often associated with intense afternoon drowsiness), and sexual dysfunction are common. CNS effects include agitation and toxic psychoses. Dietary limitations (see Table 28–7) and abstinence from medication products containing phenylpropanolamine, phenylephrine, meperidine, dextromethorphan, and pseudoephedrine are mandatory for MAO-A type inhibitors (those marketed for treatment of depression), since the reduction of available MAO leaves the patient vulnerable to exogenous amines (eg, tyramine in foodstuffs).

4. Other medications—Dextroamphetamine (5–30 mg/day orally) and methylphenidate (10–45 mg/day orally) may be effective for the short-term treatment of some depressive symptoms in medically ill and geriatric patients. The stimulants are notable for rapid onset of action (hours) and a paucity of side effects (tachycardia, agitation) in most patients. They are usually given in two divided doses early in the day (eg, 7 AM and noon) so as to avoid interfering with sleep. These agents may also be useful as adjunctive agents in refractory depression. Intravenous infusion of the dissociative anesthetic ketamine has been shown to lead to a rapid improvement in depressive symptoms in 50–70% of patients with depression. The effects of a single treatment are short-lived (about 3–7 days). Esketamine nasal spray is approved for the treatment of depression for patients who have been inadequately treated by two other antidepressant medications. However, long-term use of esketamine or ketamine may increase the risk of abuse and longer-term impacts on mood and suicidality.

Allopregnanolone, a neurosteroid, is an allosteric modulator of GABA-a receptors and is approved for the treatment of postpartum depression. Like ketamine, allopregnanolone is administered intravenously, and the antidepressant effects are rapid. The most common side effects of allopregnanolone are headache, dizziness, and somnolence. There is a rare side effect of loss of consciousness that requires the infusion be monitored in a health care facility.

5. Switching and combination therapy—If there has been a partial response, evidence supports medication augmentation. If the therapeutic response has been poor after an adequate trial with the chosen medication, the diagnosis should be reassessed. Assuming that the trial has been adequate and the diagnosis is correct, a trial with a second medication is appropriate. In switching from one group to another, an adequate "washout time" must be allowed. This is critical in certain situations—eg, in switching from an MAO inhibitor to a TCA, allow 2–3 weeks between stopping one medication and starting another; in switching from an SSRI to an MAO inhibitor, allow 4–5 weeks for fluoxetine and at least 2 weeks for other SSRIs. In switching within groups—eg, from one TCA to another (amitriptyline to desipramine, etc)—no washout time is needed, and one can rapidly decrease the dosage of one medication while increasing the other. In clinical practice, adjunctive treatment with lithium, buspirone, or thyroid hormone may be helpful in depression. The adjunctive use of low-dose atypical antipsychotics such as aripiprazole, olanzapine, and quetiapine in the treatment of patients with refractory depression may be helpful. The side effect risk is the same as when treating psychosis. Adding an atypical agent requires monitoring BMI, lipids, and glucose. Combining two antidepressants or adding an antipsychotic to an antidepressant requires caution and is usually reserved for clinicians who feel comfortable managing this or after psychiatric consultation.

6. Maintenance and tapering—When clinical relief of symptoms is obtained, medication is continued for 6–12 months in the same dosage required in the acute stage. Although there is a higher risk of relapse after tapering off medication, there is evidence that cognitive behavioral therapy can prevent symptom relapse and the need for long-term medication. The full dosage should be continued indefinitely when the individual has had three episodes. Major depression generally should be considered a chronic/intermittent disease with most patients having relapses in time and some patients never fully recovering from a depressive episode. If the medication is being tapered, it should be done gradually over several months, monitoring closely for relapse.

7. Drug interactions—There are numerous possible drug interactions that prescribers should consider. Review of potential drug interactions with available online tools or a pharmacist is recommended.

8. Electroconvulsive therapy—ECT is the most effective (about 45–85% remission rate) treatment of severe depression. The mechanism of action is not known, but it is thought to involve major neurotransmitter responses at the cell membrane. In treatment-resistant depression, remission rates from ECT are lower (around 48%). It is particularly effective for the delusions and agitation commonly seen with depression in older adults. It is indicated when medical conditions preclude the use of antidepressants, with nonresponsiveness to these medications, and for extreme suicidality. Comparative controlled studies of ECT in severe depression show that it is more effective than pharmacotherapy. It is also effective in the treatment of mania and catatonia. It has also been shown to be helpful in chronic schizophrenic disorders when clozapine alone is not fully effective.

The most common side effects of ECT are memory disturbance and headache. Memory loss or confusion is usually related to the number and frequency of ECT treatments and proper oxygenation during treatment.

Unilateral ECT is associated with less memory loss than bilateral ECT. Both anterograde and retrograde memory loss may occur, but short-term anterograde memory loss is more common. While some memory deficits may persist, memory loss tends to improve in a few weeks after the last ECT treatment.

Increased intracranial pressure is a contraindication. Other problems such as cardiac disorders, aortic aneurysms, bronchopulmonary disease, and venous thrombosis must be evaluated in light of the severity of the medical problem versus the need for ECT. Serious complications arising from ECT occur in fewer than 1 in 1000 cases. Most of these problems are cardiovascular or respiratory in nature (eg, aspiration of gastric contents, arrhythmias, MI). Poor patient understanding and lack of acceptance of the technique by the public are some of the biggest obstacles to the use of ECT.

9. Phototherapy—Phototherapy is used in major depression with seasonal onset. It consists of indirect eye exposure to a light source of > 2500 lux for 2 hours daily or 10,000 lux for 20 minutes daily to increase the photoperiod of the day. Light visors are an adaptation that provides greater mobility and an adjustable light intensity but may not be as effective.

10. Repetitive transcranial magnetic stimulation—Repetitive transcranial magnetic stimulation (rTMS) delivers electromagnetic pulses to the prefrontal cortex. It is approved by the FDA for individuals who have not tolerated or responded to at least one or more standard antidepressant medications. Traditionally delivered in a course of 30 sessions over 6 weeks, rTMS does not require general anesthesia and is not associated with cognitive side effects. Several meta-analyses have demonstrated that in nonpsychotic depression, rTMS is noninferior to ECT. The most common side effects are scalp sensitivity under the coil and transient headache. A rapid acting form of rTMS is approved that is delivered over 5 days, termed "SAINT" (Stanford Accelerated Intelligent Neuromodulation Therapy).

11. Other treatments—Vagus nerve stimulation has shown promise in about one-third of extremely refractory cases and is approved by the FDA. Data have demonstrated that the effects plateau around 18 months to 2 years and are durable at 5 years.

B. Psychological

It is often challenging to engage an individual in psychotherapeutic endeavors during the acute stage of a severe depression. While medications may be taking effect, a supportive and behavioral approach to strengthen existing coping mechanisms and appropriate consideration of the patient's continuing need to function at work, to engage in recreational activities, etc, are necessary as the severity of the depression lessens. Therapy during or just after the acute stage may focus on coping techniques, with practice of alternative choices. Depression-specific psychotherapies improve self-esteem, increase assertiveness, and lessen dependency. Interpersonal psychotherapy has shown efficacy in the treatment of acute depression, helping patients master interpersonal stresses and develop new coping strategies. Cognitive behavioral therapy for depression addresses patients' patterns of negative thoughts, called cognitive distortions, which lead to feelings of depression and anxiety. Treatment usually includes homework assignments such as keeping a journal of cognitive distortions and of positive responses to them. The combination of medication therapy plus interpersonal psychotherapy or cognitive behavioral therapy is generally more effective than either modality alone. It is sometimes helpful to involve the spouse or other significant family members early in treatment. Mindfulness-based cognitive therapy is as effective as maintenance medication in preventing relapse. This therapy incorporates meditation and teaches patients to distance themselves from depressive thinking.

C. Social

Flexible use of appropriate social services can be of major importance in the treatment of depression. Since alcohol abuse is often associated with depression, early involvement in alcohol treatment programs such as Alcoholics Anonymous can be important to future success (see Chapter 48). The structuring of daily activities during severe depression is often quite difficult for the patient, and loneliness is often a major factor. The help of family, employer, or friends is often necessary to mobilize the patient who experiences no joy in daily activities and tends to remain uninvolved and to deteriorate. Insistence on sharing activities will help involve the patient in simple but important daily functions. In some severe cases, the use of day treatment centers or support groups of a specific type (eg, mastectomy groups) is indicated. It is not unusual for a patient to have multiple legal, financial, and vocational problems requiring legal and vocational assistance.

D. Behavioral

When depression is a function of self-defeating coping techniques such as passivity, the role-playing approach can be useful. Behavioral techniques, including desensitization, may be used in problems such as phobias where depression is a by-product. When depression is a regularly used interpersonal style, behavioral counseling to family members or others can help in extinguishing the behavior in the patient. Behavioral activation, a technique of motivating depressed patients to begin engaging in pleasurable activities, has been shown to be a useful depression-specific psychotherapy. Exercise, especially aerobic and supervised by exercise professionals, has evidence in improving depressive symptoms.

▶ Treatment of Bipolar Disorder, Manic & Depressive Episodes

Acute manic or hypomanic symptoms will respond to the mood stabilizers lithium or valproic acid after several days of treatment. Antipsychotics may be used as well for mania. High-potency benzodiazepines (eg, clonazepam) may also be useful adjuncts in managing the agitation and sleep disturbance that are features of manic and hypomanic episodes.

A. Antipsychotics

Acute manic symptoms may be treated initially with a second-generation antipsychotic such as olanzapine (eg, 5–20 mg orally), risperidone (2–3 mg orally), or aripiprazole (15–30 mg) in conjunction with a benzodiazepine if indicated. Alternatively, when behavioral control is immediately necessary, olanzapine in an injectable form (2.5–10 mg intramuscularly) or haloperidol, 5–10 mg orally or intramuscularly repeated as needed until symptoms subside, may be used. The dosage of the antipsychotic may be gradually reduced after lithium or another mood stabilizer is started. Olanzapine, quetiapine, ziprasidone, aripiprazole, and the long-acting injectable risperidone are approved as maintenance treatments for bipolar disorder to prevent subsequent cycles of both mania and depression. Antipsychotic medications are FDA-approved medications for treatment of bipolar depression, including quetiapine, lurasidone, fluoxetine/olanzapine combination, cariprazine, and lumateperone. There is also strong evidence for tamoxifen, typically a breast cancer treatment, in treatment of mania. Its mechanism may be inhibition of protein kinase C.

B. Valproic Acid

Valproic acid (divalproex) is a first-line treatment for mania. This issue is particularly important in patients living with AIDS or other medically ill patients prone to dehydration or malabsorption with wide swings in serum lithium levels. Valproic acid has also been used effectively in panic disorder and migraine headache. Treatment is often started at a dose of 750 mg/day orally and titrated to achieve therapeutic serum levels. GI symptoms and weight gain are the main side effects. Liver enzyme biochemical tests, CBCs, glucose levels, and weight should be monitored at 2 weeks, 4 weeks, and 3 months initially and annually or more frequently thereafter based on clinical judgment. Significant teratogenic effects are a concern so pregnancy should be ruled out prior to initiation. Alternatives to valproate should be considered in individuals of childbearing years who might become pregnant.

C. Lithium

Lithium significantly decreases the frequency and severity of both manic and depressive attacks in about 50–70% of patients and is FDA-approved for maintenance and manic episodes.

In addition to its use in bipolar disorder, lithium is sometimes useful in the prophylaxis of recurrent unipolar depressions and in lowering the risk of suicide. Lithium may ameliorate nonspecific aggressive behaviors and dyscontrol syndromes. Many patients with bipolar disease can be managed long-term with lithium alone, although some will require continued or intermittent use of an antipsychotic or lamotrigine to help prevent depressive episodes. An excellent resource for information is the Lithium Information Center (https://www.uwhealth.org/health/topic/multum/lithium/d00061a1.html).

Before treatment, the clinical workup should include a medical history and physical examination; CBC; T_4, TSH, BUN, serum creatinine, and serum electrolyte determinations; UA; and ECG (in patients age > 45 or with a history of cardiac disease).

1. Dosage—The common starting dosage of lithium carbonate is 300–900 mg daily, usually administered in split dosing twice daily, with trough blood levels measured after 4–5 days of treatment and after changes in dose. Blood for lithium levels should be drawn 12 hours after the last dose. A slow-release form or units of different dosage may be used. Lithium citrate is available as a syrup. Dosing for acute manic episodes is adjusted to achieve therapeutic trough ranges from 0.8 mEq/L to 1.2 mEq/L.

For maintenance treatment, lithium levels should be monitored initially every 1–2 months but may be measured every 6–12 months in stable, long-term patients. For long-term maintenance therapy, many clinicians reduce the medication to achieve trough levels of 0.6–1 mEq/L in order to reduce side effects. Levels should be monitored more closely when there is any condition that causes volume depletion (eg, diarrhea, dehydration, use of diuretics). Once-a-day dosage is acceptable for maintenance therapy.

2. Side effects—Early side effects, which are usually transient, may include mild GI symptoms (take with food and in divided doses), fine tremors (treat with propranolol, 20–60 mg/day orally, only if persistent), slight muscle weakness, and somnolence. Moderate polyuria (reduced renal responsiveness to ADH) and polydipsia (associated with increased plasma renin concentration) are often present. This effect may be blunted by once-daily dosing and potassium administration. Weight gain and leukocytosis can occur.

Thyroid side effects include goiter (3%; often euthyroid) and hypothyroidism (10%). Concomitant administration of lithium with iodide or carbamazepine enhances the hypothyroid and goitrogenic effects. Lithium-induced hypothyroidism may be treated with thyroid hormone while continuing lithium therapy. Changes in glucose tolerance, nephrogenic diabetes insipidus, nephrotic syndrome, edema, folate deficiency, and pseudotumor cerebri can occur. Thyroid and kidney function should be checked at 4- to 6-month intervals. Hypercalcemia and elevated parathyroid hormone levels occur in some patients. Electrocardiographic abnormalities (principally T wave flattening or inversion) may occur during lithium administration but are not of major clinical significance. Sinoatrial block may occur, particularly in older adults. Most side effects subside when lithium is discontinued; when residual side effects exist, they are usually not serious.

Side effects from long-term lithium therapy include the development of cogwheel rigidity and, occasionally, other extrapyramidal signs. Lithium-induced delirium with therapeutic lithium levels is an infrequent complication usually occurring in older adults and may persist for several days after serum levels have become negligible. Encephalopathy has occurred in patients receiving combined lithium and antipsychotic therapy and in those who have cerebrovascular disease, thus requiring careful evaluation of patients who develop neurotoxic signs at subtoxic blood levels.

Long-term use of lithium may have adverse effects on kidney function. Persistent polyuria should require an investigation of the kidney's ability to concentrate urine. A rise in serum creatinine levels is an indication for in-depth evaluation of kidney function and consideration of alternative treatments.

Lithium exposure in early pregnancy minimally increases the frequency of rare congenital anomalies. Mothers who take lithium should use formula to feed their newborn, since concentration in breast milk is one-third to half that in serum.

Toxicity usually occurs at blood lithium levels > 2 mEq/L. Because sodium and lithium are reabsorbed at the same loci in the proximal renal tubules, any sodium loss (diarrhea, use of diuretics, or excessive perspiration) increases lithium levels. Symptoms and signs include vomiting and diarrhea. Other symptoms and signs include tremors, muscle weakness, confusion, dysarthria, vertigo, choreoathetosis, ataxia, hyperreflexia, rigidity, lack of coordination, myoclonus, seizures, opisthotonos, and coma. Toxicity is more severe in older adults, who should be maintained on slightly lower serum levels. Significant overdoses of lithium are typically managed with hemodialysis since the medication is excreted completely by the kidneys.

See Chapter 43 for the treatment of patients with massive ingestions of lithium or blood lithium levels > 2.5 mEq/L.

3. Drug interactions—Patients receiving lithium should use diuretics with caution and only under close medical supervision. The thiazide diuretics cause increased lithium reabsorption from the proximal renal tubules, resulting in increased serum lithium levels and adjustment of lithium intake must be made to compensate for this. Potential drug interactions of lithium with other medications should be considered; consultation with a pharmacist or online drug interaction tools is recommended.

D. Carbamazepine

Carbamazepine is used in the treatment of bipolar patients who cannot be satisfactorily treated with lithium (nonresponsive, excessive side effects, or rapid cycling). It is often effective at 800–1600 mg/day orally. It has also been used in the treatment of trigeminal neuralgias and alcohol withdrawal as well as in patients with behavioral dyscontrol. It has been used to treat residual symptoms in previous stimulant abusers (eg, PTSD with impulse control problems). Dose-related side effects include sedation and ataxia. Dosages start at 400–600 mg orally daily and are increased slowly to therapeutic levels. Skin rashes and a mild reduction in white count are common. SIADH secretion occurs rarely. Carbamazepine can be effective in conjunction with lithium, although there have been reports of reversible neurotoxicity with the combination. It also lowers T_4, free T_4, and T_3 levels. Cases of fetal malformation (particularly spina bifida) have been reported along with growth deficiency and developmental delay. Liver biochemical tests and CBCs should be monitored in patients taking carbamazepine. Screening for the HLA-B1502 allele in the Han Chinese population and the HLA-A3101 allele in northern Europeans may help target individuals more susceptible to a serious rash. Oxcarbazepine may have efficacy in acute mania and is a safer alternative to carbamazepine due to its lower risk of hepatotoxicity.

E. Lamotrigine

Lamotrigine is FDA-approved for the maintenance treatment of bipolar disorder. Two double-blind studies support its efficacy in the treatment of acute bipolar depression as adjunctive therapy or as monotherapy, but several other controlled studies failed to demonstrate benefit. Lamotrigine has not proven effective in the management of acute mania. More frequent mild side effects include headache, dizziness, nausea, and diplopia. Any new rash associated with lamotrigine use should be evaluated by a dermatologist. Rashes occur in 10% of patients and may be an indication for immediate cessation of dosing, since lamotrigine has been associated with Stevens-Johnson syndrome (1:1000) and toxic epidermal necrolysis. If the rash is associated with systemic symptoms including fever, lymphadenopathy, and oral mucosa ulcerations, the medication should be stopped and the patient sent to an emergency department. Dosing starts at 25–50 mg/day orally and is titrated upward slowly to decrease the likelihood of rash.

▶ Prognosis

Most depressive episodes are usually time-limited, and the prognosis with treatment is good if a pathologic pattern of adjustment does not intervene. Major affective disorders frequently respond well to a full trial of medication treatment. However, at least 20% of patients will have a more chronic illness lasting two or more years. Many patients do not sustain a complete remission of symptoms and most depressive episodes recur. At least 80% of patients who have a single major depressive episode will have one or more recurrences within 15 years of the index episode. Many patients, therefore, require long-term maintenance therapy with antidepressants.

Mania has a good prognosis with adequate treatment, although patient adherence to treatment is often quite challenging. Many patients with bipolar disorder require treatment with two or more medications such as lithium, antipsychotics, and sleeping agents. Breakthrough manic or depressive episodes are common, even with adherence to maintenance treatments, although maintenance therapy lessens the risk of recurrent episodes.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

ESSENTIALS OF DIAGNOSIS

- Persistent patterns of inability to sustain attention, excessive motor activity/restlessness/impulsivity, or both.
- Symptoms interfere with daily functioning.
- Symptoms began prior to age 12 and in at least two settings (ie, school/work, home, with friends/family).

Clinical Findings

Attention-deficit/hyperactivity disorder (ADHD) begins in childhood; however, symptoms persist into adulthood in two-thirds of patients, with half of those still requiring medication. The prevalence of ADHD in adults is estimated to be 4–5%. In some patients, ADHD was not diagnosed during childhood because they have not presented for assessment or were able to compensate for symptoms. The presenting symptoms in adulthood tend to be inattention, restlessness, and impulsivity, whereas hyperactivity has often improved. At least five inattention symptoms (such as making careless mistakes, being easily sidetracked, trouble keeping deadlines or with organization, losing belongings, being forgetful in daily chores/tasks) are required to meet criteria for this subtype of ADHD, or five hyperactivity/impulsivity symptoms (such as feeling restless and leaving a seat though expected to remain, feeling "driven by a motor," interrupting others, cannot wait his or her turn) for this subtype. It is often useful to have patients provide questionnaires to other adult observers, including those who knew them during childhood, such as parents. This collateral data can help prevent diagnosing ADHD in someone who is seeking stimulants but without symptomatology as well as aid in making the diagnosis, since evidence shows that many adults who do have ADHD underreport symptoms.

Treatment

A. Pharmacologic

Stimulants such as methylphenidate and amphetamine are the most effective treatment. These come in short-acting and long-acting formulations. Caution should be used prior to prescribing these mediations to assess for potential substance abuse or diversion as well as for comorbid mood disorders that may not respond well to a stimulant. Atomoxetine and viloxazine are nonstimulants that are second-line FDA-approved agents for ADHD. Bupropion also has evidence of efficacy and may be considered in patients in whom a stimulant is contraindicated or in those who also suffer from major depression. Desipramine can be effective for ADHD and may be considered in patients who have additional needs, such as a concomitant depression or neuropathic pain.

B. Behavioral and Other Treatments

Psychoeducation regarding ADHD should be given to all patients. Many patients are able to implement behavioral changes that either improve their functioning, such as creating calendars and organizational schemes or doing tasks in multiple timed short spurts, or can help them avoid tasks that are challenging for them in favor of complementary tasks they are more suited to (ie, selecting jobs that value more activity rather than sustained focus, or sharing in the chores at home that do not require attention to detail). Cognitive training may help with residual symptoms after medication management has been optimized.

AUTISM SPECTRUM DISORDERS

ESSENTIALS OF DIAGNOSIS

- Persistent issues with social communication and interactions.
- Repetitive behaviors, interests, or activities.
- Symptoms interfere with functioning.
- May or may not have accompanying language or intellectual impairment.

Clinical Findings

Autism spectrum disorder is a neurodevelopmental disorder in which patients suffer from pervasive difficulties with social communication and have repetitive, restricted interests and behaviors. Autism spectrum disorder affects about 1% of the adult population with an estimated heritability of about 90%. Approximately 20–30% of individuals also have a substance use problem, and there is higher risk of ADHD and mood or obsessive-compulsive disorders. The National Institute of Health and Care Excellence (NICE) guidelines recommend that assessment of autism spectrum disorder should be a comprehensive and multidisciplinary approach that includes asking about core autism spectrum disorder difficulties, early development, medical and family history, behavior, education, employment, needs assessment, and risks, as well as physical examination, potential laboratory testing, and feedback to the individual.

Treatment

Risperidone and paliperidone are approved for treating irritability in patients with autism spectrum disorders. These antipsychotics can help with some of the behavioral symptoms of autism but carry a risk of metabolic side effects and extrapyramidal symptoms. Probiotics have demonstrated some efficacy in improving behavioral symptoms. There is some evidence for use of applied behavioral analysis to address social cognitions and behaviors.

SLEEP-WAKE DISORDERS

Sleep consists of two distinct states as shown by electroencephalographic studies: (1) **REM** (rapid eye movement) sleep, also called dream sleep, D state sleep, or paradoxical sleep, and (2) **NREM** (non-REM) sleep, also called S stage sleep, which is divided into stages 1, 2, 3, and 4 and is recognizable by different electroencephalographic patterns. Stages 3 and 4 are “delta” sleep. Dreaming occurs mostly in REM and to a lesser extent in NREM sleep.

Sleep is a cyclic phenomenon, with four or five REM periods during the night accounting for about one-fourth of the total night’s sleep (1.5–2 hours). The first REM period occurs about 80–120 minutes after onset of sleep and lasts about 10 minutes. Later REM periods are longer (15–40 minutes) and occur mostly in the last several hours of sleep. Most stage 4 (deepest) sleep occurs in the first several hours.

Age-related changes in normal sleep include an unchanging percentage of REM sleep and a marked decrease in stage 3 and stage 4 sleep, with an increase in wakeful periods during the night. These normal changes, early bedtimes, and daytime naps play a role in the increased complaints of insomnia in older people. Variations in sleep patterns may be due to circumstances (eg, “jet lag”) or to idiosyncratic patterns (“night owls”) in persons who perhaps because of different “biologic rhythms” habitually go to bed late and sleep late in the morning. Creativity and rapidity of response to unfamiliar situations are impaired by loss of sleep. There are also rare individuals who have chronic difficulty in adapting to a 24-hour sleep-wake cycle (**desynchronization sleep disorder**), which can be resynchronized by altering exposure to light.

The three major sleep disorders are discussed below. Any persistent sleep disorder that is not attributable to another condition should be evaluated by a sleep specialist.

1. Insomnia

Classification & Clinical Findings

Patients may report difficulty getting to sleep or staying asleep, intermittent wakefulness during the night, early morning awakening, or combinations of any of these. Transient episodes are usually of little significance. Stress, caffeine, physical discomfort, daytime napping, and early bedtimes are common factors.

Psychiatric disorders are often associated with persistent insomnia. Depression is usually associated with fragmented sleep, decreased total sleep time, earlier onset of REM sleep, a shift of REM activity to the first half of the night, and a loss of slow wave sleep—all of which are nonspecific findings. In manic disorders, a reduced total sleep time and a decreased need for sleep are cardinal features and important early sign of impending mania. Sleep-related panic attacks occur in the transition from stage 2 to stage 3 sleep in some patients with a longer REM latency in the sleep pattern preceding the attacks.

Abuse of alcohol may cause or be secondary to the sleep disturbance. There is a tendency to use alcohol as a means of getting to sleep without realizing that it disrupts the normal sleep cycle. Acute alcohol intake produces a decreased sleep latency with reduced REM sleep during the first half of the night. REM sleep is increased in the second half of the night, with an increase in total amount of slow wave sleep (stages 3 and 4). Vivid dreams and frequent awakenings are common. Chronic alcohol abuse increases stage 1 and decreases REM sleep (most medications delay or block REM sleep), with symptoms persisting for many months after the individual has stopped drinking. Acute alcohol or other sedative withdrawal causes delayed onset of sleep and REM rebound with intermittent awakening during the night.

Heavy smoking (more than a pack a day) causes difficulty falling asleep—often independently associated with an increase in coffee drinking. Excess intake of caffeine, cocaine, and other stimulants near bedtime causes decreased total sleep time—mostly NREM sleep—with some increased sleep latency.

Sedative-hypnotics—specifically, the benzodiazepines, which are the most commonly prescribed medications to promote sleep—tend to increase total sleep time, decrease sleep latency, and decrease nocturnal awakening, with variable effects on NREM sleep. Nonbenzodiazepine hypnotics have similar effects on sleep as do the benzodiazepines, though some evidence shows improved slow wave sleep and less residual next-morning somnolence with nonbenzodiazepines, such as zolpidem. Withdrawal causes just the opposite effects and results in continued use of the medication for the purpose of preventing withdrawal symptoms. Antidepressants decrease REM sleep (with marked rebound on withdrawal in the form of nightmares) and have varying effects on NREM sleep. The effect on REM sleep correlates with reports that REM sleep deprivation produces improvement in some depressions.

Persistent insomnias are also related to a wide variety of medical conditions, particularly delirium, pain, respiratory syndromes, uremia, thyroid disorders, and nocturia due to benign prostatic hyperplasia. Sleep apnea and restless leg movement are described below. Adequate analgesia and proper treatment of medical disorders will reduce symptoms and decrease the need for sedatives. There is an increased risk of insomnia among older adults, because sleep is lighter and more easily disrupted with aging, and medical disorders are more common.

Treatment

In general, there are two broad classes of treatment for insomnia that may be combined: psychological (cognitive behavioral) and pharmacologic. In situations of acute distress, such as a grief reaction, short-term pharmacologic measures may be most appropriate. With primary insomnia, however, initial efforts should be psychologically based. This is true in older adults to avoid the potential adverse reactions of medications.

A. Psychological

Psychological strategies include educating the patient regarding good **sleep hygiene:** (1) Go to bed only when sleepy. (2) Use the bed and bedroom only for sleeping and sex. (3) If still awake after 20 minutes, leave the bedroom, pursue a restful activity (such as a bath or meditation), and only return when sleepy. (4) Get up at the same time every morning regardless of the amount of sleep during the night. (5) Discontinue caffeine and nicotine, at least in the evening if not completely. (6) Establish a daily exercise regimen; moderate aerobic exercise and mind–body exercises haves demonstrated efficacy in improving sleep. (7) Avoid alcohol as it may disrupt continuity of sleep. (8) Limit fluids in the evening. (9) Learn and practice relaxation techniques. (10) Establish a bedtime ritual and a routine time for going to sleep. Cognitive behavioral therapy for insomnia is as effective as zolpidem with benefits sustained 1 year after treatment.

B. Pharmacologic

When the above measures are insufficient, the following medications may be used: lorazepam (0.5 mg orally nightly); temazepam (7.5–15 mg orally nightly) and zolpidem (5 mg orally in women, 5–10 mg orally in men, nightly); and zaleplon (5–10 mg orally nightly). Zaleplon is often used to treat insomnia characterized by middle-of-the-night awakening with difficulty falling back to sleep. Eszopiclone (2–3 mg orally) is similar in action to zolpidem and zaleplon and has a longer duration of action. A lower dose of 1 mg is indicated in older adults or those with hepatic impairment. It is important to note that short-acting agents like triazolam or zolpidem may lead to amnestic episodes if used on a daily ongoing basis. Longer-acting agents such as flurazepam (half-life of > 48 hours) may accumulate in older adults and lead to cognitive slowing, ataxia, falls, and somnolence. In general, it is appropriate to use medications for short courses of 1–2 weeks. Antihistamines such as diphenhydramine (25 mg orally nightly) or hydroxyzine (25 mg orally nightly) may also be useful for sleep, as they produce no pharmacologic dependency; their anticholinergic effects may, however, produce confusion or urinary symptoms in older adults. Trazodone, an atypical antidepressant, is a non–habit-forming, effective sleep medication in lower than antidepressant doses (25–150 mg orally at bedtime). Priapism is a rare side effect requiring emergent treatment. Doxepin, 3–6 mg per night, is a TCA that is also effective for insomnia. It appears to be safe for ongoing use without the development of tolerance. Melatonin, which is available without a prescription, may improve the time to onset of sleep but is not effective in maintaining sleep. Melatonin (often administered at 0.5–5 mg orally) is most effective when used short term and in combination with behavioral strategies. Ramelteon, 8 mg orally at bedtime, is a melatonin receptor agonist that helps with sleep onset and does not appear to have abuse potential.

The dual orexin receptor antagonists (DORAs) class of hypnotics are approved to help initiate and maintain sleep. DORAs such as suvorexant (10–20 mg orally) and lemborexant (5–10 mg orally) given 30 minutes before bedtime may be more effective than other hypnotics for some patients. The role of DORAs have not been established relative to other hypnotics. DORAs have shown a significant increase in depressive symptoms in a subset of patients, so other hypnotics may be a better choice in depressed patients.

2. Hypersomnias (Disorders of Excessive Sleepiness)

Classification & Clinical Findings

A. Breathing-Related Sleep Disorders

Obstructive sleep apnea is by far the most common of the breathing-related sleep disorders that include **central sleep apnea** and **sleep-related hypoventilation**. Obstructive sleep apnea hypopnea is characterized by snoring, gasping, or breathing pauses during sleep and five or more apneas or hypopneas per hour or evidence by polysomnography. (See Chapter 9.)

B. Narcolepsy Syndrome

Narcolepsy syndrome develops from a selective loss or dysfunction of orexin (also known as hypocretin) neurons of the lateral hypothalamus. Approximately 85–95% of individuals with narcolepsy with cataplexy or hypocretin deficiency are positive for the HLA DQB1*06:02 haplotype. Symptoms often begin between the ages of 15 and

25 years. Narcolepsy consists of recurrent daytime naps or lapses into sleep, at least three times a week, that are accompanied by at least one of the following: (1) hypocretin deficiency; (2) cataplexy—sudden loss of muscle tone involving specific small muscle groups or generalized muscle weakness, often associated with emotional reactions and sometimes confused with seizure disorder; (3) characteristic abnormalities on nocturnal polysomnogram or multiple sleep latency test. The sleep attacks often are characterized by an abrupt transition into REM sleep.

REM sleep behavior disorder, characterized by motor dyscontrol and often violent dreams during REM sleep, may be related to narcolepsy.

C. Kleine-Levin Syndrome

This syndrome, which occurs mostly in young men, is characterized by hypersomnic attacks three or four times a year lasting up to 2 days, with hyperphagia, hypersexuality, irritability, and confusion on awakening. It has often been associated with antecedent neurologic insults. It usually remits after age 40.

D. Periodic Limb Movement Disorder

Periodic lower leg movements occur only during sleep with subsequent daytime sleepiness, anxiety, depression, and cognitive impairment. **Restless leg syndrome** includes movements while awake as well.

E. Shift Work Sleep Disorder

Shift work sleep disorder occurs when there is excessive fatigue as a consequence of work occurring during the normal sleep period.

Treatment

Narcolepsy can be managed by daily administration of a stimulant such as dextroamphetamine sulfate, 10 mg orally in the morning, with increased dosage as necessary. Modafinil and its enantiomer armodafinil are schedule IV medications FDA-approved for treating the excessive daytime fatigue of narcolepsy, sleepiness associated with obstructive sleep apnea, as well as for shift work sleep disorder. Usual dosing is 200–400 mg orally each morning for modafinil and 150–250 mg orally in the morning for armodafinil. The exact mechanism of action of modafinil and armodafinil is unknown, yet they are thought to be less of an abuse risk than stimulants that are primarily dopaminergic. Common side effects include headache and anxiety; however, modafinil appears to be generally well tolerated. Imipramine, 75–100 mg orally daily, has been effective in treatment of cataplexy but not narcolepsy.

Periodic limb movement disorder and REM sleep behavior disorder can be treated with clonazepam with variable results. There is no treatment for Kleine-Levin syndrome, although lithium can prevent recurrences in some.

Treatment of sleep apnea is discussed in Chapter 9.

3. Parasomnias (Abnormal Behaviors during Sleep)

These disorders (sleep terror, nightmares, sleepwalking, and enuresis) are common in children but less so in adults.

DISORDERS OF AGGRESSION

Aggression and violence are symptoms rather than diseases and are not necessarily associated with an underlying medical condition. Clinicians are unable to predict dangerous behavior with greater than chance accuracy. Depression, schizophrenia, personality disorders, mania, paranoia, temporal lobe dysfunction, and organic mental states may be associated with acts of aggression. Impulse control disorders are characterized by physical abuse (usually of the aggressor's domestic partner or children), by pathologic intoxication, by impulsive sexual activities, and by reckless driving. Anabolic steroid usage by athletes has been associated with increased tendencies toward violent behavior.

In the United States, a significant proportion of all violent deaths are alcohol related. The ingestion of even small amounts of alcohol can result in pathologic intoxication that resembles an acute organic mental condition. Amphetamines, crack cocaine, and other stimulants are frequently associated with aggressive behavior. Phencyclidine is a drug commonly associated with violent behavior that is occasionally of a bizarre nature, partly due to lowering of the pain threshold.

Treatment

A. Psychological

Management of any acutely potentially violent individual includes appropriate psychological maneuvers. These may be useful in the management of patients who are hospitalized or being held involuntarily for psychiatric evaluation. Move slowly, talk slowly with clarity and reassurance, and evaluate the situation. Strive to create a setting that is minimally disturbing and eliminate people or things threatening to the violent individual. Do not threaten and do not touch or crowd the person. Allow no weapons in the area. Proximity to a door is comforting to both the patient and the examiner. Use a negotiator who the violent person can relate to comfortably. Food and drink can be helpful in defusing the situation. Honesty is important. Make no false promises, bolster the patient's self-esteem, and continue to engage the subject verbally until the situation is under control. This type of individual does better with strong external controls to replace the lack of inner controls over the long term. Close probationary supervision and judicially mandated restrictions can be most helpful. There should be a major effort to help the individual avoid drug use (eg, Alcoholics Anonymous).

For less acute treatment, community-based programs as well as cognitive bias modification interventions can be useful in decreasing aggressive behaviors.

B. Pharmacologic

Pharmacologic means are often necessary whether or not psychological approaches have been successful. This is true in the agitated or psychotic patient. The medications of choice in seriously violent or psychotic aggressive states are antipsychotics, given intramuscularly if necessary, every 1–2 hours until symptoms are alleviated. A number of second-generation intramuscular antipsychotics are FDA-approved in the management of acute agitation and include aripiprazole (9.75 mg/1.3 mL), ziprasidone (10 mg/0.5 mL), and olanzapine (10 mg/2 mL). The second-generation antipsychotics appear less likely than first-generation medications like haloperidol (2.5–5 mg) to cause acute extrapyramidal symptoms. However, the second-generation medications appear no more effective than first-generation medications and generally are more expensive. Benzodiazepine sedatives (eg, diazepam, 5 mg orally or intravenously every several hours) can be used for mild to moderate agitation but are sometimes associated with a disinhibition of aggressive impulses similar to alcohol. Chronic aggressive states, particularly in patients with intellectual disabilities and brain damage (rule out causative organic conditions and medications such as anticholinergic medications in amounts sufficient to cause confusion), have been ameliorated with risperidone, 0.5–2 mg/day orally, propranolol, 40–240 mg/day orally, or pindolol, 5 mg twice daily orally (pindolol causes less bradycardia and hypotension than propranolol). Carbamazepine and valproic acid are effective in the treatment of aggression and explosive disorders, particularly when associated with known or suspected brain lesions. Lithium and SSRIs are also effective for some intermittent explosive outbursts. Buspirone (10–45 mg/day orally) is helpful for aggression, particularly in patients with intellectual disabilities. Omega-3 fatty acid supplementation has demonstrated efficacy in reducing aggressive behavior.

C. Physical

Physical management is necessary if psychological and pharmacologic means are not sufficient. It requires the active and visible presence of an adequate number of personnel (five or six) to reinforce the idea that the situation is under control despite the patient's lack of inner controls. Such an approach often precludes the need for actual physical restraint. Seclusion rooms and restraints should be used only when necessary (ambulatory restraints are an alternative), and the patient must then be observed at frequent intervals. Narrow corridors, small spaces, and crowded areas exacerbate the potential for violence in an anxious patient.

D. Other Interventions

The treatment of impacted persons (eg, battered women) is challenging and can be complicated by a reluctance to leave the situation. Reasons for staying vary, but common themes include the fear of more violence because of leaving, the hope that the situation may ameliorate (in spite of steady worsening), and the financial aspects of the situation. Concerns for the children may finally compel the person to seek help. An early step is to get the impacted person into a therapeutic situation that provides the support of others in similar straits. Al-Anon is frequently a valuable asset when alcohol is a factor. The group can support the individual while they gather strength to consider alternatives without being paralyzed by fear. Many cities offer temporary emergency centers and counseling. Use the available resources, attend to any medical or psychiatric problems, and maintain a compassionate interest. Some states require clinicians to report injuries caused by abuse or suspected abuse to police authorities.

SUBSTANCE USE DISORDERS

The term "dependency" was previously used to describe a severe form of substance abuse and drug addiction characterized by the triad of: (1) a **psychological dependence or craving** and the behavior involved in procurement of the drug; (2) **physiologic dependence**, with withdrawal symptoms on discontinuance of the drug; and (3) **tolerance**, ie, the need to increase the dose to obtain the desired effects. The terms "dependency" and "abuse" were dropped in *DSM-5* in favor of the single term "substance use disorder (SUD)," ranging from mild to severe. Many patients could have a severe and life-threatening abuse problem without ever being dependent on a drug. SUD is a treatable, chronic medical illness. Clinicians and health care systems must work against bias toward people with SUD. Medication-assisted treatment is a key element in management of SUD. Substance use is discussed fully in Chapter 48.

There is accumulating evidence that an impairment syndrome exists in many former (and current) drug users. It is believed that drug use produces damaged neurotransmitter receptor sites and that the consequent imbalance produces symptoms that may mimic other psychiatric illnesses.

"Kindling"—repeated stimulation of the brain—renders the individual more susceptible to focal brain activity with minimal stimulation. Stimulants and depressants can produce kindling, leading to relatively spontaneous effects no longer dependent on the original stimulus. These effects may be manifested as mood swings, panic, psychosis, and occasionally overt seizure activity. The imbalance also results in frequent job changes, partner problems, and generally erratic behavior. Patients with PTSD frequently have treated themselves with a variety of drugs. Chronic abusers of a wide variety of drugs exhibit cerebral atrophy on CT scans, a finding that may relate to the above symptoms. Early recognition is important, mainly to establish realistic treatment programs that are chiefly symptom-directed.

The clinician faces three problems with substance use disorders: (1) the prescribing of substances such as sedatives, stimulants, or opioids that might produce dependency; (2) the treatment of individuals who have already misused drugs, most commonly alcohol; and (3) the detection of illicit drug use in patients presenting with psychiatric symptoms. The usefulness of **UA for detection of drugs** varies markedly with different drugs and under different circumstances (see also Chapter 5). False-positives can be a problem related to ingestion of some legitimate medications (eg, phenytoin for barbiturates, phenylpropanolamine for amphetamines, chlorpromazine for opioids) and some foods (eg, poppy seeds for opioids, coca leaf tea for cocaine). Manipulations can alter the legitimacy of the testing. Dilution, either in vivo or in vitro, can be detected by checking urine-specific gravity. Hair analysis can determine drug use over longer periods, particularly sequential drug-taking patterns. The sensitivity and reliability of such tests are considered good, and the method may be complementary to UA.

Ignaszewski MJ. The epidemiology of drug abuse. J Clin Pharmacol. 2021;61(Suppl 2):S10. [PMID: 34396554]

NEUROCOGNITIVE DISORDERS

ESSENTIALS OF DIAGNOSIS

- Transient or permanent brain dysfunction with alterations in awareness or attention.
- Cognitive impairment to varying degrees.
- Impaired recall and recent memory, inability to focus attention and problems in perceptual processing, often with psychotic ideation.
- Random psychomotor activity such as stereotypy.
- Emotional disorders frequently present: depression, anxiety, irritability.
- Behavioral disturbances: impulse control, sexual acting-out, attention deficits, aggression, and exhibitionism.

General Considerations

The organic problem may be a primary brain disorder or a secondary manifestation of some general disorder. All of the cognitive disorders show *some degree of impaired thinking* depending on the site of involvement, the rate of onset and progression, and the duration of the underlying brain lesion. Emotional disturbances (eg, depression) are often present as significant comorbidities. The behavioral disturbances tend to be more common with chronicity, more directly related to the underlying personality or CNS vulnerability to drug side effects, and not necessarily correlated with cognitive dysfunction.

The causes of cognitive disorders are listed in Table 28–8.

Clinical Findings

The many manifestations include problems with orientation, short or fluctuating attention span, loss of recent memory and recall, impaired judgment, emotional lability, lack of initiative, impaired impulse control, inability to reason through problems, depression (worse in mild to moderate types), confabulation (not limited to alcohol organic brain syndrome), constriction of intellectual functions, visual and auditory hallucinations, and delusions. Physical findings will vary according to the cause. The electroencephalogram usually shows generalized slowing in delirium.

A. Delirium

Delirium (**acute confusional state**) is a transient global disorder of attention, with clouding of consciousness, usually a result of systemic problems (eg, medications, hypoxemia). See Chapters 4 and 27. Onset is usually rapid. The mental status fluctuates (impairment is usually least in the morning), with varying inability to concentrate, maintain attention, and sustain purposeful behavior. There is a marked deficit of short-term memory and recall. Anxiety and irritability are common. Orientation problems follow the inability to retain information. Perceptual disturbances (often visual hallucinations) and psychomotor restlessness with insomnia are common. "**Sundowning**"—mild to moderate delirium at night—is more common in patients with preexisting dementia and may be precipitated by hospitalization, medications, and sensory deprivation.

B. Dementia

Dementia is characterized by chronicity and deterioration of selective mental functions. See Chapters 4 and 27.

In all types of dementia, loss of impulse control (sexual and language) is common. **Pseudodementia** is a term previously applied to depressed patients who appear to be demented. These patients are often identifiable by their tendency to report memory problems vociferously rather than try to cover them up. They usually say they cannot complete cognitive tasks but with encouragement can often do so. They can be considered to have depression-induced reversible dementia that improves when the depression resolves. In many geriatric patients, however, the depression appears to be an insult that often unmasks a progressive dementia.

Table 28–8. Etiology of delirium and other cognitive disorders (listed in alphabetical order).

Disorder	Possible Causes
Cardiovascular disorders	MIs, cardiac arrhythmias, cerebrovascular spasms, hypertensive encephalopathy, hemorrhages, embolisms, and occlusions indirectly cause decreased cognitive function.
Collagen-vascular and immunologic disorders	Autoimmune disorders, including SLE, Sjögren syndrome, and AIDS.
Degenerative diseases	Alzheimer disease, Pick disease, multiple sclerosis, parkinsonism, Huntington chorea, normal pressure hydrocephalus.
Endocrine disorders	Thyrotoxicosis, hypothyroidism, adrenocortical dysfunction (including Addison disease and Cushing syndrome), pheochromocytoma, insulinoma, hypoglycemia, hyperparathyroidism, hypoparathyroidism, panhypopituitarism, diabetic ketoacidosis.
Infections	Septicemia; meningitis and encephalitis due to bacterial, viral, fungal, parasitic, or tuberculous organisms or to CNS syphilis; acute and chronic infections due to the entire range of microbiologic pathogens.
Intoxication	Alcohol, sedatives, bromides, analgesics (eg, pentazocine), psychedelic drugs, stimulants, and household solvents.
Long-term effects of alcohol	Wernicke-Korsakoff syndrome.
Medication withdrawal	Withdrawal from alcohol, sedative-hypnotics, corticosteroids.
Medications	Anticholinergic medications, antidepressants, H_2-blocking agents, digoxin, salicylates (long-term use), and a wide variety of other over-the-counter and prescribed medications.
Metabolic disturbances	Fluid and electrolyte disturbances (especially hyponatremia, hypomagnesemia, and hypercalcemia), acid-base disorders, hepatic disease (hepatic encephalopathy), kidney failure, porphyria.
Neoplasms	Primary or metastatic lesions of the CNS, cancer-induced hypercalcemia.
Nutritional deficiencies	Deficiency of vitamin B_1 (beriberi), vitamin B_{12} (pernicious anemia), folic acid, nicotinic acid (pellagra); protein-calorie malnutrition.
Respiratory disorders	Hypoxia, hypercapnia.
Seizure disorders	Ictal, interictal, and postictal dysfunction.
Trauma	Subdural hematoma, subarachnoid hemorrhage, intracerebral bleeding, concussion syndrome.

C. Amnestic Syndrome

This is a memory disturbance without delirium or dementia. It is usually associated with thiamine deficiency and chronic alcohol use (eg, Korsakoff syndrome). There is an impairment in the ability to learn new information or recall previously learned information.

D. Substance-Induced Hallucinosis

This condition is characterized by persistent or recurrent hallucinations (usually auditory) without the other symptoms usually found in delirium or dementia. Alcohol or hallucinogens are often the cause. There does not have to be any other mental disorder, and there may be complete spontaneous resolution.

Treatment

See Chapters 4 and 27 for detailed discussion.

Veronese N et al. Interventions to prevent and treat delirium: an umbrella review of randomized controlled trials. Ageing Res Rev. 2024;97:102313. [PMID: 38677599]

PSYCHIATRIC PROBLEMS ASSOCIATED WITH HOSPITALIZATION & ILLNESS

Diagnostic Categories

A. Acute Problems

1. Delirium with psychotic features secondary to the medical or surgical problem or compounded by effect of treatment.
2. Acute anxiety, often related to ignorance and fear of the immediate problem as well as uncertainty about the future.
3. Anxiety as an intrinsic aspect of the medical problem (eg, hyperthyroidism).
4. Denial of illness, which may present during acute or intermediate phases of illness.

B. Intermediate Problems

1. Depression as a function of the illness or acceptance of the illness, often associated with realistic or fantasied hopelessness about the future.

2. Behavioral problems, often related to denial of illness and, in extreme cases, causing the patient to leave the hospital against medical advice.

C. Recuperative Problems

1. Decreasing cooperation as the patient sees that improvement and compliance are not compelled.
2. Readjustment problems with family, job, and society.

General Considerations

A. Acute Problems

1. "Intensive care unit psychosis"—The ICU environment may contribute to delirium. Critical care unit factors include sleep deprivation, increased arousal, mechanical ventilation, and social isolation. Other causes include those common to delirium and require vigorous investigation (see Delirium, above).

2. Presurgical and postsurgical anxiety states—Anxiety before or after surgery is common. **Presurgical anxiety** is common and is principally a fear of death (many surgical patients make out their wills). Patients may be fearful of anesthesia, the operating room, and the disease processes that might be uncovered by the surgeon. Such fears frequently cause people to delay examinations that might result in a greater chance of cure.

The opposite of this is **surgery proneness**, the quest for surgery to escape from overwhelming life stresses. Some polysurgery patients may be classified as having factitious disorders. Motivations include the need to get dependency needs met, the desire to outwit authority figures, unconscious guilt, or a masochistic need to suffer. Frequent surgery may also be related to a somatic symptom disorder, particularly body dysmorphic disorder (an obsession that a body part is disfigured). Other reasons include an attempt to get relief from pain and a lifestyle that has become almost exclusively medically oriented.

Postsurgical anxiety states are usually related to pain, procedures, and loss of body image. Acute pain problems are quite different from chronic pain disorders (see Chronic Pain Disorders, above); the former are readily handled with adequate analgesic medication (see Chapter 5). Alterations in body image (eg, amputations, ostomies, and mastectomies) often raise concerns about relationships with others.

3. Iatrogenic problems—These include medications, complications of diagnostic and treatment procedures, and impersonal and unsympathetic staff behavior. Polypharmacy is often a factor. Patients with unsolved diagnostic problems are at higher risk due to the quest for answers that engenders further diagnostic procedures and risk of complications. The upset patient and family may be anxious and excessively demanding. Such behavior is best handled with calm and measured responses.

B. Intermediate Problems

1. Prolonged hospitalization—Prolonged hospitalization presents unique problems. There often are behavioral difficulties related to length of hospitalization and necessary procedures. Disputes with staff are common and often concern pain medication or ward privileges. Some patients regress to infantile behavior and dependency. Staff members must agree about their approach to the patient in order to ensure the smooth functioning of the unit.

2. Depression—Mood disorders, ranging from mild adjustment disorder to major depressive disorder, frequently occur during prolonged hospitalizations. Depression may be due to the individual's loss of self-esteem; they often think of themselves as worthless and are guilt ridden. Therapeutic medications (eg, corticosteroids) may be a factor. Depression can contribute to irritability and overt anger. Severe depression can lead to anorexia, which further complicates healing and metabolic balance. It is during this period that the issue of disfigurement arises—relief at survival gives way to concern about future function and appearance.

C. Recuperative Problems

1. Anxiety—Anxiety about return to the posthospital environment can cause regression to a dependent position. Complications increase, and staff forbearance again is tested.

2. Posthospital adjustment—Adjustment difficulties after discharge are related to the severity of the deficits and the use of outpatient facilities (eg, physical therapy, rehabilitation programs, psychiatric outpatient treatment). Some patients may experience posttraumatic stress symptoms (eg, from traumatic injuries or from necessary medical treatments). Lack of appropriate follow-up can contribute to depression in the patient, who may feel that he or she is making poor progress and may have thoughts of "giving up." Reintegration into work, educational, and social endeavors may be slow.

Clinical Findings

The symptoms that occur in these patients are similar to those discussed in previous sections of this chapter, eg, delirium, stress and adjustment disorders, anxiety, and depression. Behavior problems may include lack of cooperation, increased complaints, demands for medication, sexual approaches to nurses, threats to leave the hospital, and actual signing out against medical recommendations. The stress of hospitalization often brings out more primitive defense mechanisms than the patient displays in daily life.

Complications

Prolongation of hospitalization causes increased expense, deterioration of patient-staff relationships, and increased probabilities of iatrogenic and legal problems. The possibility of increasing posthospital treatment problems is enhanced.

Treatment

A. Medical

It is important to have one clinician in charge, whom the patient trusts and who is able to oversee multiple treatment approaches (see Somatic Symptom Disorders, above). In acute problems, attention must be paid to metabolic imbalance, alcohol withdrawal, and previous drug use—prescribed, recreational, or over the counter. Adequate sleep and analgesia are important in enhancing a patient's coping abilities.

Many clinicians are attuned to the early detection of the surgery-prone patient. Plastic and orthopedic surgeons are at particular risk. Appropriate consultations may help detect some problems and mitigate future ones.

Postsurgical anxiety states can be alleviated by personal attention from the surgeon. Anxiety is not as effectively lessened by ancillary personnel, whom the patient perceives as lesser authorities, until after the clinician has reassured the patient. "Patient-controlled analgesia" can improve pain control, decrease anxiety, and minimize side effects.

Depression should be recognized early. If moderate to severe, antidepressant medications (see Treatment of Depression, above) may be prescribed. High levels of anxiety can be lowered with judicious use of anxiolytic agents. Unnecessary medications tend to reinforce the patient's impression that there must be a serious illness or medication would not be required.

B. Psychological

Prepare the patient and family for what is to come. This includes the types of units where the patient will be quartered, the procedures that will be performed, and any disfigurements that will result from surgery. Repetition improves understanding. The nursing staff can be helpful, since patients frequently confide a lack of understanding to a nurse but are reluctant to do so to the physician.

Denial of illness is frequently a block to acceptance of treatment. This too should be handled with family members present (to help the patient face the reality of the situation) in a series of short interviews (for reinforcement). Dependency problems resulting from long hospitalization are best handled by focusing on the changes to come as the patient makes the transition to the outside world. Key figures are teachers, vocational counselors, and physical therapists. Challenges should be realistic and practical and handled in small steps.

Depression is usually related to the loss of familiar hospital supports, and the outpatient therapists and counselors help to lessen the impact of the loss. The impact can be alleviated by anticipating, with the patient and family, the signal features of the common depression to help prevent the patient from assuming a permanent sick role.

Suicide is a concern when a patient is faced with despair. An honest, compassionate, and supportive approach will help sustain the patient during this trying period.

C. Behavioral

Prior desensitization can significantly allay anxiety about medical procedures. A "dry run" can be done to reinforce the oral description. Cooperation during acute problem periods can be enhanced by the use of appropriate reinforcers such as a favorite nurse or helpful family member. People who are positive reinforcers are even more helpful during the intermediate phases when the patient becomes resistant to the seemingly endless procedures (eg, debridement of burned areas).

Specific situations (eg, psychological dependency on the respirator) can be corrected by weaning with appropriate reinforcers (eg, watching a favorite movie on a media player or laptop when disconnected from the ventilator). Behavioral approaches should be used in a positive and optimistic way for maximal reinforcement.

Relaxation techniques, hypnosis, and attentional distraction can be used to block side effects of a necessary treatment (eg, nausea in cancer chemotherapy).

D. Social

A change in environment requires adaptation. Because of the illness, admission and hospitalization may be more easily handled than discharge. A predischarge evaluation must be made to determine whether the family will be able to cope with the physical or mental changes in the patient. Working with the family while the patient is in the acute stage may presage a successful transition later on.

Development of a new social life can be facilitated by various self-help organizations (eg, the stoma club). Sharing problems with others in similar circumstances eases the return to a social life, which may be quite different from that prior to the illness.

▶ Prognosis

The prognosis is good in all patients who have reversible medical and surgical conditions. It is guarded when there is serious functional loss that impairs vocational, educational, or societal possibilities—especially in the case of progressive and ultimately life-threatening illness.

Austin E et al. Improving emergency department care for adults presenting with mental illness: a systematic review of strategies and their impact on outcomes, experience, and performance. Front Psychiatry. 2024;15:1368129. [PMID: 38487586]

Disorders of the Pituitary, Thyroid, & Adrenal Glands

29

Paul A. Fitzgerald, MD

DISEASES OF THE HYPOTHALAMUS & PITUITARY GLAND

ANTERIOR HYPOPITUITARISM

ESSENTIALS OF DIAGNOSIS

- ACTH deficiency: low adrenal secretion of cortisol and epinephrine; normal aldosterone secretion.
- Growth hormone (GH) deficiency: short stature in children; asthenia, obesity, and increased cardiovascular risk in adults.
- Prolactin (PRL) deficiency: postpartum lactation failure.
- TSH deficiency: secondary hypothyroidism.
- LH and FSH deficiency: hypogonadism and infertility in men and women.

General Considerations

The anterior pituitary hormones are GH, PRL, ACTH, TSH, LH, and FSH. The hypothalamus synthesizes hormones that regulate anterior pituitary secretion, including corticotropin-releasing hormone (CRH), growth hormone–releasing hormone, gonadotrophin-releasing hormone (GnRH), thyrotropin-releasing hormone, and somatostatin. The hypothalamus also secretes dopamine that inhibits PRL secretion. These hypothalamic regulatory hormones are transported by a portal venous system down the pituitary stalk to the anterior pituitary. The hypothalamus also synthesizes oxytocin and arginine vasopressin (AVP), also known as ADH. Nerves from the hypothalamus carry oxytocin and AVP to the posterior pituitary, where they are stored and released. Hypopituitarism can be caused by either hypothalamic or pituitary dysfunction. Patients with hypopituitarism may have single or multiple hormonal deficiencies.

1. Hypopituitarism with mass lesions—Lesion in the sellar or perisellar area may cause hypopituitarism by impingement on the hypothalamus, pituitary stalk, or pituitary.

A. PITUITARY NEUROENDOCRINE TUMORS—These tumors, also known as pituitary adenomas, can cause anterior hypopituitarism, particularly when they are large macroadenomas (1 cm or larger). Nonfunctioning pituitary neuroendocrine tumors are more likely than functioning pituitary adenomas to grow large enough to cause anterior hypopituitarism; they rarely cause diabetes insipidus. Pituitary adenomas are usually sporadic but 5% arise in familial tumor syndromes. Pituitary adenomas most frequently secrete PRL or (less commonly) GH or ACTH.

B. PITUITARY METASTASES—These lesions are usually from breast cancer (45%); 50% present over 10 years after the primary tumor. Lung cancer accounts for about 21% of pituitary metastases that typically present within 1 year of the primary cancer. Pituitary metastases often present with visual loss or ophthalmoplegia, ACTH deficiency (71%), TSH deficiency (65%), diabetes insipidus (26%), or gonadotropin deficiency (88%).

C. OTHER MASS LESIONS—These lesions include craniopharyngioma, plasmacytoma, germ cell tumors, glioma, lymphomas, cysts (Rathke cleft, dermoid, epidermoid, arachnoid), meningioma, and hemangiopericytoma.

D. VASCULAR LESIONS—These lesions include pituitary tumor apoplexy, cavernous sinus aneurysm, and subarachnoid hemorrhage.

E. INFLAMMATORY/INFILTRATIVE LESIONS—These include granulomatosis with polyangiitis, xanthomatosis, giant cell granuloma, Langerhans cell histiocytosis, sarcoidosis, syphilis, hypophysitis, and tuberculosis. Infectious lesions can be bacterial, fungal, or parasitic. Lymphocytic hypophysitis is an autoimmune disorder that is characterized by infiltration of the infundibulum and pituitary by lymphocytes, macrophages, and plasma cells. Spontaneous lymphocytic hypophysitis is more common in women (71%) and most frequently presents during pregnancy or postpartum. Immune checkpoint inhibitor hypophysitis can be caused by several immunity-enhancing drugs.

F. Pituitary stalk thickening—This disorder is caused most frequently by lymphocytic hypophysitis, metastases, neurosarcoidosis, or a congenital ectopic posterior pituitary, but often the cause is never determined. Pituitary stalk damage frequently causes central diabetes insipidus and one or more anterior pituitary hormone deficiencies.

2. Hypopituitarism without mass lesions—

A. Congenital hypopituitarism—This disorder occurs in syndromes such as septo-optic dysplasia and in patients with various gene mutations that cause a progressive loss of anterior pituitary function in childhood. Prader-Willi syndrome is a genetic disorder where genes on the paternal chromosome 15 are deleted or unexpressed. Kallmann syndrome is caused by various gene mutations that impair the development or migration of GnRH-synthesizing neurons from the olfactory bulb to the hypothalamus, causing hypogonadism with hyposmia or anosmia. Congenital GH deficiency occurs as an isolated pituitary hormone deficiency in one-third of cases.

B. Acquired hypopituitarism—This disorder can result from cranial radiation therapy, pituitary surgery, encephalitis, cerebral malaria, COVID-19 infection, parasitic infection, viper bites, hemochromatosis, autoimmunity, or coronary artery bypass grafting. GH deficiency can also occur following peptide receptor radionuclide therapy for neuroendocrine tumors. *Hypopituitarism can occur acutely, usually with severe secondary adrenal insufficiency that may be fatal unless recognized and treated.* Acute hypopituitarism may also be associated with diabetes insipidus.

At least one pituitary hormone deficiency develops in 25–30% of survivors of moderate to severe **traumatic brain injury** and in about 55% of survivors of **aneurysmal subarachnoid hemorrhage.** Some degree of hypopituitarism, most commonly GH deficiency and hypogonadotropic hypogonadism, occurs in one-third of **ischemic stroke** patients. Other cases of acquired hypopituitarism can be idiopathic or associated with an empty sella on MRI.

Sheehan syndrome refers to hypopituitarism caused by postpartum pituitary necrosis, usually following severe postpartum uterine hemorrhage. It is usually characterized by postpartum amenorrhea and inability to lactate. Hypopituitarism in Sheehan syndrome usually occurs gradually over 10–20 years; the diagnosis is typically delayed an average of 9 years. Manifestations in affected women are typically hyponatremia, hypoglycemia, or anemia. In acute Sheehan syndrome, MRI shows an enlarged pituitary with only a thin rim of enhancement with gadolinium.

C. Functional hypopituitarism—Functional hypogonadotropic hypogonadism can occur in both women and men secondary to excessive exercise or weight loss. Partial hypogonadotropic hypogonadism commonly develops in men with normal aging or obesity, with serum free testosterone levels that are low or near the lower end of normal reference ranges but normal serum FSH and LH levels. Women may develop hypothalamic amenorrhea during periods of severe emotional or physical stress. LH and FSH deficiency with hypogonadotropic hypogonadism occur in serious illness, malnutrition, anorexia nervosa, alcohol use disorder, Cushing syndrome (spontaneous or iatrogenic), and hyperprolactinemia (drug-induced or spontaneous). Opioid use causes partial hypogonadotropic hypogonadism in about 60% of long-term (including methadone) users and secondary adrenal insufficiency in about 15% of patients; it is less likely to cause GH or TSH deficiency. Therapy with GnRH agonists (eg, leuprolide) also causes hypogonadotropic hypogonadism that can persist after therapy is stopped.

Functional GH deficiency can occur with normal aging, malnutrition, and CKD. ACTH suppression with functional isolated secondary adrenal insufficiency occurs in patients receiving megesterol acetate, high-dose opioid therapy (15%), and endogenous or exogenous corticosteroids. Chemotherapy with **bexarotene** may cause secondary hypothyroidism and hypopituitarism. **Mitotane** therapy for adrenocortical carcinoma causes central hypothyroidism.

Clinical Findings

When hypopituitarism is caused by a mass lesion or hypophysitis, patients may have headaches or visual field defects. Nonspecific symptoms, such as fatigue, dizziness and hypotension, confusion, cognitive dysfunction, sexual dysfunction, polydipsia, or cold intolerance, can develop. Other symptoms and signs attributed to specific pituitary hormone deficiencies are described below.

A. Symptoms and Signs

1. GH (somatropin) deficiency—GH deficiency in adults is often undiagnosed, Nonspecific symptoms, varying from mild to severe, include mild to moderate central obesity, reduced physical and mental energy, impaired concentration and memory, and depression. Patients may also have reduced muscle mass, increased LDL cholesterol, and reduced cardiac output with exercise. Chronic GH deficiency leads to osteopenia and an increased risk of fractures. When other more recognizable pituitary hormone deficits are present, there is a high likelihood of concurrent GH deficiency.

2. Gonadotropin deficiency (hypogonadotropic hypogonadism)—In gonadotropin deficiency, insufficiencies of LH and FSH cause hypogonadism and infertility.

Congenital gonadotropin deficiency is characterized by partial or complete lack of pubertal development. Isolated hypogonadal hypogonadism occurs in as many as 1 in 4000 males but is less common in females. About 30% of cases have been linked to genetic variants with variable phenotypic expressions. Patients may have normal or abnormal olfaction (Kallmann syndrome), abnormal genitalia, kidney abnormalities, midline craniofacial defects, neurologic deficits, or musculoskeletal malformations. Some affected women have menarche followed by secondary amenorrhea. Affected boys who survive childhood may present with failure to enter puberty.

Prader-Willi syndrome presents with cryptorchidism, mental retardation, short stature, hyperflexibility, autonomic dysregulation, cognitive impairment, obesity, hypogonadotropic hypogonadism, or primary hypogonadism.

Acquired gonadotropin deficiency is characterized by the gradual loss of facial, axillary, pubic, and body hair. Men may note diminished libido, erectile dysfunction, muscle atrophy, infertility, and osteopenia. Women have amenorrhea, infertility, and osteoporosis.

3. TSH deficiency—TSH deficiency causes hypothyroidism (see Hypothyroidism, below).

4. ACTH deficiency—Central adrenal insufficiency is caused by ACTH deficiency. There is functional atrophy of the adrenal cortex within 2 weeks of pituitary damage, which results in diminished cortisol. Adrenal mineralocorticoid secretion continues, so manifestations of adrenal insufficiency in hypopituitarism may be less striking than in bilateral adrenal gland destruction (see Primary Adrenal Insufficiency [Addison disease]). Central adrenal insufficiency from pituitary metastases typically presents with nausea, weight loss, and fatigue; these symptoms are often incorrectly attributed to chemotherapy or to the malignancy itself. Patients with partial ACTH deficiency have some cortisol secretion and may not have symptoms until stressed by illness or surgery.

5. PRL deficiency—This presents in women with failure to lactate in the puerperium.

6. Panhypopituitarism—This refers to a deficiency of several or all pituitary hormones. There may be hypogonadotropic hypogonadism (62%), diabetes insipidus (54%), headache (50%), hypothyroidism (48%), ACTH deficiency (47%), GH deficiency (37%), and hyperprolactinemia (36%), which clinicians may mistake for a prolactinoma. Hypopituitarism typically presents in women with amenorrhea.

7. Hypothalamic damage—This can cause obesity and cognitive impairment. Hypopituitarism occurs but usually along with *increased* serum levels of PRL. Local tumor effects can cause headache or optic nerve compression with visual field impairment.

B. Laboratory Findings

Initially, there may be hyponatremia and hypoglycemia, with secondary hypoadrenalism, hypothyroidism, or GH deficiency. Hyponatremia can be caused by hypothyroidism or hypoadrenalism. Hyperkalemia usually does not occur, since aldosterone production is not affected. Patients with lymphocytic hypophysitis frequently have elevated serum antinuclear or anticytoplasmic antibodies. Patients with hypopituitarism without an established etiology should be screened for hemochromatosis with a serum ferritin or iron and transferrin saturation.

Male hypogonadotropic hypogonadism is diagnosed by drawing blood before 10 AM after an overnight fast in men without an acute or subacute illness. Affected men have a low fasting serum total or free serum testosterone with a low or normal serum LH. A serum PRL is also obtained, since hyperprolactinemia of any cause can result in hypogonadism.

Female hypogonadotropic hypogonadism is suspected in nonpregnant women with amenorrhea or oligomenorrhea, who do not have acute illness, hyperthyroidism, or hyperandrogenism. The serum estradiol is low and the serum FSH is low or normal. In nonpregnant women, a serum PRL is obtained, since hyperprolactinemia of any cause can result in hypogonadism. In postmenopausal women, the absence of an elevated serum FSH (in a woman not taking estrogen replacement) indicates gonadotropin deficiency.

Central hypothyroidism is diagnosed with a low serum free thyroxine (FT_4) in the setting of pituitary disease. The serum TSH can be low or normal. Central hypothyroidism can emerge when patients begin GH replacement, so thyroid levels must be monitored in that setting. Patients undergoing pituitary surgery should be assessed for central hypothyroidism preoperatively and again 6 weeks postoperatively.

Central adrenal insufficiency is diagnosed after withholding corticosteroid replacement for at least 18–24 hours. Blood is drawn at 8–9 AM for baseline plasma ACTH and serum cortisol. A serum cortisol < 3 mcg/dL (80 nmol/L) usually indicates adrenal insufficiency, whereas AM serum cortisol > 15 mcg/dL (400 nmol/L) usually excludes adrenal insufficiency. For AM cortisol levels between 3 and 15 mcg/dL, a cosyntropin test is often required. For the cosyntropin test, patients should hold any corticosteroid replacement for at least 18–24 hours. At 8–9 AM, blood is drawn for serum cortisol, ACTH, and dehydroepiandrosterone (DHEA); then cosyntropin (synthetic $ACTH_{1-24}$) 0.25 mg is administered intramuscularly or intravenously. Another serum cortisol is obtained 45 minutes after the cosyntropin injection; a stimulated serum cortisol of < 20 mcg/dL (550 nmol/L) indicates probable adrenal insufficiency. With gradual pituitary damage and early in the course of ACTH deficiency, patients can have a stimulated serum cortisol of ≥ 20 mcg/dL (550 nmol/L) but a baseline 8 AM serum cortisol of ≤ 5 mcg/dL (138 nmol/L), which is suspicious for adrenal insufficiency. The baseline serum ACTH level is low or normal in secondary hypoadrenalism, distinguishing it from primary adrenal disease. Serum DHEA is a proxy for ACTH; levels are usually low in patients with secondary adrenal deficiency, helping confirm the diagnosis. Hyponatremia may occur, especially when ACTH and TSH deficiencies are both present.

For patients with signs of secondary adrenal insufficiency (hyponatremia, hypotension, pituitary tumor) but borderline cosyntropin test results, treatment can be instituted empirically and the test repeated at a later date.

GH deficiency in adults is difficult to diagnose, since GH secretion is normally pulsatile and serum GH levels are normally undetectable for much of the day. Also, adults (particularly men) physiologically tend to produce less GH when they are over age 50 or have abdominal obesity.

Therefore, pathologic GH deficiency is often inferred by symptoms of GH deficiency in the presence of pituitary destruction or other pituitary hormone deficiencies. GH deficiency is present in 96% of patients with three or more other pituitary hormone deficiencies and a low serum IGF-1. GH stimulates the production of IGF-1, but the serum IGF-1 level is neither a sensitive (about 50%) nor specific test for GH deficiency in adults. Very low serum IGF-1 levels (< 84 mcg/L) are usually indicative of GH deficiency but also occur in malnutrition, prolonged fasting, hypothyroidism, uncontrolled diabetes mellitus, and liver failure, as well as with estrogen therapy. A therapeutic trial of GH therapy should be considered for symptomatic patients who have either a serum IGF-1 < 84 mcg/L or three other pituitary hormone deficiencies.

Provocative GH stimulation testing to help diagnose adult GH deficiency has a sensitivity of only 66%; however, tests are sometimes indicated or required for insurance coverage of GH therapy. In the absence of a serum IGF-1 level < 84 mcg/L or multiple other pituitary hormone deficiencies, provocative GH-stimulation testing may be indicated for the following patients: (1) young adult patients who have completed GH therapy for childhood GH deficiency and have achieved maximal linear growth; (2) patients who have a hypothalamic or pituitary tumor or who have received surgery or radiation therapy to these areas; and (3) patients who have had prior head trauma, cerebrovascular accident, or encephalitis. Testing usually entails measuring serum GH following provocative stimuli, including macimorelin or glucagon.

C. Imaging

MRI of the hypothalamus and pituitary is indicated when a mass lesion is suspected. MRI can detect lesions of the pituitary, hypothalamus or pituitary stalk, including pituitary adenoma, lymphocytic hypophysitis, neurosarcoidosis, Langerhans cell histiocytosis, craniopharyngioma, germinoma, astrocytoma, and metastatic malignancy. MRI shows pituitary enlargement in 75% of cases of ipilimumab-associated hypophysitis but only 25% of cases of anti-PD-1 agent–induced hypophysitis. MRI is not warranted in cases of functional hypopituitarism associated with severe obesity, drugs, or nutritional disorders.

Differential Diagnosis

The failure to enter puberty may simply reflect a constitutional delay in growth and puberty.

Reversible, second hypothyroidism with suppression of TSH and T_4 can be caused by severe illness, hyperthyroxinemia, and administration of triiodothyronine, mitotane, or bexarotene, resulting in temporary central hypothyroidism. Corticosteroids and megestrol reversibly suppress endogenous ACTH and cortisol secretion. High-dose corticosteroid therapy can cause secondary adrenal insufficiency that may persist for many months.

GH deficiency occurs normally with aging and physiologically with obesity (reversible with sufficient weight loss). Very low serum IGF-1 levels can be seen with prolonged fasting, malnutrition, liver failure, hypothyroidism, and uncontrolled diabetes mellitus.

Complications

During a stressful illness, patients with untreated hypoadrenalism may become febrile and comatose and die of hyponatremia and shock.

Rarely, acute hemorrhage may occur in large pituitary tumors, manifested by rapid loss of vision, headache, and evidence of acute pituitary failure (pituitary apoplexy) requiring emergency decompression of the sella. Among patients with craniopharyngiomas, diabetes insipidus is found in 16% preoperatively and in 60% postoperatively. Hyponatremia often presents abruptly during the first 2 weeks following any pituitary surgery. Conventional radiation therapy for intracranial disorders can result in an increased incidence of small vessel ischemic strokes, second tumors and damaged hypothalamic-pituitary function.

Treatment

A. Corticosteroid Replacement

Long-term therapy is initiated with hydrocortisone 10–25 mg orally in the morning and 5–15 mg in the late afternoon. Prednisone or methylprednisolone may also be used; the dosing and timing must be individually tailored. No mineralocorticoid replacement is required. See Corticosteroid Replacement Therapy-Primary Adrenal Insufficiency (Addison Disease) below.

B. Thyroid Hormone Replacement

Levothyroxine is given to correct hypothyroidism only after the patient is assessed for cortisol deficiency or is already receiving corticosteroids. The typical maintenance dose is about 1.6 mcg/kg body weight, averaging 125 mcg daily with a wide range of 25–300 mcg daily. Because assessment of serum TSH is useless for monitoring patients with hypopituitarism, the optimal replacement dose of levothyroxine is determined clinically by raising or lowering the dose, according to the patient's symptoms and clinical examination. With clinically optimized levothyroxine replacement, serum FT_4 levels are usually in the mid to high-normal range. Some patients do not feel clinically euthyroid until they receive levothyroxine in doses at which the serum FT_4 levels are mildly elevated; however, serum T_3 or FT_3 levels should be in the low-normal range. During pregnancy, clinical status and serum FT_4 or total T_4 levels need to be monitored frequently, since higher doses of levothyroxine are usually required.

C. Sex Hormone and Gonadotropin Hormone Replacement

Hyperprolactinemia-related hypogonadotropic hypogonadism improves or resolves with treatment. Sex hormone replacement may be required. See Male Hypogonadism and Female Hypogonadism.

Women with panhypopituitarism have profound androgen deficiency caused by the combination of both secondary hypogonadism and adrenal insufficiency. When serum DHEA levels are < 400 ng/mL, women may also be treated with compounded USP-grade DHEA 25–50 mg/day orally. DHEA therapy tends to increase pubic and axillary hair and may improve libido, alertness, stamina, and overall psychological well-being.

For men with oligospermia, human chorionic gonadotropin (hCG) (equivalent to LH) may be given at a dosage of 1500–3000 units intramuscularly three times weekly and testosterone replacement discontinued. The dose of hCG is adjusted to normalize serum testosterone levels. After 6–12 months of hCG treatment, if the sperm count remains low, hCG injections are continued along with injections of follitropin β (synthetic recombinant FSH) or urofollitropins (urine-derived FSH). An alternative for patients with an intact pituitary is the use of leuprolide (GnRH analog) by intermittent subcutaneous infusion. With treatment, testicular volumes increase within 5–12 months, and some spermatogenesis occurs in most cases.

For men with secondary hypogonadism, treatment with hCG achieves serum testosterone levels that are typically higher than with transdermal testosterone therapy and more consistent than intramuscular testosterone therapy. Many men prefer hCG over testosterone replacement, even when fertility is not at issue.

Clomiphene, 25–50 mg/day orally, can sometimes stimulate men's own pituitary gonadotropins (when their pituitary is intact), thereby increasing testosterone and sperm production. For fertility induction in females, ovulation may be induced with clomiphene, 50–100 mg/day orally for 5 days every 2 months. Ovulation induction with FSH and hCG can induce multiple births and should be used only by those experienced with their administration.

D. Human Growth Hormone (hGH) Replacement

Symptomatic adults with GH deficiency may be treated with subcutaneous recombinant human growth hormone (rhGH, somatropin) injections, at a starting dose of 0.2 mg/day (0.6 IU/day), administered three times weekly. The dosage of rhGH is increased every 2–4 weeks by increments of 0.1 mg (0.3 IU) until side effects occur or a sufficient salutary response and a normal serum IGF-1 level are achieved. If the desired effects (eg, improved energy and mentation, reduction in visceral adiposity) are not seen within 3–6 months at maximum tolerated dosage, rhGH therapy is discontinued. Therapy with hGH can bring out central hypothyroidism, so serum FT_4 levels require monitoring when beginning hGH therapy.

RhGH may be safely administered to pregnant women with hypopituitarism at their usual pregestational dose during the first trimester, tapering the dose during the second trimester, and discontinuing rhGH during the third trimester.

Oral estrogen replacement reduces hepatic IGF-1 production. Therefore, prior to commencing rhGH therapy, oral estrogen should be changed to transdermal or transvaginal estradiol.

Treatment of adult GH deficiency usually improves the patient's overall quality of life, with better emotional sense of well-being, increased muscle mass, and decreased visceral fat and waist circumference. Long-term treatment with rhGH does not appear to affect mortality.

Side effects of rhGH therapy may include peripheral edema, hand stiffness, arthralgias and myalgias, paresthesias, carpal tunnel syndrome, tarsal tunnel syndrome, headache, pseudotumor cerebri, gynecomastia, hypertension, and proliferative retinopathy. Treatment with rhGH can also cause sleep apnea, insomnia, dyspnea, sweating, and fatigue. Side effects usually remit promptly after a sufficient reduction in dosage. Replacement therapy with rhGH does not increase the risk of any malignancy or the regrowth of pituitary or brain neoplasms; serum IGF-1 levels should be kept in the normal range.

GH should not be administered during critical illness, since administration of very high doses of rhGH increased mortality in patients receiving intensive care. There is no proven role for GH replacement for the physiologic GH deficiency that is seen with abdominal obesity or normal aging.

E. Other Treatment

Selective transsphenoidal surgery is usually performed to resect non-prolactinoma pituitary masses and Rathke cleft cysts that cause local symptoms or hypopituitarism. Such surgery reverses hypopituitarism in a minority of cases. Patients with lymphocytic hypophysitis have been treated with corticosteroid therapy and other immunosuppressants without much response and without reversing hypopituitarism.

▶ Prognosis

Functionally, most patients with hypopituitarism do well with hormone replacement. Men with infertility who are treated with hCG/FSH or GnRH are likely to resume spermatogenesis if they have had sexual maturation and have descended testicles with a baseline serum inhibin B level over 60 pg/mL. Women under age 40 years with infertility from hypogonadotropic hypogonadism can usually have successful ovulation induction.

Hypopituitarism resulting from a pituitary tumor may be reversible with dopamine agonists for prolactinomas (see Prolactinoma, below) or with careful selective resection of the tumor. Spontaneous recovery from hypopituitarism associated with pituitary stalk thickening has been reported. Patients can also recover from functional hypopituitarism due to excessive exercise or weight loss if they greatly reduce exercise and gain weight; about half of men regain normal serum testosterone levels. Spontaneous reversal of idiopathic isolated hypogonadotropic hypogonadism occurs in about 10% of patients after several years of hormone replacement therapy (HRT). However, hypopituitarism is usually permanent, and long-term HRT is ordinarily required.

Patients with hypopituitarism have an increased mortality risk, particularly women and those in whom diagnosis was made at a younger age, who have a craniopharyngioma, or who required transcranial surgery or radiation therapy. There is also an increased risk of death from infections with adrenal crisis in patients with untreated secondary insufficiency. Some pituitary tumors are locally invasive. Asymptomatic Rathke cleft cysts may not require surgery but do require endocrine, ophthalmic, and scan surveillance.

ANTIDIURETIC HORMONE DEFICIENCY (Central Diabetes Insipidus)

ESSENTIALS OF DIAGNOSIS

- ADH deficiency with polyuria (2.5–20 L/day) and polydipsia.
- Hypernatremia occurs if fluid intake is inadequate.

General Considerations

Antidiuretic hormone (ADH), also called arginine vasopressin, is secreted by the posterior pituitary. Deficiency of pituitary secretion, also called central diabetes insipidus, is uncommon.

Primary ADH deficiency (ADH-D) without an identifiable lesion noted on MRI of the pituitary and hypothalamus accounts for one-third of cases of diabetes insipidus. It may be idiopathic or due to autoimmunity against hypothalamic ADH-secreting cells. Reversible central diabetes insipidus can occur with administration of propofol anesthesia, ketamine, temozolomide, or the anti-PD-L1 monoclonal antibody avelumab, and in the myelodysplastic preleukemic phase of acute myelogenous leukemia.

Secondary ADH-D frequently occurs after traumatic brain injury. It usually presents within 2 weeks after injury, although delayed presentations are reported. Other causes of damage to the hypothalamus or pituitary stalk include tumor, hypophysitis, infarction, hemorrhage, anoxic encephalopathy, or surgery involving the pituitary or hypothalamus. Less commonly, it is caused by infection (eg, encephalitis, tuberculosis, syphilis), craniopharyngioma, germinoma, or granulomas (sarcoidosis or Langerhans cell granulomatosis). Metastases to the pituitary or infundibulum are more likely to cause ADH-D (33%) than are pituitary adenomas (1%).

Clinical Findings

A. Symptoms and Signs

The symptoms of ADH-D are intense thirst, especially a craving for ice water, with the volume of ingested fluid varying from 2.5 L to 20 L daily, and polyuria, with large urine volumes and low urine specific gravity (usually < 1.006 with ad libitum fluid intake). The urine is otherwise normal. Partial ADH-D presents with less intense symptoms and should be suspected in patients with enuresis. Most patients with ADH-D are able to maintain fluid balance by continuing to ingest large volumes of water.

Patients with ADH-D who do not have free access to water become dehydrated and develop hypernatremia. Similarly, patients with damage to the anterior hypothalamic thirst center have adipsic central diabetes insipidus (ADI) and develop dehydration and hypernatremia with reduced urine output. ADI commonly occurs following neurosurgical clipping of an anterior communicating artery aneurysm. ADI is usually permanent when associated with hypothalamic damage but may be temporary in patients with critical illness.

B. Laboratory Findings

Diagnosis of ADH-D is a clinical one; there is no single diagnostic laboratory test. Evaluation should include a 24-hour urine collection for volume and creatinine. The urine is collected during ad libitum fluid intake. A urine volume of < 2.5 L/24 hours (in the absence of hypernatremia) rules out diabetes insipidus. Blood testing includes plasma vasopressin and serum glucose, urea nitrogen, calcium, potassium, sodium, and uric acid.

Plasma ADH levels are usually low (< 1 pg/mL) with both central diabetes insipidus and primary polyuria. By contrast, plasma ADH levels are normal or elevated (> 2.5 pg/mL) with nephrogenic diabetes insipidus. Plasma osmolality of 300 mOsm/kg or more implies either central or nephrogenic diabetes insipidus, whereas plasma osmolality of 280 mOsm/kg or less implies primary polydipsia as the diagnosis. Urine osmolality is low (300 mOsm/L or lower) in all three polyuric conditions and is not a helpful test. Hyperuricemia occurs frequently with both central and nephrogenic diabetes insipidus, whereas it is uncommon with primary polydipsia.

The most sensitive test for ADH-D involves the intravenous administration of hypertonic 3% saline (250 mL bolus, followed by a continuous infusion of 0.15 mL/kg/min) with plasma sodium measurements every 30 minutes. When the sodium level reaches 150 mmol/L, a plasma copeptin level of ≤ 4.9 pmol/L helps confirm the diagnosis.

The arginine-stimulation test for ADH-D involves intravenous administration over 30 minutes of l-arginine hydrochloride 0.5 g/kg (maximum of 40 g in 500 mL of 0.9 normal saline). Serum copeptin is measured at 60 and 90 minutes after the start of the infusion. Copeptin levels < 2.4 pmol/L indicate severe ADH-D; levels of 2.4–3.8 pmol/L indicate partial deficiency; and levels of > 3.8 pmol/L indicate primary polydipsia.

A less cumbersome "vasopressin challenge test" may be done. Desmopressin acetate 0.05–0.1 mL (5–10 mcg) intranasally (or 1 mcg subcutaneously or intravenously) is given, with measurement of urine volume for 12 hours before and 12 hours after administration. A serum sodium is obtained at baseline, 12 hours after the desmopressin, and immediately if symptoms of hyponatremia develop. Patients with ADH-D usually notice a distinct reduction in thirst and polyuria; serum sodium usually remains normal. The dosage of desmopressin is doubled if the response is marginal. In patients with primary polydipsia and nephrogenic diabetes insipidus, a desmopressin challenge causes no significant reduction in thirst or urine volume.

C. Imaging

A posterior pituitary "bright spot" on noncontrast MRI T1-weighted imaging indicates the functional integrity of the posterior pituitary. The bright spot is undetectable or small with central diabetes insipidus whereas it is usually present in primary polydipsia and nephrogenic diabetes insipidus. MRI can also detect pathology responsible for central diabetes insipidus. Pituitary MRI must be interpreted cautiously. Patients with nephrogenic diabetes insipidus may sometimes have an absent or faint pituitary bright spot due to high AVP secretion resulting in posterior pituitary AVP depletion.

Differential Diagnosis

Central diabetes insipidus must be distinguished from polyuria caused by psychogenic polydipsia, diabetes mellitus, Cushing syndrome, hypercalcemia, hypokalemia, and nocturnal polyuria of Parkinson disease.

Vasopressinase-induced diabetes insipidus may be seen in the last trimester of pregnancy, associated with oligohydramnios, preeclampsia, or liver dysfunction, and in the puerperium. Maternal circulating vasopressin is destroyed by placental vasopressinase; however, synthetic desmopressin is unaffected.

Nephrogenic diabetes insipidus is caused by unresponsiveness of the kidney tubules to the normal secretion of vasopressin. A congenital form is familial and transmitted as an X-linked trait. Acquired forms are usually less severe and occur in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjögren syndrome, sickle cell anemia, chronic hypercalcemia, or recovery from ATN. Certain medications (eg, corticosteroids, diuretics, demeclocycline, lithium, foscarnet, or methicillin) may induce nephrogenic diabetes insipidus.

Complications

If water is not readily available, the excessive output of urine will lead to severe dehydration and worsening hypernatremia. Patients with an impaired thirst mechanism are very prone to hypernatremia, as are those with impaired mentation who forget to take their desmopressin. Excessive desmopressin acetate can induce water intoxication and hyponatremia.

Treatment

Mild cases of diabetes insipidus require no treatment other than adequate fluid intake. Reduction of aggravating factors (eg, corticosteroids) will improve polyuria.

Desmopressin acetate is the treatment of choice for central diabetes insipidus and for vasopressinase-induced diabetes insipidus associated with pregnancy or the puerperium. Desmopressin acetate (100 mcg/mL solution) is given intranasally every 8–24 hours as needed for thirst and polyuria. It may be administered via metered-dose nasal inhaler containing 0.1 mL (10 mcg/spray) or via a calibrated rhinal tube. The starting dose is one metered-dose spray or 0.05–0.1 mL every 12–24 hours; the dose is then individualized according to response. Patients with adipsic diabetes insipidus require daily administration of desmopressin on a schedule determined by daily weights and frequent testing of serum sodium concentrations.

Oral desmopressin is useful for patients in whom rhinitis or conjunctivitis develops from the nasal preparation. It is initiated at 0.05 mg twice daily and increased to a maximum of 0.4 mg every 8 hours, if required. Sublingual desmopressin is not available in the United States.

Desmopressin can be given intravenously, intramuscularly, or subcutaneously in doses of 1–4 mcg every 12–24 hours as needed.

Desmopressin may cause hyponatremia, but this is uncommon if minimum effective doses are used and the patient allows thirst to occur every 1–2 days. Desmopressin can sometimes cause agitation, emotional changes, and depression with an increased risk of suicide. Patients should be monitored by family, friends, and medical staff when desmopressin therapy is started.

Prognosis

Central diabetes insipidus after pituitary surgery or head trauma usually remits after days to weeks but may be permanent if the hypothalamus or upper pituitary stalk is damaged.

Chronic central diabetes insipidus is ordinarily more an inconvenience than a dire medical condition. Hypernatremia can occur, especially when the hypothalamic thirst center is damaged, but diabetes insipidus does not otherwise reduce life expectancy, and the prognosis is that of the underlying disorder. Treatment with desmopressin allows normal sleep and activity.

ACROMEGALY & GIGANTISM

ESSENTIALS OF DIAGNOSIS

- Pituitary neuroendocrine tumor with over secretion of GH.
- **Gigantism:** begins before puberty before closure of epiphyses.
- **Acromegaly:** occurs after puberty with excessive growth of hands, feet, jaw, internal organs.
- Amenorrhea, hypertension, headaches, visual field loss, weakness.
- Soft, doughy, sweaty handshake.
- Elevated serum IGF-1.
- Serum GH not suppressed following oral glucose.

General Considerations

GH exerts much of its growth-promoting effects by stimulating the release of IGF-1 from the liver and other tissues.

Acromegaly is a rare condition, with a yearly incidence of about 10 cases per million. It is nearly always caused by a pituitary adenoma. About 70% are macroadenomas (1 cm or larger) when diagnosed. These tumors may be locally invasive, particularly into the cavernous sinus. Less than 1% are malignant. Acromegaly is usually sporadic but may rarely be familial, with $< 3\%$ being due to multiple endocrine neoplasia (MEN) types 1 or 4. Acromegaly may also be seen rarely in McCune-Albright syndrome and Carney complex. Acromegaly is rarely caused by ectopic secretion of growth hormone–releasing hormone or GH secreted by a neuroendocrine tumor or lymphoma.

Clinical Findings

A. Symptoms and Signs

Excessive GH causes tall stature and gigantism if it occurs in youth, before closure of epiphyses. Afterward, acromegaly develops. The manifestations of acromegaly usually present insidiously; median time to diagnosis after symptom onset is 10 years. The hands enlarge and a doughy, moist handshake is characteristic. The fingers widen, causing patients to enlarge their rings. Carpal tunnel syndrome is common. The feet also grow, particularly in shoe width. Facial features coarsen since the bones and sinuses of the skull enlarge; hat size increases. The mandible becomes more prominent, causing prognathism and malocclusion. Tooth spacing widens. Older photographs of the patient can be a useful comparison.

Macroglossia occurs, as does hypertrophy of pharyngeal and laryngeal tissue; this causes a deep, coarse voice and sometimes makes intubation difficult. Snoring and obstructive sleep apnea are common. A goiter may be noted. Hypertension (50%) and cardiomegaly are common. At diagnosis, about 10% of acromegalic patients have a dilated LV and HF with reduced EF. Weight gain is typical, particularly of muscle and bone. Insulin resistance is usually present and frequently causes diabetes mellitus (30%). Polyarticular arthralgias and degenerative arthritis are present in about 70% of patients. Overgrowth of vertebral bone can cause spinal stenosis. Colon polyps are found in about 30%, especially in patients with skin papillomas. The skin may also manifest hyperhidrosis, thickening, cystic acne, skin tags, and acanthosis nigricans.

GH-secreting pituitary tumors usually cause some hypogonadism, either by cosecretion of PRL or by direct pressure upon normal pituitary tissue. Decreased libido and erectile dysfunction are common in men and irregular menses or amenorrhea occur in women. Women who become pregnant have an increased risk of gestational diabetes and hypertension. Secondary hypothyroidism sometimes occurs; hypoadrenalism is unusual. Headaches are frequent. Temporal hemianopia may occur as a result of the optic chiasm being impinged by suprasellar extension of the tumor.

B. Laboratory Findings

For screening purposes, a random serum IGF-1 can be obtained. If it is normal for age, acromegaly is ruled out.

For further evaluation, the patient should be fasting for at least 8 hours (except for water), not be acutely ill, and not have exercised on the day of testing. Assay for the following: serum GH, IGF-1 (increased and usually over five times normal in acromegaly), PRL (cosecreted by many GH-secreting tumors), glucose (diabetes mellitus is common in acromegaly), liver enzymes and serum creatinine or urea nitrogen (liver failure or kidney disease can misleadingly elevate GH), serum calcium (to exclude hyperparathyroidism), serum inorganic phosphorus (frequently elevated), serum free T_4, and TSH (secondary hypothyroidism is common in acromegaly; primary hypothyroidism may increase PRL). Acromegaly is excluded if any serum GH is < 1 mcg/L; however, many normal individuals can have a serum GH above this level. Therefore, the glucose suppression test is usually performed. Glucose syrup (100 g) is administered orally, and serum GH is measured 60 minutes afterward; acromegaly is excluded if the serum GH is suppressed to below 0.4 mcg/L with an ultrasensitive GH assay. The serum IGF-1 and glucose-suppressed GH are usually complementary tests; however, disparities between the two occur in up to 30% of patients.

C. Imaging

MRI shows a pituitary tumor in over 96% of acromegalic patients. When MRI fails to demonstrate a tumor in the pituitary or surrounding bone, CT imaging of the chest and abdomen may demonstrate an ectopic source of GH or GHRH. Radiographs may show an enlarged sella and thickened skull and tufting of the terminal phalanges of the fingers and toes.

Differential Diagnosis

Active acromegaly must be distinguished from familial coarse features, large hands and feet, and isolated prognathism and from inactive ("burned-out") acromegaly in which there has been a spontaneous remission due to infarction of the pituitary adenoma. GH-induced gigantism must be differentiated from familial tall stature and from aromatase deficiency.

High serum GH levels can be caused by exercise or eating just prior to the test; acute illness or agitation; liver failure or kidney disease; malnourishment; diabetes mellitus; or concurrent treatment with oral estrogens, β-blockers, or clonidine. Acromegaly can be difficult to diagnose during pregnancy, since the placenta produces GH and commercial GH assays may not be able to distinguish between pituitary and placental GH. During normal adolescence, serum IGF-1 is usually elevated and GH may fail to be suppressed.

Complications

Complications include hypopituitarism, hypertension, hyperglycemia, cardiac enlargement, HF, and colon polyps. Arthritis of hips, knees, and spine can be troublesome as can carpal tunnel syndrome. Cord compression may occur. Visual field defects may be severe and progressive. Acute loss of vision or cranial nerve palsy may occur if the tumor undergoes spontaneous hemorrhage and necrosis (pituitary apoplexy).

Treatment

A. Pituitary Microsurgery

Transsphenoidal pituitary surgery achieves a remission in about 70% of patients. With tumors smaller than 2 cm and GH levels below 50 ng/mL, transsphenoidal pituitary surgery is successful in 80% of patients. Extrasellar extension of the pituitary tumor, particularly cavernous sinus invasion, reduces the likelihood of surgical cure. Complications of transsphenoidal surgery occur in about 12% of patients, including infection, CSF leak, and hypopituitarism.

B. Medications

Acromegalic patients with an incomplete biochemical remission after pituitary surgery may benefit from medical therapy with dopamine agonists, somatostatin analogs, tamoxifen, or pegvisomant.

Cabergoline is the oral dopamine agonist of choice. It is most successful for tumors that secrete both PRL and GH but can also be effective for patients with normal serum PRL levels. Cabergoline may be tried as monotherapy for patients with serum IGF-1 levels above normal but < 2.5 times the upper limit of normal. Cabergoline will shrink one-third of acromegaly-associated pituitary tumors by more than 50%. It appears to be safe during pregnancy. The initial dose is 0.25 mg orally twice weekly, which is gradually increased to a maximum dosage of 1 mg three times weekly (based on serum GH and IGF-1 levels).

Somatostatin receptor ligands (SRLs) include octreotide LAR, lanreotide depot, and pasireotide LAR. SRLs inhibit GH secretion and tumor growth by activating tumor somatostatin receptors. They can achieve serum GH levels below 2 ng/mL in 79% of patients and normal serum IGF-1 levels in 53% of patients.

Raloxifene is a selective estrogen receptor modulator (SERM) that may be useful for persistent acromegaly in men and in women who are postmenopausal or who have had breast cancer.

Pegvisomant, a GH receptor antagonist, can be helpful for patients resistant to other treatments, especially when there is associated diabetes mellitus. It blocks hepatic IGF-1 production but does not shrink GH-secreting tumors. Pegvisomant therapy produces symptomatic relief and normalizes serum IGF-1 levels in 63% of patients.

C. Stereotactic Radiosurgery

Acromegalic patients who do not achieve a complete remission with transsphenoidal surgery or medical therapy may be treated with stereotactic radiosurgery: linear accelerator (eg, CyberKnife), gamma knife radiosurgery, and proton beam radiosurgery. Following any pituitary radiation therapy, patients are advised to take lifelong daily low-dose aspirin because of the increased risk of small-vessel stroke. Stereotactic radiosurgery to pituitary tumors causes anterior hypopituitarism in 35–60% of patients within 5 years, so patients must have regular monitoring of their pituitary function.

Prognosis

Acromegaly is usually chronic and progressive unless treated. Spontaneous remissions are rare but have been reported following clinical or subclinical apoplexy (hemorrhage) within the tumor. Patients with acromegaly experience increased mortality from cardiovascular disorders and progressive acromegalic symptoms. Those who are treated and have a random serum GH under 1.0 ng/mL or a glucose-suppressed serum GH under 0.4 ng/mL with normal age-adjusted serum IGF-1 levels have reduced morbidity and mortality.

Postoperatively, normal pituitary function is usually preserved. Soft tissue swelling regresses but bone enlargement is permanent. Hypertension frequently persists despite successful surgery. Adjuvant medical therapy is successful in treating patients who are not cured by pituitary surgery. Gamma knife or CyberKnife radiosurgery reduces GH levels an average of 77%, with 20% of patients having a full remission after 12 months. Proton beam radiosurgery produces a remission in 80% of patients by 5 years. Radiation therapy eventually produces some degree of hypopituitarism in most patients. Patients must receive lifelong follow-up, with regular monitoring of serum GH and IGF-1 levels. Serum GH levels over 5 ng/mL and rising IGF-1 levels usually indicate a recurrent tumor.

HYPERPROLACTINEMIA

ESSENTIALS OF DIAGNOSIS

- Women: Oligomenorrhea, amenorrhea; galactorrhea; infertility.
- Men: Hypogonadism; decreased libido and erectile dysfunction; infertility.
- Elevated serum PRL.
- CT or MRI may show a pituitary adenoma.

General Considerations

Some causes of hyperprolactinemia are shown in Table 29–1. PRL-secreting pituitary tumors (prolactinomas) are the most common secretory pituitary tumor; they are usually sporadic but may rarely be familial as part of MEN type 1 or 4. Most are microadenomas (smaller than 1 cm), which are more common in women and typically do not grow even with pregnancy or oral contraceptives. Aggressive macroprolactinomas (larger than 1 cm) are more common in men and can spread into the cavernous sinuses and suprasellar areas; rarely, they may erode the floor of the sella to invade the paranasal sinuses. Hyperprolactinemia (without a pituitary adenoma) may also be familial.

Table 29–1. Causes of hyperprolactinemia.

Physiologic Causes	Pharmacologic Causes	Pathologic Causes
Assay interference Breastfeeding Exercise Familial (mutant prolactin receptor) Idiopathic Macroprolactin ("big prolactin") Nipple stimulation Neonatal Pregnancy Sleep (REM phase) Stress (trauma, surgery)	Amoxapine Amphetamines Anesthetic agents Antipsychotics (conventional and atypical) Androgens Butyrophenones Cimetidine (not famotidine or nizatidine) Cocaine use or withdrawal Domperidone Estrogens Hydroxyzine Licorice (real) Lorcaserin MAO inhibitors Methyldopa Metoclopramide Opioids Nicotine Phenothiazines Protease inhibitors Progestins Reserpine SSRIs Tricyclic antidepressants Verapamil	Acromegaly Adrenal insufficiency Chronic chest wall stimulation (thoracotomy, augmentation or reduction mammoplasty, mastectomy, herpes zoster, chest acupuncture, nipple rings, etc) Hypophysitis Hypothalamic or pituitary stalk damage Hypothyroidism Liver disease Multiple sclerosis Optic neuromyelitis Prolactin-secreting tumors Pseudocyesis (false pregnancy) Renal insufficiency (especially with zinc deficiency) Spinal cord lesions SLE

REM, rapid eye movement.

Clinical Findings

A. Symptoms and Signs

Hyperprolactinemia may cause hypogonadotropic hypogonadism and reduced fertility. Men usually have diminished libido and erectile dysfunction that may not respond to testosterone replacement; gynecomastia sometimes occurs.

About 90% of premenopausal women with prolactinomas experience amenorrhea, oligomenorrhea, or infertility. Estrogen deficiency can cause decreased vaginal lubrication, irritability, anxiety, and depression. Galactorrhea (lactation in the absence of nursing) is common. During pregnancy, clinically significant enlargement of a microprolactinoma (< 10 mm) occurs in < 3%; clinically significant enlargement of a macroprolactinoma occurs in about 30%.

Pituitary prolactinomas may cosecrete GH and cause acromegaly. Large tumors may cause headaches, visual symptoms, and pituitary insufficiency.

Aside from pituitary tumors, some women secrete an abnormal form of PRL that appears to cause peripartum cardiomyopathy.

B. Laboratory Findings

An elevated serum prolactin level should be verified with a repeat determination, ideally in a different laboratory.. Evaluate for conditions known to cause hyperprolactinemia, particularly pregnancy (serum hCG), hypothyroidism (serum FT_4 and TSH), kidney disease (BUN and serum creatinine), cirrhosis (liver tests), and hyperparathyroidism (serum calcium). Screen for acromegaly with a random serum IGF-1 level. Men are evaluated for hypogonadism with serum total and free testosterone, LH, and FSH. Women who have amenorrhea are assessed for hypogonadism with serum estradiol, LH, and FSH. Patients with macroprolactinomas or manifestations of possible hypopituitarism should be evaluated for hypopituitarism. Patients with hyperprolactinemia who are relatively asymptomatic and have no apparent cause for hyperprolactinemia should have an assay for macroprolactinemia, which is an increased circulating level of a high molecular weight PRL that is biologically inactive but is detected on assays.

C. Imaging

Patients with hyperprolactinemia not induced by drugs, hypothyroidism, or pregnancy should be examined by pituitary MRI. Small prolactinomas may be demonstrated, but clear differentiation from normal variants is not always possible. The normal pituitary grows during pregnancy. MRI is therefore generally not performed during pregnancy unless there are visual-field defects or other neurologic symptoms, in which case a limited MRI study without gadolinium should be done.

Differential Diagnosis

The differential diagnosis for galactorrhea includes the small amount of breast milk that can normally be expressed from the nipple in many parous women. Nipple stimulation from nipple rings, chest surgery, or acupuncture can cause galactorrhea; serum PRL levels may be normal or minimally elevated. Some women can have idiopathic galactorrhea with normal serum PRL levels. Normal breast milk may be various colors besides white. However, bloody galactorrhea requires evaluation for breast cancer.

About 40% of nonfunctional pituitary macroadenomas produce some degree of hyperprolactinemia. These and other lesions and malignancies can be misdiagnosed as prolactinomas. One distinguishing characteristic is that the serum PRL is usually only marginally elevated in the latter tumors, whereas with pituitary macroprolactinomas the serum PRL typically exceeds 100 mcg/L.

Pregnant women have high serum PRL levels, with physiological hyperplastic enlargement of the pituitary on MRI. Increased pituitary size is a normal variant in young women. Primary hypothyroidism can cause hyperprolactinemia and hyperplasia of the pituitary that can be mistaken for a pituitary adenoma. Macroprolactinemia occurs in 3.7% of the general population and accounts for 10–25% of all cases of hyperprolactinemia; pituitary MRI shows a nonpathological abnormality in 22% of such patients.

Treatment

Medications known to increase PRL should be stopped if possible (Table 29–1). Hyperprolactinemia due to hypothyroidism is corrected by levothyroxine.

Women with microprolactinomas who have amenorrhea or who desire contraception may safely take estrogen replacement or oral contraceptives; there is minimal risk of stimulating enlargement of the microadenoma. Patients with infertility and hyperprolactinemia may be treated with a dopamine agonist to improve fertility.

Pituitary macroprolactinomas have a higher risk of progressive growth, particularly during estrogen or testosterone HRT or during pregnancy. Therefore, patients with macroprolactinomas should not be treated with HRT or oral contraceptives unless they are in remission with dopamine agonist medication or surgery.

Pregnant women with macroprolactinomas should continue to receive treatment with dopamine agonists throughout the pregnancy to prevent tumor growth. If dopamine agonists are not used during pregnancy in a woman with a macroprolactinoma, visual field testing is required in each trimester. Measurement of PRL is not useful surveillance for tumor growth due to the fact that PRL increases greatly during normal pregnancy.

A. Dopamine Agonists

Dopamine agonists (cabergoline, bromocriptine, quinagolide, or aripiprazole) are the initial treatment of choice for patients with giant prolactinomas and those with hyperprolactinemia desiring restoration of normal sexual function and fertility. Cabergoline is the most effective and usually best-tolerated ergot-derived dopamine agonist. Begin with 0.25 mg orally once weekly for 1 week, then 0.25 mg twice weekly for the next week, then 0.5 mg twice weekly. Further dosage increases may be required monthly, based on serum PRL levels, up to a maximum of 1.5 mg twice weekly. Bromocriptine (1.25–20 mg/day orally) is an alternative. Aripiprazole may be added to conventional dopamine agonist therapy to optimally reduce high PRL levels caused by antipsychotics or antidepressants. Patients whose tumor is resistant to one dopamine agonist may be switched to another in an effort to induce a remission.

Dopamine agonists are given at bedtime to minimize side effects of fatigue, nausea, dizziness, and orthostatic hypotension, which occur in up to 50% of patients. These symptoms usually improve with dosage reduction and continued use. Dopamine agonists can cause a variety of psychiatric side effects (particularly depression, impulse control disorder, and hypersexuality) that are not dose related and may take weeks to resolve once the drug is discontinued.

Dopamine agonists do not increase the risk of miscarriage or teratogenicity. Pregnant women with microprolactinomas may safely stop treatment during pregnancy and breastfeeding. However, over 20% of macroadenomas enlarge significantly during pregnancy; if therapy is withdrawn, patients must be monitored with serum PRL determinations and computer-assisted visual fields. Women with macroprolactinomas who have responded to dopamine agonists may safely receive oral contraceptives as long as they continue receiving dopamine agonist therapy.

B. Surgical Treatment

Transsphenoidal pituitary surgery may be urgently required for large tumors undergoing apoplexy or those severely compromising visual fields. It is also used electively for patients who do not tolerate or respond to dopamine agonists. Transsphenoidal pituitary surgery is generally well tolerated, with a mortality rate of < 0.5%. For pituitary microprolactinomas, skilled neurosurgeons are successful in normalizing PRL in 87% of patients and some patients prefer surgery to long-term therapy with dopamine agonists.

Complications, such as CSF leakage, meningitis, stroke, or visual loss, occur in about 3% of cases; sinusitis, nasal septal perforation, or infection complicates about 6.5% of transsphenoidal surgeries. Diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–14 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. Mild hyponatremia (Na ≥ 125 mmol/L) can usually be managed as an outpatient restriction of free water plus tolvaptan, if necessary. Symptomatic or severe hyponatremia (Na < 125 mmol/L) usually requires inpatient management.

C. Stereotactic Radiosurgery

Stereotactic radiosurgery is seldom required for prolactinomas since they usually respond to cabergoline or surgery. It is reserved for patients with macroadenomas that are growing despite treatment with dopamine agonists or patients who are intolerant to dopamine agonists.

D. Chemotherapy

Some patients with aggressive pituitary macroadenomas or carcinomas are not surgical candidates and do not respond to dopamine agonists or radiation therapy. A small percentage of patients with aggressive tumors respond to cabergoline with the addition of either temozolomide or everolimus.

Prognosis

Pituitary microprolactinomas are typically indolent, and only 15% grow after diagnosis. However, macroprolactinomas tend to be more aggressive. Prolactinomas generally respond well to dopamine agonist therapy. Ninety percent of patients with prolactinomas experience a fall in serum PRL to 10% or less of pretreatment levels and 80% achieve a normal serum PRL level. Shrinkage of a pituitary adenoma occurs early, but the maximum effect may take up to 1 year. Nearly half of prolactinomas—even massive tumors—shrink > 50%. During pregnancy, growth of a pituitary prolactinoma occurs in 3% of women with a microprolactinoma and in 23% of those with a macroprolactinoma. If cabergoline is stopped after 2 years of therapy, hyperprolactinemia recurs in 68% of patients with idiopathic hyperprolactinemia, 79% with microprolactinomas, and 84% with macroprolactinomas.

The 10-year recurrence rate is 13% for pituitary microadenomas after transsphenoidal surgery; pituitary function can be preserved in over 95% of cases. However, the surgical success rate for macroprolactinomas is much lower, and the complication rates are higher.

NONFUNCTIONING PITUITARY ADENOMAS

ESSENTIALS OF DIAGNOSIS

- Clinical and biochemical evaluation for pituitary hormone hypersecretion is negative.
- MRI shows a pituitary microadenoma (< 1 cm) or macroadenoma (≥ 1 cm).
- Headache, visual field compromise, and anterior hypopituitarism are common with macroadenomas.
- Elevated serum PRL with macroadenomas may be due to stalk compression.

General Considerations

Although pituitary adenomas may secrete PRL, GH, or ACTH, most are nonfunctional and do not produce symptoms of hormone oversecretion. Pituitary nonfunctioning adenomas occur more frequently in men than women and are more common with age. Pituitary adenomas are found on about 16% of brain MRIs; most are microadenomas < 1 cm diameter.

Clinical Findings

A. Symptoms and Signs

Nonfunctioning pituitary macroadenomas (1 cm or larger) tend to be more aggressive than functioning pituitary adenomas. Those with nonfunctioning macroadenomas are much more likely to be symptomatic from mass effect with visual field compromise, headache, cranial nerve palsies affecting extraocular muscles, and pituitary apoplexy. Larger macroadenomas frequently cause some hypopituitarism, particularly hypogonadotropic hypogonadism. Nonfunctioning pituitary microadenomas are asymptomatic.

B. Laboratory Findings

1. Pituitary hormone hypersecretion—All patients with a pituitary adenoma require testing for pituitary hormone hypersecretion. Obtain a serum PRL to screen for prolactin hypersecretion; women with hyperprolactinemia are tested for pregnancy with a serum hCG. Testing for Cushing disease or acromegaly should be obtained, if clinically indicated.

2. Anterior hypopituitarism—Patients should have the following tests: serum free T_4, TSH, morning serum testosterone and free testosterone. Serum LH and FSH should be obtained in men with low serum testosterone, women who are postmenopausal, and younger women with amenorrhea. Serum sodium and glucose should be obtained in all patients. A cosyntropin stimulation test is performed for patients with hyponatremia or symptoms of possible hypoadrenalism. A serum IGF-1 is drawn to screen for GH deficiency. Younger patients with short stature who have not fused their epiphyses should have a full evaluation for growth hormone deficiency.

3. Pituitary macroadenomas—Patients with a macroadenoma that impinges upon the optic chiasm require formal visual field testing.

C. Imaging

Pituitary dynamic contrast-enhanced MRI (3T) is the imaging modality of choice for the evaluation and follow-up of pituitary adenomas. Nonfunctioning pituitary microadenomas that are smaller than 0.5 cm require no further MRI follow-up. For nonfunctioning pituitary adenomas 0.5 cm or larger, repeat MRI is recommended at 6 months, then yearly for 3 years. If no enlargement is noted, MRI surveillance can then be done less frequently.

Differential Diagnosis

Mass lesions that can mimic pituitary adenoma include pituitary craniopharyngiomas, gliomas, meningiomas, skull base osteosarcomas, Rathke cysts, lymphocytic hypophysitis, infection, or metastases. Large normal pituitary glands and physiologic pituitary enlargement during primary hypothyroidism or pregnancy should also be considered; serum prolactin levels are elevated in primary hypothyroidism and pregnancy. Hyperprolactinemia also occurs when there is pituitary stalk compression from pituitary macroadenomas and other mass lesions; with pituitary stalk compression, serum prolactin is typically lower than expected for the size of the pituitary mass.

Treatment

Patients with asymptomatic pituitary nonfunctioning microadenomas ordinarily require no treatment. Surgery is the preferred treatment option for patients whose adenoma is causing mass effect symptoms, premature development of puberty, hormonal deficiencies, or the emergence of symptomatic hormonal hypersecretion. A trial of oral cabergoline may be considered for patients with macroadenomas who have progressive disease. Radiation therapy can be used for select individuals with pituitary macroadenomas.

Prognosis

The prognosis is excellent for patients with nonfunctioning microadenomas smaller than 0.5 cm. Patients with larger nonfunctioning microadenomas also have a very good prognosis but require follow-up. Transsphenoidal surgery is 65% successful in completely resecting pituitary macroadenomas, improves hypopituitarism in 50%, and reverses visual field compromise in 80% of patients. Following surgery, deficiencies of anterior pituitary hormones occur in 10% of patients. The 6-year postoperative recurrence rate has been reported to be 36% following surgery alone and 13% after surgery plus adjuvant radiation therapy.

DISEASES OF THE THYROID GLAND

THYROIDITIS

ESSENTIALS OF DIAGNOSIS

Autoimmune thyroiditis

- Chronic lymphocytic (Hashimoto) thyroiditis is the most common thyroiditis and often progresses to hypothyroidism.
- Postpartum thyroiditis and subacute lymphocytic thyroiditis (silent thyroiditis) can cause transient hyperthyroidism due to passive release of stored thyroid hormone.
- Thyroid peroxidase antibodies (TPO Ab) or thyroglobulin antibodies (Tg Ab) are usually high.

Painful subacute thyroiditis (de Quervain thyroiditis)

- Tender thyroid gland with painful dysphagia.
- Viral etiology.
- Antithyroid antibodies are absent or low.

Infectious (suppurative) thyroiditis

- Severe, painful thyroid gland.
- Febrile with leukocytosis and elevated ESR.

IgG_4-related thyroiditis (Riedel thyroiditis)

- Most often in middle age or older women.
- Usually part of a systemic fibrosing syndrome.

General Considerations

A. Autoimmune Thyroiditis

Several clinical entities are classified as autoimmune thyroiditis, including chronic lymphocytic thyroiditis, postpartum thyroiditis, and painless (silent) sporadic subacute thyroiditis. Dietary iodine supplementation (especially when excessive) and certain medications can cause autoimmune thyroiditis. The incidence of autoimmune thyroiditis varies by kindred, race, and sex. It is commonly familial. Elevated serum levels of antithyroid antibodies are detectable in the general population in 3% of men and 13% of women. Among United States adults, elevated levels of antithyroid antibodies are found in 14.3% of those who self-identify as White, 10.9% as Latino/a, and 5.3% as Black. Subclinical thyroiditis is extremely common; autopsy series have found focal thyroiditis in 40% of women and 20% of men.

1. Chronic lymphocytic thyroiditis—Also known as "Hashimoto thyroiditis," chronic lymphocytic thyroiditis is the most common thyroid disorder in the United States. Cell-mediated T-lymphocyte invasion gives the microscopic appearance of "lymphocytic thyroiditis." Humoral autoimmunity, with detectable serum antithyroid antibodies (TPO Ab or Tg Ab, or both), is present in most but not all affected patients.

2. Postpartum thyroiditis—Postpartum thyroiditis occurs soon after delivery in about 7% of women. The affected thyroid releases stored thyroid hormone, resulting in transient hyperthyroidism (often mild and undiagnosed) followed by hypothyroidism. The thyroid gland is not acutely tender, but some women report mild thyroid discomfort. Most women recover normal thyroid function. Women in whom postpartum thyroiditis develops have a 70% chance of recurrence after subsequent pregnancies. It occurs most commonly in women who have high levels of TPO Ab in the first trimester of pregnancy or immediately after delivery.

3. Painless (silent) sporadic subacute thyroiditis—This form of autoimmune thyroiditis is similar to postpartum thyroiditis, except that it is not related to pregnancy. Causes include amiodarone and immunotherapy. Hyperthyroidism results from the release of stored thyroid hormone. This accounts for about 1% of cases of thyrotoxicosis and is followed by hypothyroidism that may or may not resolve spontaneously.

4. Other causes—Dietary iodine supplementation (especially when excessive) and certain medications, including tyrosine kinase inhibitors, alemtuzumab, interferon-α, interleukin-2, thalidomide, lenalidomide, lithium, amiodarone, and immune checkpoint inhibitors, are other causes of autoimmune thyroiditis. Chronic hepatitis C increases the risk for autoimmune thyroiditis: 21% of affected patients have antithyroid antibodies and 13% have hypothyroidism. COVID-19 infection increases the risk for autoimmune thyroiditis and subacute thyroiditis. Vaccination against SARS-CoV-2 can trigger subacute thyroiditis as well as Graves disease.

Autoimmune thyroiditis often progresses to hypothyroidism, which may be linked to thyrotropin receptor–blocking antibodies, detected in 10% of patients with autoimmune thyroiditis. High serum levels of TPO Ab also predict progression from subclinical to symptomatic hypothyroidism. Although the hypothyroidism is usually permanent, up to 11% of patients experience a remission after several years. Hyperthyroidism can be caused by the destructive release of thyroid hormones (followed by hypothyroidism) or by increased synthesis of thyroid hormones (Graves disease).

Autoimmune thyroiditis is sometimes associated with other endocrine deficiencies as part of autoimmune polyendocrine syndrome type 2 (APS-II). Adults with APS-II are prone to autoimmune thyroiditis, type 1 diabetes mellitus, autoimmune gonadal failure, hypoparathyroidism, and adrenal insufficiency. Thyroiditis is frequently associated with other autoimmune conditions: pernicious anemia, Sjögren syndrome, vitiligo, IBD, celiac disease, and gluten sensitivity.

B. Painful Subacute Thyroiditis

Also called de Quervain thyroiditis, granulomatous thyroiditis, and giant cell thyroiditis, painful subacute thyroiditis is relatively common. Like painless subacute thyroiditis, most affected patients have transient hyperthyroidism, followed by hypothyroidism. Painful subacute thyroiditis is typically associated with viral upper respiratory infection (including COVID-19) and may follow vaccinations, including SARS-CoV-2. Some patients also have antithyroid antibodies. Its incidence peaks in the summer to early autumn. It affects both sexes, but over 75% are middle-aged women. Subacute thyroiditis can also be a sequela of a drug-induced hypersensitivity syndrome.

C. Infectious (Suppurative) Thyroiditis

Infectious thyroiditis is rare among immunocompetent patients. It is usually bacterial but mycobacterial, fungal, and parasitic infections can occur, particularly in immunosuppressed individuals.

D. IgG$_4$-Related (Riedel) Thyroiditis

IgG$_4$-related thyroiditis, also called Riedel thyroiditis, invasive fibrous thyroiditis, Riedel struma, woody thyroiditis, ligneous thyroiditis, and invasive thyroiditis, is the rarest form of thyroiditis. It is found most frequently in middle-aged or older women and is usually part of a multifocal systemic fibrosis syndrome. It may occur as a thyroid manifestation of IgG$_4$-related systemic disease.

Clinical Findings

A. Symptoms and Signs

In **autoimmune thyroiditis,** the thyroid gland may be diffusely enlarged, firm, and finely nodular but is frequently not palpable. One thyroid lobe may be asymmetrically enlarged, raising concerns about neoplasm. Although patients may report neck tightness, pain and tenderness are not usually present. Other patients have no palpable goiter and no neck symptoms. The thyroid is fibrotic and atrophic in about 10% of cases, particularly in older women.

Symptoms and signs are mostly related to levels of thyroid hormone. Affected patients may have combinations of hyperthyroidism and hypothyroidism. For example, a patient with hypothyroidism might later develop hyperthyroidism that can wax and wane. Depression and chronic fatigue are more common, even after correction of hypothyroidism.

About one-third of patients have mild dry mouth (xerostomia) or dry eyes (keratoconjunctivitis sicca) related to Sjögren syndrome. Associated myasthenia gravis is usually of mild severity, mainly affecting the extraocular muscles and having a relatively low incidence of detectable AChR Ab or thymic disease. Associated celiac disease or gluten intolerance can produce fatigue or depression, sometimes in the absence of GI symptoms.

Postpartum thyroiditis is typically manifested by hyperthyroidism that begins 1–6 months after delivery and persists for only 1–2 months. Then, hypothyroidism tends to develop beginning 4–8 months after delivery.

In painless sporadic thyroiditis, thyrotoxic symptoms are usually mild; a small, nontender goiter may be palpated in about 50% of patients. The course is similar to postpartum thyroiditis.

Painful subacute thyroiditis presents with an acute, usually painful enlargement of the one or both lobes of the thyroid gland, often with dysphagia. Those with bilateral involvement are likely to be more hyperthyroid. The majority of patients experience pain that may radiate to the ears, jaw, or upper chest. Patients usually have a low-grade fever and fatigue. The manifestations may persist for weeks or months. Thyrotoxicosis develops in 50% of affected patients and tends to last for several weeks. Subsequently, hypothyroidism develops that lasts 4–6 months. Normal thyroid function typically returns within 12 months, but persistent hypothyroidism develops in 5% of patients.

Infectious suppurative thyroiditis patients usually are febrile and have severe pain, tenderness, redness, and fluctuation in the region of the thyroid gland.

In **IgG4-related thyroiditis,** thyroid enlargement is often asymmetric; the gland is stony hard and adherent to the neck structures, causing signs of compression and invasion, including dysphagia, dyspnea, pain, and hoarseness. Related conditions include retroperitoneal fibrosis, fibrosing mediastinitis, sclerosing cervicitis, subretinal fibrosis, and sclerosing cholangitis.

B. Laboratory Findings

In **autoimmune thyroiditis** (including postpartum thyroiditis), there are usually increased circulating levels of the antithyroid antibodies TPO Ab (90%) or Tg Ab (40%). However, 5% of patients have no detectable antithyroid antibodies. Most patients with thyroiditis caused by immune checkpoint inhibitors have no detectable antithyroid antibodies. Antithyroid antibodies decline during pregnancy and are often undetectable in the third trimester. Once autoimmune thyroiditis has been diagnosed, monitoring of antibody levels is not helpful. If autoimmune thyroiditis leads to inadequate thyroid hormone release, the serum TSH level is elevated and thyroid hormone levels may be normal or decreased (hypothyroidism). Autoimmune thyroiditis may also lead to passive release of stored thyroid hormones, resulting in hyperthyroidism increased serum FT_4 levels that are proportionally higher than T_3 levels and suppressed TSH levels. Because T_4 is less active than T_3, the hyperthyroidism seen in autoimmune thyroiditis is usually less severe than with Graves disease.

Patients with autoimmune thyroiditis have a 15% incidence of having serum IgA tissue transglutaminase (tTG) antibody and at least 5% have clinically significant celiac disease.

In **painful subacute thyroiditis,** the ESR is markedly elevated while antithyroid antibody titers are low, distinguishing it from autoimmune thyroiditis. Subacute thyroiditis may result in passive release of stored thyroid hormones, resulting in hyperthyroidism. In **infectious thyroiditis,** both the leukocyte count and ESR are usually elevated.

C. Imaging

Ultrasound typically shows diffuse heterogeneous thyroid density and reduced echogenicity. It is useful to distinguish autoimmune thyroiditis from multinodular goiter, thyroid nodules that are suspicious for malignancy, and Graves disease. In thyroiditis, vascularity is reduced or normal, whereas in Graves disease, the thyroid gland is hypervascular.

Radioiodine (RAI) uptake and scan can help distinguish thyroiditis from Graves disease; painful subacute thyroiditis exhibits very low RAI uptake. RAI uptake may be normal or high with uneven uptake in chronic autoimmune thyroiditis (euthyroid or hypothyroid); CT or MRI is not useful in diagnosis.

[^{18}F] Fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) scanning frequently shows diffuse thyroid uptake of isotope in cases of thyroiditis.

D. Fine-Needle Aspiration Cytology

Patients with autoimmune thyroiditis who have a thyroid nodule should have an ultrasound-guided FNA biopsy, since the risk of papillary thyroid cancer is about 8% in such nodules. When infectious (suppurative) thyroiditis is suspected, an FNA biopsy with Gram stain and culture is required. FNA biopsy is usually not required for painful subacute thyroiditis but shows characteristic giant multinucleated cells.

Complications

Autoimmune thyroiditis may lead to hypothyroidism. Hyperthyroidism may develop, either due to the emergence of Graves disease or due to the release of stored thyroid hormone, a condition variably termed "hashitoxicosis" or "painless sporadic thyroiditis." Euthyroid women with high serum TPO Ab may have an increased risk of miscarriage and preterm birth; unfortunately, treatment with levothyroxine fails to improve these risks. Perimenopausal women with high serum levels of TPO Ab have a higher relative risk of depression, independent of ambient thyroid hormone levels.

Subacute and chronic thyroiditis are complicated by the effects of pressure on the neck structures: dyspnea and, in Riedel struma, vocal cord palsy. Papillary thyroid carcinoma or thyroid lymphoma may rarely be associated with chronic thyroiditis and must be considered in the diagnosis of uneven painless enlargements that continue despite treatment; such patients require FNA biopsy. In the suppurative forms of thyroiditis, any complication of infection may occur.

Differential Diagnosis

All types of goiters must be considered in the differential diagnosis of thyroiditis, especially if enlargement is rapid.

Unlike in goiters, in subacute thyroiditis there is very low RAI uptake and the T_4 and T_3 are elevated. Thyroid autoantibody tests have been helpful in the diagnosis of autoimmune thyroiditis, but the tests are not specific (positive in patients with multinodular goiters, malignancy [eg, thyroid carcinoma, lymphoma], and concurrent Graves disease). The subacute and suppurative forms of thyroiditis may resemble any infectious process in or near the neck structures. Chronic thyroiditis may resemble thyroid carcinoma, especially if the enlargement is uneven and if there is pressure on surrounding structures; both disorders may be present in the same gland.

Treatment

A. Autoimmune Thyroiditis

If hypothyroidism is present, levothyroxine should be given in usual replacement doses (0.05–0.2 mg orally daily) (see Hypothyroidism & Myxedema, below). If hyperthyroidism is present, see Hyperthyroidism (Thyrotoxicosis), below.

In patients with a large goiter and normal or elevated serum TSH, an attempt is made to shrink the goiter with levothyroxine in doses sufficient to drive the serum TSH below the reference range while maintaining clinical euthyroidism. Suppressive doses of T_4 tend to shrink the goiter an average of 30% over 6 months. If the goiter does not regress, lower replacement doses of levothyroxine may be given. If the thyroid gland is only minimally enlarged and the patient is euthyroid, regular observation is indicated, since hypothyroidism may develop, often years later.

B. Painful Subacute Thyroiditis

All treatment is empiric and must be continued for several weeks. Recurrence is common. The drug of choice is aspirin (325–650 mg orally every 4–6 hours, which relieves pain and inflammation) or NSAIDs. For patients with severe pain, prednisone, 20 mg orally daily for about 2 weeks, can be effective. Thyrotoxic symptoms are treated with propranolol, 10–40 mg orally every 6 hours, or propranolol ER, 60–160 mg orally daily. Iodinated contrast agents cause a prompt fall in serum T_3 levels and a dramatic improvement in thyrotoxic symptoms. Ipodate sodium (Bilivist, Oragrafin) or iopanoic acid (Telepaque) is given orally in doses of 500 mg orally daily until serum FT_4 levels return to normal. Transient hypothyroidism is treated with T_4 (0.05–0.1 mg orally daily) if symptomatic.

C. Infectious (Suppurative) Thyroiditis

Treatment is with antibiotics and with surgical drainage when fluctuation is marked. Surgical thyroidectomy may be required.

D. IgG_4-Related (Riedel) Thyroiditis

The treatment of choice is tamoxifen, 20 mg orally twice daily, which must be continued for years. Tamoxifen can induce partial to complete remissions in most patients within 3–6 months. Its mode of action appears to be unrelated to its antiestrogen activity. Short-term corticosteroid treatment may be added for partial alleviation of pain and compression symptoms. Surgical decompression usually fails to permanently alleviate compression symptoms; surgery is difficult due to dense fibrous adhesions, making surgical complications more likely. Rituximab may be useful for Riedel thyroiditis that is refractory to tamoxifen and corticosteroids.

Prognosis

Patients with Hashimoto autoimmune thyroiditis generally have an excellent prognosis, since the condition either remains stable for years or progresses slowly to hypothyroidism, which is easily treated. Although 80% of women with postpartum thyroiditis subsequently recover normal thyroid function, permanent hypothyroidism eventually develops in about 50% within 7 years. In subacute painful thyroiditis, spontaneous remissions and exacerbations are common; the disease process may smolder for months.

HYPOTHYROIDISM & MYXEDEMA

ESSENTIALS OF DIAGNOSIS

- Hashimoto autoimmune thyroiditis is the most common cause.
- Fatigue, cold intolerance, constipation, weight change, depression, menorrhagia, hoarseness.
- Dry skin, bradycardia, delayed return of deep tendon reflexes.
- FT_4 is usually low.
- TSH elevated in primary hypothyroidism.

General Considerations

Hypothyroidism is common, with 0.3% of the population having overt disease. About 85% of affected individuals are women. Thyroid hormone deficiency affects almost all body functions. The degree of severity ranges from mild and unrecognized hypothyroid states to striking myxedema. Maternal hypothyroidism during pregnancy results in offspring with IQ scores that are an average 7 points lower than those of euthyroid mothers.

Hypothyroidism may be due to failure or resection of the thyroid gland itself (primary hypothyroidism) or deficiency of pituitary TSH (secondary hypothyroidism; see Hypopituitarism). Autoimmune thyroiditis is the most common cause of hypothyroidism (see Thyroiditis). A hypothyroid phase also occurs in subacute (de Quervain) viral thyroiditis following initial hyperthyroidism.

Goiter (thyroid enlargement) may be present with thyroiditis, iodide deficiency, genetic thyroid enzyme defects, food goitrogens in iodide-deficient areas (eg, turnips, cassavas), or infiltrating diseases (eg, cancer, sarcoidosis). Goitrogenic medications include iodide, propylthiouracil (PTU) or methimazole, sulfonamides, amiodarone, interferon-α, interferon-β, interleukin-2, and lithium. About 50% of patients taking lithium long term have an ultrasound-detectable goiter. Goiter is often absent in patients with autoimmune thyroiditis or hypothyroidism due to destruction of the gland by head-neck or chest-shoulder radiation therapy or ^{131}I therapy. Total thyroidectomy causes hypothyroidism; after hemithyroidectomy, hypothyroidism develops in 22% of patients.

Amiodarone, because of its high iodine content, causes clinically significant hypothyroidism in 15–20% of patients as well as thyrotoxicosis (see Amiodarone-induced thyrotoxicosis, below). Hypothyroidism occurs most often in patients with preexisting autoimmune thyroiditis. The T_4 level is low or low-normal, and the TSH is elevated, usually over 20 mIU/L. Another 17% of patients taking amiodarone are asymptomatic with normal serum T_4 levels despite elevations in serum TSH; they can be closely monitored without levothyroxine therapy.

Hypothyroidism may also develop in patients with a high iodine intake, especially if they have underlying lymphocytic thyroiditis. Some malignancies overexpress thyroid hormone inactivating enzyme (type 3 deiodinase) and cause "consumptive hypothyroidism." This has occurred with large hemangiomas or a heavy tumor burden of colon cancer, basal cell cancer, fibrous tumors, or gastrointestinal stromal tumors (GISTs).

Chemotherapeutic agents that can cause silent thyroiditis include tyrosine kinase inhibitors, denileukin diftitox, alemtuzumab, interferon-α, interleukin-2, thalidomide, lenalidomide, and immune checkpoint inhibitors. Thyroiditis usually starts with hyperthyroidism (often unrecognized) and then progresses to hypothyroidism. RAI-based targeted radioisotope therapy can also cause hypothyroidism. Mifepristone causes primary hypothyroidism and an increased dose requirement for thyroid hormone replacement. Mitotane causes secondary hypothyroidism.

Clinical Findings

A. Symptoms and Signs

1. Common manifestations—Mild hypothyroidism often escapes detection. Patients typically have nonspecific symptoms that include weight gain, fatigue, lethargy, depression, weakness, dyspnea on exertion, arthralgias or myalgias, muscle cramps, menorrhagia, constipation, dry skin, headache, paresthesias, cold intolerance, carpal tunnel syndrome, and Raynaud syndrome. Physical findings can include bradycardia; diastolic hypertension; thin, brittle nails; thinning of hair; peripheral edema; puffy face and eyelids; and skin pallor or yellowing (carotenemia). Delayed relaxation of deep tendon reflexes may be present. Patients often have a goiter that arises due to elevated serum TSH levels or the underlying thyroid pathology.

2. Less common manifestations—Less common symptoms of hypothyroidism include diminished appetite and weight loss, hoarseness, decreased sense of taste and smell, and diminished auditory acuity. Some patients with goiter may report dysphagia or neck discomfort. Although most menstruating women have menorrhagia, some women have scant menses or amenorrhea. Physical findings may include loss of eyelash and eyebrow hairs; thickening of the tongue; hard pitting edema; and effusions into the pleural and peritoneal cavities as well as into joints. Galactorrhea may also be present. Cardiac enlargement ("myxedema heart") and pericardial effusions may develop. Psychosis "myxedema madness" can occur from severe hypothyroidism or from toxicity of other drugs whose metabolism is slowed in hypothyroidism.

Some hypothyroid patients with autoimmune thyroiditis have symptoms that are not due to hypothyroidism but rather to conditions associated with autoimmune thyroiditis; these include Addison disease, hypoparathyroidism, diabetes mellitus, pernicious anemia, Sjögren syndrome, vitiligo, biliary cirrhosis, gluten sensitivity, and celiac disease.

B. Laboratory Findings

The single best screening test for hypothyroidism is the serum TSH (Table 29–2). In primary hypothyroidism, the serum TSH is increased in a reflex effort to stimulate the failing gland, while the serum FT_4 is low or low-normal. The normal reference range for ultrasensitive TSH levels is generally 0.4–4.0 mIU/L. The normal range of TSH varies with age.

Other laboratory abnormalities can include hypoglycemia or anemia (with normal or increased mean corpuscular volume). Hyponatremia due to the syndrome of inappropriate ADH secretion (SIADH) or decreased GFR is common. Additional frequent findings include increased serum levels of LDL cholesterol, triglycerides, lipoprotein(a), liver enzymes, creatine kinase, or PRL. In patients with autoimmune thyroiditis, titers of antibodies against TPO and TG are high; serum ANA may be present but are rarely indicative of lupus.

Subclinical hypothyroidism is defined as the state of having a normal serum FT_4 with a serum TSH that is above the reference range. It occurs most often in persons aged 65 years or older, in whom the prevalence is 13%. Subclinical hypothyroidism is often transient, and serum TSH levels normalize spontaneously in about 60% of cases within 5 years. The likelihood of TSH normalization is higher in patients without antithyroid antibodies and those with a marginally elevated serum TSH. The term "subclinical" is

Table 29–2. Appropriate use of thyroid tests.

	Test	Comment
For screening	Serum TSH Free thyroxine (FT_4)	Most sensitive test for primary hypo- and hyperthyroidism Excellent test
For hypothyroidism	Serum TSH Thyroid peroxidase and thyroglobulin antibodies	High in primary and low in secondary hypothyroidism Elevated in autoimmune (Hashimoto) thyroiditis
For hyperthyroidism	Serum TSH Triiodothyronine (T_3) or free triiodothyronine (FT_3) ^{123}I uptake and scan Thyroid peroxidase and thyroglobulin antibodies Thyroid-stimulating immunoglobulin (TSI)	Suppressed except in TSH-secreting pituitary tumor or pituitary hyperplasia (rare) Elevated Increased uptake; diffuse versus "hot" foci on scan Elevated in Graves disease Usually (65%) positive in Graves disease
For thyroid nodules	Fine-needle aspiration (FNA) biopsy ^{123}I uptake and scan ^{99m}Tc scan Ultrasonography	Best diagnostic method for thyroid cancer Cancer is usually "cold"; less reliable than FNA biopsy Vascular versus less vascular Useful to assist FNA biopsy. Useful in assessing the risk of malignancy (multinodular goiter or pure cysts are less likely to be malignant). Useful to monitor nodules and patients after thyroid surgery for carcinoma.

somewhat misleading, since it refers to the serum hormone levels and not the patient's symptoms.

C. Imaging

Radiologic imaging is usually not necessary for patients with hypothyroidism. On CT or MRI, a goiter may be noted in the neck or in the mediastinum (retrosternal goiter). An enlarged thymus is frequently seen in cases of autoimmune thyroiditis. On MRI, the pituitary is often quite enlarged in primary hypothyroidism, due to hyperplasia of TSH-secreting cells.

Differential Diagnosis

The differential diagnosis for subclinical hypothyroidism (low serum T_4 or high serum TSH in the absence of hypothyroidism) includes antibody interference with the serum TSH assay, macro-TSH, sleep deprivation, exercise, recovery from nonthyroidal illness, acute psychiatric emergencies, and other conditions and medications (Table 29–3).

Euthyroid sick syndrome should be considered in patients without known thyroid disease who are found to have a low serum FT_4 with a serum TSH that is not elevated. This syndrome can be seen in patients with severe illness, caloric deprivation, or major surgery. Treatment with levothyroxine is not indicated for patients with euthyroid sick syndrome.

Serum TSH tends to be suppressed in severe nonthyroidal illness, making the diagnosis of concurrent primary hypothyroidism difficult, although the presence of a goiter suggests the diagnosis. The clinician must decide whether such severely ill patients (with a low serum T_4 and low TSH) might have hypothyroidism due to hypopituitarism. Patients without symptoms of prior brain lesion or hypopituitarism are very unlikely to suddenly develop hypopituitarism during an unrelated illness. Patients with diabetes insipidus, hypopituitarism, or other signs of a CNS lesion may be given T_4 empirically.

Complications

Severe or long-standing hypothyroidism may increase susceptibility to bacterial pneumonia or rarely cause megacolon or infertility. Organic psychoses with paranoid delusions may occur ("myxedema madness"). Rhabdomyolysis may occur and cause kidney dysfunction. Untreated hypothyroidism during pregnancy often results in miscarriage. Thyroid therapy may exacerbate preexistent CAD or HF and rarely may precipitate adrenal crisis.

Myxedema crisis refers to severe symptoms of hypothyroidism that become a threat to life. Of patients with myxedema crisis, 94% have primary hypothyroidism, 50% have previously undiagnosed hypothyroidism, and 80% are women. Myxedema crisis can also result from failure to take prescription levothyroxine. It can occur spontaneously in severely hypothyroid patients with prolonged exposure to the cold, with resultant hypothermia. It also can also be induced by a stroke, HF, infection (particularly pneumonia), or trauma. Myxedema crisis is often precipitated by the administration of sedatives, antidepressants, hypnotics, anesthetics, or opioids, the metabolism of which is slowed in hypothyroidism. These drugs further impair cognition and respiratory drive and can precipitate respiratory arrest. All patients with myxedema crisis have some degree of obtundation, ranging from somnolence to coma. The term "myxedema coma" is a misnomer, since the alertness of affected patients varies from simple lethargy to coma. Convulsions and abnormal CNS signs may occur. Patients may also present with hyponatremia (65%), hypothermia (50%), hypotension (40%), bradycardia (20%), hypoglycemia (15%), rhabdomyolysis, and AKI. The mortality rate is high.

Table 29–3. Factors that may cause aberrations in laboratory tests that may be mistaken for primary hypothyroidism.[1]

Low Serum T_4 or T_3	High Serum TSH
Acute psychiatric illness	Acute psychiatric illness (transient) (14%)
Cirrhosis	Amiodarone
Familial thyroid-binding globulin deficiency	Anti-mouse antibodies
Laboratory error	Antithyrotropin antibodies
Nephrotic syndrome	Anti-TSH receptor antibodies
Severe illness	Autoimmune disease (assay interference)
Drugs	Drugs
Androgens	Allopurinol
Antiseizure drugs	Amphetamines
Carbamazepine	Atypical antipsychotics
Phenobarbital	Dopamine agonists
Phenytoin	Heroin
Asparaginase	Phenothiazines
Carbamazepine (T_4)	Exercise before testing
Chloral hydrate	Following prolonged primary hypothyroidism
Corticosteroids	Heterophile antibodies
Diclofenac (T_3), naproxen (T_3)	Laboratory error
Didanosine	Macro-thyrotropin
Fenclofenac	Nonadherence to thyroid replacement therapy
5-Fluorouracil	Older adults (especially women)
Halofenate	Pituitary TSH hypersecretion
Imatinib	Recovery from acute nonthyroidal illness (transient)
Mitotane	Strenuous exercise (acute)
Nicotinic acid	Sleep deprivation (acute)
Oxcarbazepine	TSH resistance
Phenobarbital	
Phenytoin	
Salicylates in large doses (T_3 and T_4)	
Sertraline	
Stavudine	
T_3 therapy (T_4)	

[1] True primary hypothyroidism may coexist.

T_4, levothyroxine; T_3, triiodothyronine.

Treatment

Before beginning therapy with thyroid hormone, the hypothyroid patient requires a clinical assessment for adrenal insufficiency and angina. The presence of either condition requires further evaluation and management.

For patients with subclinical hypothyroidism, levothyroxine therapy is sometimes given to women attempting pregnancy, young adult patients aged 30 years or younger, patients with serum TSH levels 20 mIU/L or higher, and those with significant symptoms attributable to hypothyroidism. Other patients with subclinical hypothyroidism do not require levothyroxine therapy but must be monitored regularly for the emergence of symptoms.

A. Treatment of Hypothyroidism

Synthetic levothyroxine is the preferred preparation for treating hypothyroidism. Generic levothyroxine preparations have met FDA criteria for bioequivalence. Lyophilized preparations of levothyroxine are available for reconstitution and intravenous administration, when indicated.

Desiccated natural porcine thyroid preparations containing both T_4 and T_3 (eg, Armour Thyroid, Nature-Throid, NP Thyroid) are prescribed by some clinicians. About 65 mg (1 grain) of desiccated thyroid is equivalent to 100 mcg of levothyroxine. Several professional societies discourage the use of desiccated thyroid preparations but many patients prefer them.

Otherwise healthy young and middle-aged adults with hypothyroidism may be treated initially with levothyroxine in average doses of about 1.6 mcg/kg/day. Lower doses can be used for very mild hypothyroidism, while full doses are given for more symptomatic hypothyroidism and during pregnancy. The initial hormonal goal of levothyroxine replacement therapy should be to normalize serum TSH levels. Bedtime levothyroxine administration results in somewhat higher serum T_4 and lower TSH levels than morning administration. Therefore, the administration timing for levothyroxine should be kept constant. After beginning daily administration, significant increases in serum T_4 levels are seen within 1–2 weeks and near-peak levels within 3–4 weeks.

Pregnant women with overt hypothyroidism or myxedema should be treated immediately with levothyroxine at full replacement doses.

Patients with stable CAD or those who are over age 60 years are treated with smaller initial doses of levothyroxine, 25–50 mcg orally daily; higher initial doses may be used if such patients are severely hypothyroid. The dose can be increased by 25 mcg every 1–3 weeks until the patient is euthyroid. Ideally, patients with hypothyroidism and unstable CAD or uncontrolled atrial fibrillation should begin levothyroxine replacement following medical or interventional therapy.

Myxedema crisis can be treated with full replacement doses of oral levothyroxine. Intravenous levothyroxine may be required in some situations, including for obtunded patients with hypercapnia requiring mechanical ventilation. Levothyroxine sodium 500 mcg is given intravenously as a loading dose, followed by 50–100 mcg intravenously daily; the lower dose is given to patients with suspected CAD. In patients with severe myxedema crisis, liothyronine (T_3, Triostat) can be given intravenously with a loading bolus of 10–20 mcg, followed by 10 mcg intravenous boluses every 8–12 hours for the first 48 hours. Patients with hypothermia are warmed only with blankets, since faster warming can precipitate cardiovascular collapse. Patients with hypoglycemia are given 5% dextrose intravenously.

Hyponatremia in any hypothyroid patient requires evaluation for adrenal insufficiency. Medications and hypotonic intravenous solutions that can cause or aggravate hyponatremia are discontinued. Patients who are mildly symptomatic with a serum sodium 120–129 mEq/mL are treated with fluid restriction, unless they are dehydrated. Symptomatic patients with a serum sodium 120–129 mEq/mL must be managed as an inpatient (see Chapter 24, Hyponatremia).

When giving intravenous saline to myxedematous patients, care must be taken to avoid fluid overload.

Patients with hypercapnia require mechanical assistance with ventilation. Opioid medications must be stopped or used in very low doses. Infections must be treated aggressively. Patients in whom concomitant adrenal insufficiency is suspected are treated with hydrocortisone at initial doses of 100 mg intravenously, followed by 25–50 mg every 6–8 hours.

B. Monitoring and Optimizing Treatment of Hypothyroidism

Regular clinical and laboratory monitoring is critical to determine the optimal levothyroxine dose. After initiating levothyroxine replacement, serum TSH levels are monitored monthly and the dose adjusted with an aim to normalize the serum TSH levels (0.4–2.0 mIU/L). The patient should be prescribed sufficient levothyroxine to restore a clinically euthyroid state; this can usually be attained by maintaining the serum TSH levels in the lower half of the reference range (0.4–2.0 mIU/L). Serum levels of both FT_4 and FT_3 are also measured.

Pregnancy usually increases the levothyroxine dosage requirement, which may be required as early as the fifth week of gestation. Postpartum, levothyroxine replacement requirements ordinarily return to prepregnancy level.

Decreased levothyroxine dose requirements occur in women after delivery, after bilateral oophorectomy or natural menopause, after cessation of oral estrogen replacement, or during therapy with GnRH agonists.

1. Elevated serum TSH level—For most patients, a high serum TSH indicates underreplacement with levothyroxine. However, patient nonadherence to prescribed levothyroxine is surprisingly common; before increasing the levothyroxine dosage, it is important to confirm patient compliance. For patients with CAD or recurrent atrial fibrillation, it may be prudent to administer lower doses of levothyroxine to keep serum TSH in the high-normal or even slightly elevated range.

Increased levothyroxine dosage requirements (low serum T_4 levels) can occur with drugs that increase the hepatic metabolism of levothyroxine and with oral estrogen (Table 29–3). Amiodarone can increase or decrease levothyroxine dose requirements. Malabsorption of levothyroxine can be caused by GI disorders (malabsorption, atrophic gastritis); by coadministration of binding substances, such as iron, fiber; raloxifene; sucralfate; aluminum hydroxide antacids; sevelamer; orlistat; bile acid–binding resins (cholestyramine and colesevelam); PPIs, calcium, magnesium, milk, coffee, and soy milk.

Serum TSH may be elevated transiently in acute psychiatric illness, with antipsychotics and phenothiazines, and during recovery from nonthyroidal illness.

2. Normal serum TSH level—For most patients, the goal of levothyroxine replacement is to maintain the serum TSH in the low normal range (0.4–2.0 mIU/L). Patients taking levothyroxine replacement with normalized serum TSH levels frequently have serum FT_4 levels above the reference range (28%) or serum FT_3 levels below the reference range (7%), which may explain why some patients taking levothyroxine continue to have subjective symptoms of mild hypothyroidism and higher serum LDL cholesterol compared with matched euthyroid controls. Such patients must be assessed for concurrent conditions, such as an adverse drug reaction, Addison disease, depression, hypogonadism, anemia, celiac disease, or gluten sensitivity. If such conditions are not present or are treated and hypothyroid-type symptoms persist, a serum T_3 or free T_3 level may be helpful. Low serum T_3 levels may reflect inadequate peripheral deiodinase activity to convert inactive T_4 to active T_3. Unless contraindicated by unstable angina, such patients with continued hypothyroid-type symptoms may be carefully administered a slightly higher dose of levothyroxine to suppress the serum TSH slightly while achieving clinical euthyroidism and a serum FT_3 in the lower half of the reference range. For most patients with hypothyroidism, an ideal stable maintenance dose of levothyroxine can usually be found.

3. Low or suppressed serum TSH level—A serum TSH level below the reference range (adults 0.4–4.0 mIU/L) is either "low" (0.1–0.39 mIU/L) or "suppressed" (< 0.1 mIU/L). Clinically euthyroid patients receiving levothyroxine who have "low" TSH levels do not have increased morbidity. However, a "suppressed" serum TSH often indicates overreplacement with levothyroxine; such patients may have symptoms of hyperthyroidism with an increased risk for atrial fibrillation, osteoporosis, and clinical hyperthyroidism. The differential diagnosis for a suppressed serum TSH includes hypopituitarism, severe nonthyroidal illness, and some medications. Aside from the latter circumstances, when the serum TSH is suppressed, the dosage of levothyroxine is reduced. However, some patients feel unmistakably hypothyroid while taking the reduced dose of levothyroxine and have low serum T_3 or free T_3 levels. For such patients, a higher levothyroxine dose may be resumed or substituted with desiccated thyroid, with close surveillance for atrial fibrillation, osteoporosis, and subtle manifestations of hyperthyroidism.

Prognosis

Patients with mild hypothyroidism caused by autoimmune thyroiditis have a remission rate of 11%. With levothyroxine treatment of hypothyroidism, return to a normal state is usually the rule, but relapses will occur if treatment is interrupted. Patients with myxedema crisis have a mortality rate of 30–100%, with higher rates in patients with severe symptoms.

When to Refer

- Difficulty titrating levothyroxine replacement to normal TSH or clinically euthyroid state.
- Any patient with significant CAD needing levothyroxine therapy.

When to Admit

- Suspected myxedema crisis.
- Hypercapnia.

HYPERTHYROIDISM (Thyrotoxicosis)

ESSENTIALS OF DIAGNOSIS

- Sweating, weight loss or gain, anxiety, palpitations, loose stools, heat intolerance, menstrual irregularity.
- Tachycardia; warm, moist skin; stare; tremor.
- Graves disease: most common cause of hyperthyroidism; palpable goiter in most; ophthalmopathy common.
- Amiodarone: most common cause of thyrotoxic crisis (“thyroid storm”).
- Suppressed TSH in primary hyperthyroidism; usually increased T_4, FT_4, T_3, FT_3.

General Considerations

The term “thyrotoxicosis” refers to the clinical manifestations associated with elevated serum levels of T_4 or T_3 that are excessive for the individual (hyperthyroidism).

A. Graves Disease

Graves disease is the most common cause of thyrotoxicosis. It is an autoimmune disorder, characterized by an increase in synthesis and release of thyroid hormones. Autoantibodies, known as thyroid-stimulating immunoglobulins (TSI) or thyrotropin receptor antibodies (TRAb), bind to the TSH receptors in the thyroid cell membranes and stimulate the gland to overproduce thyroid hormones. The presence of these antibodies distinguishes Graves disease from autoimmune chronic lymphocytic (Hashimoto) thyroiditis. Both conditions usually have present serum antithyroid antibodies (TPO Ab or Tg Ab or both).

Graves disease is more common in women than in men (8:1). Its usual onset is between the ages of 20 and 40 years. It may be accompanied by infiltrative ophthalmopathy (Graves exophthalmos) and, less commonly, by infiltrative dermopathy (pretibial myxedema). The thymus gland is typically enlarged and serum ANA levels are usually elevated. Many patients with Graves disease have a family history of either Graves disease or Hashimoto autoimmune thyroiditis.

Viral infections, including infections with SARS-CoV-2, have been reported to precipitate Graves disease. Vaccinations against SARS-CoV-2 also have triggered de novo Graves disease as well as relapses 4–30 days after infection or vaccination.

Patients with Graves disease have an increased risk of other systemic autoimmune disorders, including Sjögren syndrome, celiac disease, pernicious anemia, Addison disease, alopecia areata, vitiligo, type 1 diabetes mellitus, hypoparathyroidism, myasthenia gravis, and cardiomyopathy.

B. Toxic Multinodular Goiter and Thyroid Nodules

Autonomous hyperfunctioning thyroid nodules that produce hyperthyroidism are known as toxic multinodular goiter (Plummer disease). They are more prevalent among older adults and in iodine-deficient regions. A single hyperfunctioning nodule can also produce hyperthyroidism. Thyroid cancer is found in 5% of patients with toxic multinodular goiter.

C. Autoimmune (Postpartum or Silent) Thyroiditis and Subacute Thyroiditis

These conditions cause thyroid inflammation with release of stored hormone. They all produce a variable triphasic course: variable hyperthyroidism is followed by transient euthyroidism and progression to hypothyroidism (see Thyroiditis, above).

D. Medication-Induced Hyperthyroidism

1. Amiodarone-induced thyrotoxicosis (AIT)—Amiodarone causes thyrotoxicosis in about 5% of patients in the United States, with a higher incidence in iodine-deficient geographic areas. Amiodarone is 37% iodine by weight and its metabolites have a half-life of about 100 days. In the short term, amiodarone normally increases serum TSH (without hypothyroidism), though usually not over 20 mIU/L. Serum T_4 and FT_4 rise about 40% and may become elevated in clinically euthyroid patients, while serum T_3 levels typically decline. After 3 months, the serum TSH usually normalizes. Thyroid function tests (TSH, FT_4, T_3) should be checked before starting amiodarone, after 3–6 months of therapy, and thereafter at least every 6 months (sooner if clinically warranted). Due to early short-term changes, it is best to not check thyroid function tests during the first 3 months of therapy.

Amiodarone-induced thyrotoxicosis (AIT) can occur at any time during treatment and may develop several months after treatment discontinuation. It is diagnosed when serum TSH levels are suppressed and serum T_3 or FT_3 levels are high or high-normal. Amiodarone is the leading cause for thyrotoxic crisis (“thyroid storm”); however, the manifestations can be missed since amiodarone tends to cause bradycardia. Type 1 AIT is caused by the *active* production of excessive thyroid hormone and typically occurs within 2–6 months after starting amiodarone. Type 2 AIT is caused by the *passive* release of stored thyroid hormone and occurs an average of 30 months after starting amiodarone.

2. Iodine-induced hyperthyroidism (Basedow disease)— The recommended iodine intake for nonpregnant adults is 150 mcg/day. Higher iodine intake can precipitate hyperthyroidism in patients with nodular goiters, autonomous thyroid nodules, or asymptomatic Graves disease, and less commonly in patients with no detectable underlying thyroid disorder. Common sources of excess iodine include intravenous oral potassium iodine supplements, certain foods (eg, kelp, nori), topical iodinated antiseptics (eg, povidone iodine), and medications (eg, amiodarone or potassium iodide). Intravenous iodinated radiocontrast dye can rarely induce a painful, destructive subacute thyroiditis, similar to type 2 amiodarone-induced thyrotoxicosis.

3. Tyrosine kinase inhibitors—Silent autoimmune thyroiditis that releases stored thyroid hormone, resulting in hyperthyroidism, develops in about 3% of patients receiving chemotherapy with tyrosine kinase inhibitors (eg, axitinib, sorafenib, sunitinib). Hypothyroidism usually follows hyperthyroidism and occurs in 19% of patients taking these drugs.

4. Immune checkpoint inhibitor cancer therapy— Immune checkpoint inhibitor therapy directed against either PD-1/PD-L1 or CTLA-4/B7-1/B7-2 frequently precipitates autoimmune adverse reactions. Thyroid autoimmunity commonly causes thyroiditis, hypothyroidism (primary or secondary), or hyperthyroidism from either passive release of thyroid hormone or active production of thyroid hormone (Graves disease).

E. Pregnancy, hCG-Secreting Trophoblastic Tumors, and Testicular Choriocarcinoma

Human chorionic gonadotropin (hCG) can bind to the thyroid's TSH receptors. Very high levels of serum hCG, particularly during the first 4 months of pregnancy may cause sufficient receptor activation to cause gestational thyrotoxicosis. About 20% of pregnant women have a low serum TSH during pregnancy, but only 1% of such women have clinical hyperthyroidism that requires treatment. Pregnant women are more likely to have hCG-induced thyrotoxicosis if they have high levels of serum asialo-hCG, a subfraction of hCG that has a greater affinity for TSH receptors. Such women are also more likely to suffer from hyperemesis gravidarum. This condition must be distinguished from true Graves disease in pregnancy, which usually predates conception and may be associated with high serum levels of TSI and antithyroid antibodies or with exophthalmos.

F. Rare Causes of Hyperthyroidism

Thyrotoxicosis factitia is due to intentional or accidental ingestion of excessive amounts of exogenous thyroid hormone. Struma ovarii is thyroid tissue contained in about 3% of ovarian dermoid tumors and teratomas. Pituitary TSH hypersecretion by a pituitary thyrotroph tumor or hyperplasia can rarely cause hyperthyroidism; serum TSH is elevated or inappropriately normal in the presence of true thyrotoxicosis. Metastatic functioning thyroid carcinoma can cause hyperthyroidism in patients with a heavy tumor burden.

High levels of hCG can also cause thyrotoxicosis in some cases of pregnancies with gestational trophoblastic disease (molar pregnancy, choriocarcinoma). Some such pregnancies have produced thyrotoxic crisis. Men have developed hyperthyroidism from high levels of serum hCG secreted by a testicular choriocarcinoma.

Clinical Findings

A. Symptoms and Signs

Thyrotoxicosis can produce nervousness, restlessness, heat intolerance, increased sweating, palpitations, pruritus, fatigue, muscle weakness, muscle cramps, frequent bowel movements, weight change (usually loss), or menstrual irregularities. There may be fine resting finger tremors, moist warm skin, fever, hyperreflexia, fine hair, and onycholysis. Angina or atrial fibrillation may also be present, sometimes in the absence of other thyrotoxic symptoms (apathetic hyperthyroidism). Women with postpartum thyroiditis are often asymptomatic or experience only minor symptoms, such as palpitations, heat intolerance, and irritability. Chronic thyrotoxicosis may cause osteoporosis.

Patients with Graves disease usually have a diffusely enlarged thyroid that is frequently asymmetric and often accompanied by a bruit. However, there may be no palpable thyroid enlargement. The thyroid gland in painful subacute thyroiditis is usually moderately enlarged and tender. There is often dysphagia and pain that can radiate to the jaw or ear. With toxic multinodular goiter, there are usually palpable nodules. Patients with silent thyroiditis or postpartum thyroiditis have either no palpable goiter or a small, nontender goiter.

Cardiopulmonary manifestations of thyrotoxicosis commonly include a forceful heartbeat, premature atrial contractions, and sinus tachycardia. Patients often have exertional dyspnea. Atrial fibrillation or atrial tachycardia occurs in about 8% of patients with thyrotoxicosis, The ventricular response from the atrial fibrillation may be difficult to control. Thyrotoxicosis can cause a thyrotoxic cardiomyopathy, and the onset of atrial fibrillation can precipitate HF. Echocardiogram reveals pulmonary artery hypertension in about 40% of hyperthyroid patients. Even "subclinical hyperthyroidism" increases the risk for atrial fibrillation and overall mortality. Hemodynamic abnormalities and pulmonary hypertension are reversible with restoration of euthyroidism.

Thyrotoxic crisis or "thyroid storm" is an extreme form of severe thyrotoxicosis and an immediate threat to life. The most common manifestations are cardiac (HF, severe sinus tachycardia [60%], ventricular fibrillation [13%], MI, and cardiogenic shock), agitation or delirium

(63%), high fever, vomiting, diarrhea, dehydration, and hepatic impairment (52%).

Eye manifestations that occur with hyperthyroidism are discussed in Thyroid Eye Disease, below.

Graves dermopathy (pretibial myxedema) occurs in about 3% of patients with Graves disease. It usually affects the pretibial region but can also affect the dorsal forearms and wrists and dorsum of the feet. It is more common in patients with high levels of serum TSI and severe Graves ophthalmopathy. Glycosaminoglycans accumulation and lymphoid infiltration occur in affected skin, which becomes erythematous with a thickened, rough texture.

Thyroid acropachy is a rare skeletal manifestation of Graves disease. It presents with digital clubbing, swelling of fingers and toes, and radiographic findings of periostitis involving phalangeal and metacarpal bones.

Clinical hyperthyroidism during pregnancy has a prevalence of about 0.2%. It may commence before conception or emerge during pregnancy, particularly the first trimester. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease, with decreasing antibody titers and decreasing serum T_4 levels as the pregnancy advances; about 30% of affected women experience a remission by late in the second trimester. Undiagnosed or undertreated hyperthyroidism carries an increased risk of miscarriage, preeclampsia-eclampsia, preterm delivery, abruptio placenta, maternal HF, and thyrotoxic crisis (thyroid storm). Such thyrotoxic crisis can be precipitated by trauma, infection, surgery, or delivery and confers a fetal/maternal mortality rate of about 25%.

Hypokalemic periodic paralysis occurs in about 15% of Asian or American Indian men with thyrotoxicosis and is 30 times more common in men than women. It is marked by sudden symmetric flaccid paralysis, along with hypokalemia and hypophosphatemia, that occurs during hyperthyroidism (often after intravenous dextrose, oral carbohydrates, or vigorous exercise) despite few, if any, of the classic signs of thyrotoxicosis. Attacks last 7–72 hours.

Table 29–4. Factors that can cause misleading laboratory tests for hyperthyroidism.

High Serum T_4 or T_3	Low Serum TSH
Laboratory error	Laboratory error
Collection vial contains gel barrier for T_3	African descent (3–4%)
Acute psychiatric problems (30%)	Autonomous thyroid or thyroid nodule
Acute or chronic active hepatitis, primary biliary cirrhosis	Corticosteroids (short-term use)
AIDS (increased TBG)	Drugs
Autoimmunity	Amphetamines
Euthyroid sick	Biotin supplements (certain assays)
Familial thyroid-binding abnormalities	Calcium channel blockers (nifedipine, verapamil)
Familial resistance to thyroid (Refetoff syndrome)	Dobutamine
Pregnancy: morning sickness, hyperemesis gravidarum	Dopamine
Drugs	Dopamine agonists
Amiodarone	Glucocorticoids
Amphetamines	Metformin
Biotin supplements (certain assays)	Somatostatin analogs
Capecitabine	Thyroid hormone
Clofibrate	Elderly euthyroid
Estrogens (oral)	hCG-secreting trophoblastic tumors
Heparin	Hypopituitarism
Heroin, methadone	Nonthyroidal illness (severe)
Perphenazine	Pregnancy (especially with morning sickness)
Tamoxifen	Suppression after recent therapy for hyperthyroidism
Thyroid hormone therapy (excessive or factitious)	TSH variants not detected by commercial assays

hCG, human chorionic gonadotropin; T_4, levothyroxine; T_3, triiodothyronine; TBG, thyroid-binding globulin.

B. Laboratory Findings

Serum FT_4, T_3, FT_3, and T_4, thyroid resin uptake, and FT_4 index are all usually increased. Sometimes the FT_4 level may be normal but with an elevated serum T_3 (T_3 toxicosis). The severity of the elevation of serum FT_4 and FT_3 levels does not always correlate with the severity of thyrotoxic manifestations; patients with thyrotoxic crisis tend to have serum thyroid levels that are not significantly higher than those with less pronounced symptoms. Serum T_4 or T_3 can be elevated in other nonthyroidal conditions (Table 29–4).

Serum TSH is suppressed in hyperthyroidism (except in the very rare cases of pituitary inappropriate secretion of thyrotropin). Serum TSH may be misleadingly low in other nonthyroidal conditions (Table 29–4). The term **"subclinical hyperthyroidism"** is used to describe individuals with a low serum TSH but normal serum levels of FT_4 and T_3; in such patients, the overall prevalence of symptomatic hyperthyroidism is 0.7–1.8% in iodine-sufficient patients and 2–15% in patients with iodine deficiency. About two-thirds of patients with subclinical hyperthyroidism have serum TSH levels of 0.1–0.4 mIU/L (mild subclinical hyperthyroidism), while the remainder have serum TSH levels below 0.1 mIU/L (severe subclinical hyperthyroidism).

Hyperthyroidism can cause microcytic anemia, neutropenia, hypercalcemia, and increased liver enzymes. Hyperthyroidism also increases urinary magnesium excretion, which can lead to hypomagnesemia, functional hypoparathyroidism with hypocalcemia, and tetany (rarely). Hypokalemia and hypophosphatemia occur in thyrotoxic periodic paralysis.

Problems of diagnosis occur in patients with acute psychiatric disorders; about 30% of these patients have elevated serum T_4 levels without clinical thyrotoxicosis. The TSH is not usually suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T_4 levels return to normal gradually.

In **Graves disease**, serum thyroid-stimulating immunoglobulin (TSI) and serum thyrotropin receptor antibody (TRAb) levels are usually detectable (90%). Very high serum TSI levels predispose to Graves ophthalmopathy. TPO Ab or Tg Ab are usually elevated, reflecting concurrent autoimmune thyroiditis. Serum ANA levels are also usually elevated without evidence of rheumatologic disease.

With painful **subacute thyroiditis,** patients often have an increased WBC, ESR, and CRP. About 25% have antithyroid antibodies (usually in low titer); serum TSI and TRAb levels are normal. Patients with iodine-induced hyperthyroidism have undetectable serum TSI, TRAb, and serum TPO Ab, and an elevated urinary iodine concentration. In thyrotoxicosis factitia, serum thyroglobulin levels are low, distinguishing it from other causes of hyperthyroidism.

With **hyperthyroidism during pregnancy,** women have an elevated serum total T_4 and FT_4 while the TSH is suppressed. An apparent lack of full TSH suppression in hyperthyroidism can be seen due to misidentification of hCG as TSH in certain assays. The serum FT_4 assay is difficult to interpret in pregnancy. Although the serum T_4 is elevated in most pregnant women, values over 20 mcg/dL (257 nmol/L) are encountered only in hyperthyroidism. The T_3 resin uptake, which is low in normal pregnancy because of high thyroxine-binding globulin (TBG) concentration, is normal or high in thyrotoxic persons.

Since high levels of T_4 and FT_4 are normally seen in patients taking **amiodarone,** a suppressed TSH must be present along with a greatly elevated T_4 (> 20 mcg/dL [257 nmol/L]) or T_3 (> 200 ng/dL [3.1 nmol/L]) in order to diagnose hyperthyroidism. In type 1 amiodarone-induced thyrotoxicosis, the presence of proptosis and serum TSI (TSHrAb) is diagnostic. In type 2 amiodarone-induced thyrotoxicosis, serum levels of interleukin-6 (IL-6) are usually quite elevated.

C. Radioisotope Uptake and Imaging

Note: *All radioisotope testing is contraindicated during pregnancy or breastfeeding.*

Radioiodine (^{123}I) scanning can be helpful in some situations to determine the cause of hyperthyroidism but is unnecessary for diagnosis in patients with obvious Graves disease who have elevated serum TSI or associated Graves ophthalmopathy. A high thyroid RAI uptake is seen in Graves disease and toxic nodular goiter. A low ^{123}I RAI uptake is characteristic of iodine-induced hyperthyroidism and thyroiditis (subacute, silent, or postpartum), distinguishing them from Graves disease.

Technetium (Tc-99m) pertechnetate thyroid uptake is increased or normal with Graves disease, whereas those with thyrotoxicosis from thyroiditis (silent, subacute, postpartum) have reduced uptake.

99mTc-sestamibi (MIBI) scanning usually shows increased uptake with type 1 amiodarone-induced thyrotoxicosis (AIT), decreased uptake in type 2 AIT, and intermediate uptake in mixed AIT.

D. Other Imaging

Thyroid ultrasound can be helpful in hyperthyroid patients with palpable thyroid nodules. Thyroid ultrasound shows a variably heterogeneous, hypoechoic gland in thyroiditis. Color flow Doppler sonography is helpful to distinguish type 1 amiodarone-induced thyrotoxicosis (enlarged gland with normal to increased blood flow velocity and vascularity) from type 2 amiodarone-induced thyrotoxicosis (distorted gland without increased vascularity).

MRI and CT scanning of the orbits are the imaging methods of choice to visualize Graves ophthalmopathy affecting the extraocular muscles. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos that must be distinguished from orbital pseudotumor, tumors, and other lesion. Chest CT in Graves disease often detects an enlarged thymus gland.

Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions that elevate serum T_4 and T_3 or suppress serum TSH without affecting clinical status (see Table 29–4). Serum TSH is commonly suppressed in early pregnancy and only about 10% of pregnant women with a low TSH have clinical hyperthyroidism.

States of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycythemia, cancer, and pheochromocytoma—rarely cause confusion. Acromegaly may also produce tachycardia, sweating, and thyroid enlargement.

The differential diagnosis for thyroid-associated ophthalmopathy includes an orbital tumor (eg, lymphoma) or pseudotumor. Ocular myasthenia gravis is another autoimmune condition that occurs more commonly in Graves disease.

Diabetes mellitus and Addison disease may coexist with thyrotoxicosis and can aggravate the weight loss, fatigue, and muscle weakness seen with hyperthyroidism.

Complications

Hypercalcemia, osteoporosis, and nephrocalcinosis may occur in hyperthyroidism. Decreased libido, erectile dysfunction, diminished sperm motility, and gynecomastia may be noted in men. Other complications include cardiac arrhythmias and HF, thyroid crisis, ophthalmopathy, dermopathy, and thyrotoxic hypokalemic periodic paralysis.

Treatment

A. Treatment of Graves Disease

Table 29–5 outlines the treatment options for hyperthyroidism.

1. Propranolol—Propranolol is used for symptomatic relief of tachycardia, tremor, diaphoresis, and anxiety until the hyperthyroidism is resolved. It is the initial treatment of choice for thyrotoxic crisis and effectively treats thyrotoxic hypokalemic periodic paralysis. Treatment usually starts with propranolol ER, which is given every 12 hours for severe hyperthyroidism due to accelerated metabolism of the propranolol; it may be given once daily as hyperthyroidism improves (Table 29–5).

2. Thiourea drugs—Methimazole or PTU is used for most patients with Graves disease or toxic nodular goiter. Methimazole is preferred, but PTU is used for women

Table 29–5. Medications for the treatment of hyperthyroidism.[1]

Medication	Dose and Frequency	Indications
Propranolol ER	Dose: 60–80 mg orally once daily, increasing every 3 days until heart rate < 90 beats per minute. Maximum dose: 320 mg daily	Symptomatic relief of tachycardia, tremor, diaphoresis, anxiety Thyrotoxic crisis Hypokalemic periodic paralysis
Thiourea: Methimazole	Initial dose: usually 30–60 mg orally once daily Dose may be divided and given twice daily to avoid GI upset Lower dose of 10–20 mg for very mild symptoms During pregnancy or breastfeeding, dose should not exceed 20 mg daily	Young adults Older adult patients Mild thyrotoxicosis Small goiter Fear of isotopes Precautions during pregnancy[2]
Propylthiouracil (PTU)	Dose: 300–600 mg orally daily in four divided doses During pregnancy or breastfeeding, dose should not exceed 200 mg daily	Precautions during pregnancy[2]
Iodinated contrast agents Iopanoic acid or ipodate sodium	Initial dose: 500 mg orally twice daily for 3 days Maintenance dose: 500 mg once daily	Effective temporary treatment of thyrotoxicosis, especially for patients who are very symptomatic Alternative treatment for patients intolerant of thioureas
Radioactive iodine (RAI, ^{131}I)		Destroys overactive thyroid tissue See text for Precautions Avoid with thyroid eye disease (Graves ophthalmopathy)
Prednisone	Initial dose: 0.5–0.7 mg/kg orally daily After 2 weeks: begin to slowly taper and stop after about 3 months	Type 2 amiodarone-induced thyrotoxicosis

[1] See text for expanded discussion of these agents.
[2] See Treatment of Hyperthyroidism During Pregnancy-Planning, Pregnancy, and Lactation in text.

planning pregnancy or during pregnancy. See Treatment of Hyperthyroidism During Pregnancy-Planning, Pregnancy, and Lactation, below. There is a 50% chance of remission of hyperthyroidism with long-term thiourea therapy. A better likelihood of long-term remission occurs in patients with small goiters, mild hyperthyroidism, those requiring small doses of thiourea, and those with serum TSI (TSHrAb) < 2 mU/L. Patients whose TPO Ab and Tg Ab remain low after 2 years of therapy have only a 10% rate of relapse. There should be no rush to discontinue thiourea therapy in favor of RAI or surgery, even after years of treatment. Thioureas may be continued long term for patients who are tolerating them well. The exception is women with thyrotoxic Graves disease who are planning pregnancy in the near future; thyroid surgery or RAI should be considered at least 4 months in advance of conception. Thiourea drugs are also useful for preparing nonpregnant hyperthyroid patients for surgery and older patients for RAI treatment.

Agranulocytosis (absolute neutrophil count below 500/mcL [0.5×10^9/L]) or pancytopenia may occur abruptly in 0.4% of patients taking either methimazole or PTU. All patients receiving thiourea therapy must be informed of the danger of agranulocytosis or pancytopenia and the need to stop the drug and seek medical attention immediately with the onset of any infection or unusual bleeding. Nearly 85% of agranulocytosis cases occur within 90 days of commencing therapy; however, continued long-term blood test monitoring is required. Agranulocytosis generally remits spontaneously with discontinuation of the thiourea.

Other common side effects include pruritus, allergic dermatitis, nausea, and dyspepsia. Since the two thiourea drugs are similar, patients who have a major allergic reaction to one should not be given the other.

The patient's thyroid status is best monitored clinically and with serum FT_4 levels. The patient may become clinically hypothyroid for 2 weeks or more before TSH levels rise.

A. Methimazole—Except during the first trimester of pregnancy, methimazole is generally preferred over PTU since it is more convenient to use and is less likely to cause fulminant hepatic necrosis. Methimazole therapy is also less likely to cause ^{131}I treatment failure. Rare complications peculiar to methimazole include serum sickness, cholestatic jaundice, alopecia, nephrotic syndrome, hypoglycemia, and loss of taste.

B. Propylthiouracil—Acute liver failure occurs in about 1 in 1000 patients, making PTU a second-line medication for treating patients with Graves hyperthyroidism. The onset of severe liver toxicity varies from 3 days to 12 months after starting PTU. Therefore, PTU is ordinarily reserved for treating women actively seeking fertility and during the first trimester of pregnancy, when it is preferred over methimazole. See Treatment of Hyperthyroidism During Pregnancy-Planning, Pregnancy, and Lactation, below.

3. Iodinated contrast agents—Iopanoic acid (Telepaque) and ipodate sodium (Bilivist, Oragrafin) are iodinated contrast agents that inhibit peripheral 5′-monodeiodination of T_4, thereby blocking its conversion to active T_3. They provide effective temporary treatment for thyrotoxicosis of any cause and are particularly useful for patients who are symptomatically very thyrotoxic. Within 24 hours, serum T_3 levels fall an average of 62%. For patients with **Graves disease,** methimazole is begun first to block iodine organification; the next day, ipodate sodium or iopanoic acid may be added. They offer a therapeutic option for patients with subacute thyroiditis, amiodarone-induced thyrotoxicosis, T_4 overdosage, and for those intolerant to thioureas.

4. Radioactive iodine (RAI, ^{131}I)—^{131}I therapy destroys overactive thyroid tissue (either diffuse or toxic nodular goiter). Patients who have been treated with ^{131}I in adulthood do not have an increased risk of subsequent thyroid cancer, leukemia, or offspring with congenital abnormalities. Conflicting evidence has shown either no increased risk or a slightly increased risk of subsequent solid tumor malignancies following ^{131}I treatment for hyperthyroidism.

Precautions: Because radiation is harmful to the fetus and children, *RAI should not be given to pregnant or lactating women or to mothers who lack childcare. Women are advised to avoid pregnancy for at least 4 months following ^{131}I therapy. A pregnancy test should be obtained within 48 hours before therapy for any woman with childbearing potential. Men have been found to have abnormal spermatozoa for up to 6 months following ^{131}I therapy and are advised to use contraceptive methods during that time.*

Patients may receive ^{131}I while being symptomatically treated with propranolol ER, which is then reduced in dosage as hyperthyroidism resolves. Radioiodine therapy fails to fully correct hyperthyroidism in about 20% of patients, particularly those with larger glands, very high free T_4 levels, and prior thiourea therapy. However, therapy with ^{131}I will usually be effective if methimazole is discontinued at least 3–4 days before RAI therapy.

The presence of Graves ophthalmopathy is a relative contraindication to ^{131}I therapy. Following ^{131}I treatment for hyperthyroidism, Graves ophthalmopathy appears or worsens in 15% of patients. Therefore, patients with Graves ophthalmopathy who are to be treated with ^{131}I should be considered for prophylactic prednisone (20–40 mg orally daily) for 2 months following administration of ^{131}I; among patients receiving prednisone following ^{131}I treatment, preexistent ophthalmopathy improves in 67% and worsens in none.

Cigarette use increases the risk of having a flare in ophthalmopathy following ^{131}I treatment and also reduces the effectiveness of prednisone treatment.

There is a high incidence of hypothyroidism in the months to years after ^{131}I. Patients with Graves disease treated with ^{131}I also have an increased lifetime risk of developing hyperparathyroidism, particularly when ^{131}I therapy was administered in childhood or adolescence. Lifelong clinical follow-up is mandatory, with measurements of serum TSH, FT_4, and calcium when indicated.

5. Thyroid surgery—Surgery may be indicated for patients with Graves disease who are intolerant to thioureas, women planning pregnancy in the near future, patients who choose not to have RAI therapy, and patients with Graves ophthalmopathy. The surgical procedure of choice is a total resection of one lobe and a subtotal resection of the other lobe, leaving about 4 g of thyroid tissue (Hartley–Dunhill operation).

Patients are ordinarily rendered euthyroid preoperatively with a thiourea drug (Table 29–5). Propranolol ER is given until the heart rate is < 90 beats per minute and continued until the serum T_3 (or free T_3) is normal preoperatively. The patient should be euthyroid by the time of surgery.

The risks of subtotal or total thyroidectomy includes damage to a recurrent laryngeal nerve, with resultant vocal fold paralysis. Hypoparathyroidism also occurs; serum calcium levels must be checked postoperatively.

B. Treatment of Toxic Solitary Thyroid Nodules

Toxic solitary thyroid nodules are usually benign but may rarely be malignant. If a nonsurgical therapy is elected, the nodule should be evaluated with a fine-needle aspiration (FNA) biopsy. **Medical therapy** for hyperthyroidism caused by a single hyperfunctioning thyroid nodule may be treated symptomatically with propranolol ER and methimazole or PTU, as in Graves disease (Table 29–5). The dose of methimazole should be adjusted to keep the TSH slightly suppressed, so the risk of TSH-stimulated growth of the nodule is reduced. **Surgical treatment** is usually recommended for patients under age 40 years, for healthy older patients with toxic solitary thyroid nodules, and for nodules that are suspicious for malignancy. Patients are made euthyroid with a thiourea preoperatively and given several days of iodine, ipodate sodium, or iopanoic acid before surgery. Postoperative hypothyroidism usually resolves spontaneously, but permanent hypothyroidism occurs in about 14% of patients by 6 years after surgery. **^{131}I therapy** may be offered to patients with a toxic solitary nodule who are over age 40 or in poor health (see **Precautions** for RAI use, above).

If the patient has been receiving methimazole preparatory to ^{131}I, the TSH should be kept slightly suppressed in order to reduce the uptake of ^{131}I by the normal thyroid. Nevertheless, permanent hypothyroidism occurs in about one-third of patients by 8 years after ^{131}I therapy. The nodule remains palpable in 50% and may grow in 10% of patients after ^{131}I.

C. Treatment of Toxic Nodular Goiter

Medical therapy for patients with toxic nodular goiter consists of propranolol ER (while hyperthyroid) and a thiourea, as in Graves disease (Table 29–5). Thioureas (methimazole or PTU) reverse hyperthyroidism but do not shrink the goiter. There is a 95% recurrence rate if the drug is stopped.

Surgical therapy is the definitive treatment for a large toxic nodular goiter, following therapy with a thiourea to render them euthyroid. Surgery is particularly indicated to relieve pressure symptoms or for cosmetic indications. Patients with toxic nodular goiter are not treated preoperatively with potassium iodide. Total or near-total thyroidectomy is recommended, since surgical pathology reveals unsuspected differentiated thyroid cancer in 18.3% of cases.

^{131}I therapy may be used to treat patients with toxic nodular goiter. See **Precautions** for RAI use, above. Any suspicious nodules should be evaluated beforehand for malignancy with FNA cytology.

The patient follows a low-iodine diet in order to enhance the thyroid gland's uptake of ^{131}I, which may be relatively low in this condition (compared to Graves disease). Relatively high doses of ^{131}I are usually required. Hypothyroidism can occur but less commonly than seen with RAI therapy for Graves disease. Recurrent thyrotoxicosis can occur, so patients must be monitored closely. Peculiarly, in about 1–5% of patients with diffusely nodular toxic goiter, the administration of ^{131}I therapy may induce Graves disease.

D. Treatment of Hyperthyroidism from Thyroiditis

Patients with thyroiditis (subacute, postpartum, or silent) are treated with propranolol during the hyperthyroid phase, which usually subsides spontaneously within weeks to months. For symptomatic relief, begin propranolol ER until the heart rate is < 90 beats per minute (Table 29–5). Ipodate sodium or iopanoic acid, 500 mg orally daily, promptly corrects elevated T_3 levels and is continued for 15–60 days until the serum FT_4 level normalizes. Thioureas are ineffective since thyroid hormone production is actually low in this condition. Patients are monitored carefully for the development of hypothyroidism and treated with levothyroxine as needed. With subacute thyroiditis, pain can usually be managed with NSAIDs and corticosteroids, but opioid analgesics are sometimes required.

E. Treatment of Hyperthyroidism During Pregnancy-Planning, Pregnancy, and Lactation

Due to the increased risk of congenital anomalies with every thiourea, all women who are planning to become pregnant are encouraged to consider definitive therapy with ^{131}I or surgery well before conception. Both men and women who are planning pregnancy should not have ^{131}I treatment within about 4 months of conception. See **Precautions** for RAI use, above. Dietary iodine must not be restricted for such women to protect the fetus from iodine deficiency.

First-trimester fetal exposure to thioureas (methimazole or PTU) increases the risk of birth defects by about 2%. The fetal anomalies associated with PTU are typically less severe than those associated with methimazole; therefore, PTU is the preferred thiourea for women actively seeking fertility and during the first trimester of pregnancy, despite the very low risk for hepatic necrosis. Women should be treated with PTU immediately prepregnancy and through the first trimester; during pregnancy, the dose of PTU is kept below 200 mg daily to avoid goitrous hypothyroidism in the infant. PTU can be switched to methimazole in the second trimester (see Thiourea drugs, above). Thiourea should be given in the smallest dose possible, permitting mild subclinical hyperthyroidism to occur, since it is usually well tolerated. About 30% of women with Graves disease experience a remission by the late second trimester.

Both PTU and methimazole cross the placenta and can induce hypothyroidism, with fetal TSH hypersecretion and goiter. Fetal ultrasound at 20–32 weeks' gestation can visualize any fetal goiter, allowing fetal thyroid dysfunction to be diagnosed and treated. Thyroid hormone administration to the mother does not prevent hypothyroidism in the fetus, since T_4 and T_3 do not freely cross the placenta. Fetal hypothyroidism is rare if the mother's hyperthyroidism is controlled with small daily doses of PTU (50–150 mg/day orally) or methimazole (5–15 mg/day orally). Serum total T_4 levels during pregnancy should be kept at about 1.5 × the prepregnancy level. Maternal serum TSI levels over 500% at term predict an increased risk of neonatal Graves disease in the infant.

Subtotal thyroidectomy is indicated for pregnant women with Graves disease or for fertile women of reproductive age who are sexually active and decline contraceptives, under the following circumstances: (1) severe adverse reaction to thioureas; (2) high dosage requirement for thioureas (methimazole ≥ 30 mg/day or PTU ≥ 450 mg/day); or (3) uncontrolled hyperthyroidism due to nonadherence to thiourea therapy. Surgery is best performed during the second trimester.

Both methimazole and PTU are secreted in breast milk but not in amounts that affect the infant's thyroid hormone levels. No adverse reactions to these drugs have been reported in breast-fed infants. See Table 29–5 for recommended doses. It is recommended that the medication be taken just after breastfeeding.

F. Treatment of Amiodarone-Induced Thyrotoxicosis (AIT)

Patients with either type 1 or type 2 AIT require treatment with propranolol ER for symptomatic relief and methimazole (Table 29–5). After two doses of methimazole, iopanoic acid or sodium ipodate may be added to the regimen to further block conversion of T_4 to T_3 until the thyrotoxicosis is resolved. Amiodarone may be withdrawn but this does not have a significant therapeutic impact for several months because of its long half-life. For patients with type 1 AIT, therapy with ^{131}I may be successful, but only for those with sufficient RAI uptake. Patients with type 2 AIT are usually also treated with prednisone for about 2 weeks, which is slowly tapered and withdrawn after about 3 months. Subtotal thyroidectomy should be considered for patients with AIT that is resistant to treatment.

G. Treatment of Complications

1. Thyroid eye disease—See Thyroid Eye Disease (Graves Ophthalmopathy below).

2. Cardiac complications—

A. Sinus tachycardia—Treatment consists of treating the thyrotoxicosis. A β-blocker such as propranolol is used in the interim unless there is an associated cardiomyopathy.

B. Atrial fibrillation—Hyperthyroidism must be treated immediately. Other drugs, including digoxin, β-blockers, and anticoagulants, may be required. Electrical cardioversion is unlikely to convert atrial fibrillation to normal sinus rhythm while the patient is thyrotoxic. Spontaneous conversion to normal sinus rhythm occurs in 62% of patients with return of euthyroidism, but that likelihood decreases with age. Following conversion to euthyroidism, there is a 60% chance that atrial fibrillation will recur, despite normal thyroid function tests. Those with persistent atrial fibrillation may have elective cardioversion following anticoagulation 4 months after resolution of hyperthyroidism.

(1) β-Blockers—β-Blockers will reduce the ventricular rate, but they must be used with caution in patients with HF with reduced EF. Propranolol is generally preferred over metoprolol and other β-blockers for thyrotoxicosis-induced atrial fibrillation. Sotalol is sometimes preferred in patients with HF and reduced LVEF.

(2) Non-dihydropyridine calcium channel blockers (NDCC)—Diltiazem or verapamil slows the ventricular response during atrial fibrillation. However, these drugs have negative inotropic effects and must be used with caution in patients with HF and reduced EF.

(3) Anticoagulants—Thyrotoxicosis induces a prothrombotic state and increases the risk of embolic stroke in atrial fibrillation. Anticoagulation is usually required. DOACs are preferred over warfarin in thyrotoxicosis-induced atrial fibrillation, since DOACs are associated with a lower all-cause mortality and lower risk for hemorrhagic complications.

(4) Digoxin—Digoxin is now a second-line agent for ventricular rate control in thyrotoxicosis-induced atrial fibrillation; larger than normal doses are usually required in thyrotoxicosis. Digoxin doses are reduced as hyperthyroidism is corrected. Serum digoxin levels should be kept below 1.2 ng/mL, since higher levels are associated with increased mortality.

C. Heart failure—Thyrotoxicosis can cause high-output HF due to extreme tachycardia, cardiomyopathy, or both. Aggressive treatment of the hyperthyroidism is required in either case.

HF may also occur as a result of low-output dilated cardiomyopathy. It is uncommon and may be caused by an idiosyncratic severe toxic effect of hyperthyroidism upon certain hearts. Cardiomyopathy may occur at any age and without preexisting cardiac disease. See Chapter 11 for treatment of HF and dilated cardiomyopathy. The patient should be rendered euthyroid. However, the HF usually persists despite correction of the hyperthyroidism.

D. Apathetic hyperthyroidism—Apathetic hyperthyroidism may present with angina pectoris. Treatment is directed at reversing the hyperthyroidism as well as providing standard antianginal therapy. PCI or coronary artery bypass grafting can often be avoided by prompt diagnosis and treatment.

3. Thyrotoxic crisis or "thyroid storm"—ICU admission is required. A thiourea drug is given (eg, methimazole, 15–25 mg orally every 6 hours, or PTU, 150–250 mg orally every 6 hours). Ipodate sodium (500 mg/day orally) can be helpful if begun 1 hour *after* the first dose of thiourea. Iodide is given 1 hour later as potassium iodide (10 drops three times daily orally). Propranolol is given in a dosage of 0.5–2 mg intravenously every 4 hours or 20–120 mg orally every 6 hours. Hydrocortisone is usually given in doses of 50 mg orally every 6 hours, with rapid dosage reduction as the clinical situation improves. Plasmapheresis has been successfully used in refractory cases to directly remove thyroid hormone. Aspirin is avoided since it displaces T_4 from thyroxine-binding globulin (TBG), raising FT_4 serum levels. For refractory cases, emergency surgical thyroidectomy is an option.

Supportive care is usually required, including vasopressors, mechanical ventilation, dialysis, and extracorporeal membrane oxygenation (ECMO) for cardiogenic shock.

4. Hyperthyroidism from postpartum thyroiditis—Propranolol ER is given during the hyperthyroid phase followed by levothyroxine during the hypothyroidism phase.

5. Graves dermopathy—Treatment involves application of a topical corticosteroid (eg, fluocinolone) with nocturnal plastic occlusive dressings. Compression stockings may improve any associated edema.

6. Thyrotoxic hypokalemic periodic paralysis—Therapy with oral propranolol, 3 mg/kg in divided doses, normalizes the serum potassium and phosphate levels and reverses the paralysis within 2–3 hours. No intravenous potassium or phosphate is usually required. Intravenous dextrose and oral carbohydrate aggravate the condition and are to be avoided. Therapy is continued with propranolol, 60–80 mg orally every 8 hours (or propranolol ER daily at equivalent daily dosage), along with a thiourea drug (eg, methimazole) to treat the hyperthyroidism.

Prognosis

Mild **Graves disease** may sometimes subside spontaneously. Graves disease that presents in early pregnancy has a 30% chance of spontaneous remission before the third trimester. The ocular, cardiac, and psychological complications can become serious and persistent even after treatment. Permanent hypoparathyroidism and vocal cord palsy are risks of surgical thyroidectomy. If thiourea therapy is stopped, recurrence of hyperthyroidism occurs in about 55% of patients with persistently positive TSI and in about 35% of those with undetectable TSI. Recurrence of hyperthyroidism can also occur after low-dose ^{131}I therapy or subtotal thyroidectomy. With adequate treatment and long-term follow-up, the results are usually good. However, despite treatment for hyperthyroidism, women experience an increased long-term risk of death from thyroid disease, CVD, stroke, and fracture of the femur. Posttreatment hypothyroidism is common. It may occur within a few months or up to several years after RAI therapy or subtotal thyroidectomy. Patients with thyrotoxic crisis have a high mortality rate despite treatment.

Subclinical hyperthyroidism generally subsides spontaneously. Progression to symptomatic thyrotoxicosis occurs at a rate of 1–2% per year in patients without a goiter and at a rate of 5% per year in patients with a multinodular goiter. Most patients do well without treatment and the serum TSH usually reverts to normal within 2 years. Most such patients do not have accelerated bone loss. However, if a baseline bone density shows significant osteopenia, bone densitometry may be performed periodically. In persons over age 60 years, serum TSH is suppressed (below 0.1 mIU/L) in 3% and mildly low (0.1–0.4 mIU/L) in 9%. The chance of developing atrial fibrillation is 2.8% yearly in older patients with a suppressed TSH and 1.1% yearly in those with mildly low TSH. Asymptomatic persons with very low serum TSH are monitored closely but are not treated unless atrial fibrillation or other manifestations of hyperthyroidism develop.

When to Admit

- Thyroid crisis.
- Hyperthyroidism-induced atrial fibrillation with severe tachycardia.
- Thyroidectomy.

THYROID EYE DISEASE

General Considerations

Thyroid eye disease (TED, Graves orbitopathy) is a syndrome of clinical and orbital imaging abnormalities caused by deposition of mucopolysaccharides and infiltration with chronic inflammatory cells of the orbital tissues, particularly the extraocular muscles. In patients with Graves disease, 26% have clinically apparent eye disease and 6% experience moderate to severe orbitopathy. The severity of eye disease is not correlated with the severity of thyrotoxicosis. In fact, about 10% of patients with thyroid eye disease have no clinical or laboratory evidence of Graves disease at presentation or on long-term follow-up; the absence of laboratory evidence requires consideration of other diagnoses.

Thyroid eye disease (TED) has an early inflammatory stage, typically lasting 18–36 months, where there is active lymphocytic infiltration into retrobulbar tissues. The active inflammatory stage then tends to evolve to a chronic, fibrotic, "burned out" stage in which treatment of the exophthalmos is medically resistant to glucocorticoid treatment. Aggravation of TED has occurred with smoking, thiazolidinediones, and after vaccination against COVID-19. Radioiodine therapy for Graves disease can also aggravate TED.

Clinical Findings

The primary clinical features of TED of any etiology include upper eyelid retraction, lid lag with downward gaze, and a staring appearance. With Graves orbitopathy, there can be exophthalmos, conjunctival chemosis, episcleral inflammation, and weakness of upward gaze. Corneal drying may occur with inadequate lid closure. Eye changes may be asymmetric or unilateral. Patients with severe exophthalmos can experience diplopia from extraocular muscle entrapment and optic nerve compression, causing progressive loss of color vision, visual acuity, and visual fields (inferior especially).

Symptoms of active retrobulbar inflammation include (1) retrobulbar aching, (2) orbital inflammation and edema worse after recumbent sleep, (3) edematous or erythematous eyelids, (4) conjunctival redness or chemosis (edema), (5) recent progression in exophthalmos, (6) recent diplopia or strabismus, and (7) recent loss of visual acuity.

Exophthalmometry is performed on all patients with Graves disease to document their degree of exophthalmos and detect progression of orbitopathy. The protrusion of the eye beyond the orbital rim is measured with a prism instrument (Hertel exophthalmometer).

The primary imaging features are enlargement of the extraocular muscles, usually affecting both orbits.

Differential Diagnosis

The clinical and imaging abnormalities of thyroid eye disease may be mimicked by congenital proptosis, asymmetry in orbital protrusion, or dural carotid-cavernous sinus fistula. Ocular myasthenia and TED are associated and may coexist, with the presence of ptosis rather than lid retraction being more characteristic of the former.

Treatment

General eye protective measures include wearing glasses to protect the protruding eye, use of methylcellulose drops or gels ("artificial tears"), and taping the lids shut during sleep if corneal drying is a problem. Most patients with TED are treated with selenium 100 mcg orally twice daily, which appears to slow its progression.

The Mourits clinical activity score helps grade the severity of thyroid eye disease. Therapy in addition to selenium is warranted for active TED with a clinical activity point score ≥ 3.

Therapy with intravenous pulse methylprednisolone, 500 mg weekly for 6 weeks, then 250 mg weekly for

6 weeks, begun promptly for active TED, is superior to oral prednisone. If oral prednisone is used, 40–60 mg daily with dosage reduction over several weeks must be given promptly. Higher initial daily prednisone doses of 80–120 mg are used when there is optic nerve compression.

Corticosteroid-resistant acute TED may be treated with monoclonal antibodies that reduce immune-mediated inflammation. Teprotumumab is FDA-approved for TED and is effective in reducing proptosis in the majority of affected patients.

Statin medications appear to reduce the risk of TED by 80% in patients with newly diagnosed Graves disease and should be considered as an off-label adjuvant treatment.

Progressive active exophthalmos may be treated with retrobulbar radiation therapy over 2 weeks. Prednisone in high doses is given concurrently. Patients who respond well to orbital radiation include those with signs of acute inflammation, recent exophthalmos (< 6 months), or optic nerve compression. Patients with chronic proptosis and orbital muscle restriction respond less well.

Diplopia should be treated conservatively (eg, with prisms) in the active stages of the disease and only by surgery when the disease has been static for at least 6 months. For severe cases, orbital decompression surgery may save vision, though diplopia often persists postoperatively. Tarsorrhaphy or canthoplasty can frequently help protect the cornea and provide improved appearance.

When to Refer

All patients with TED should be referred to an ophthalmologist, urgently if there is reduced vision.

THYROID NODULES & MULTINODULAR GOITER

ESSENTIALS OF DIAGNOSIS

- Single or multiple thyroid nodules are commonly palpated by the patient or clinician or discovered incidentally on imaging studies.
- Thyroid function tests recommended.
- FNA cytology for thyroid nodules ≥ 1 cm or for smaller nodules when prior head-neck or chest-shoulder radiation.
- Ultrasound guidance improves FNA diagnosis for palpable and nonpalpable nodules.
- Clinical follow-up required.

General Considerations

Thyroid nodules are common. Palpable nodules occur in about 5% of adults; however, neck ultrasound reveals a thyroid nodule in 50% of adults. They are more common in women than men and become more prevalent with age. Most patients with a thyroid nodule are euthyroid; however, there is a high incidence of hypo- or hyperthyroidism. Patients with palpable nodules require thyroid function testing and evaluation for thyroid malignancy.

Thyroid nodules may be detected incidentally on neck imaging done for another purpose. When such scans detect a nodule, a thyroid ultrasound is performed to help determine the risk for malignancy and to establish a baseline for follow-up examinations. Most nodules that are 1 cm or more in diameter require fine needle aspiration cytology (FNAc). Smaller nodules may be selected for FNAc if their ultrasound appearance is suspicious for malignancy or if they arise in a patient who has an increased risk for thyroid malignancy.

The overall risk of malignancy (ROM) for thyroid nodules 1 cm or larger in diameter is 1.2% overall and 2.8% in patients under age 30 (excluding papillary microfollicular carcinoma). The risk of a thyroid nodule being malignant is higher in (1) men; (2) patients with a history of head-neck radiation or exposure to radioactive fallout as a child; (3) patients with a personal history of malignancy; (4) patients with a family history of thyroid cancer or a thyroid cancer syndrome, such as multiple endocrine neoplasia type 2, familial polyposis, Carney syndrome, or Cowden syndrome; (5) patients with large solitary nodules; and (6) patients with hoarseness, vocal fold paralysis, adherence to the trachea or strap muscles, or cervical lymphadenopathy.

Clinical Findings

Table 29–6 illustrates how to evaluate thyroid nodules based on the index of suspicion for malignancy.

A. Symptoms and Signs

Most small thyroid nodules cause no symptoms. They may sometimes be detected only by having the patient swallow during inspection and palpation of the thyroid.

A thyroid nodule or multinodular goiter can grow to become visible and of concern to the patient. Large nodular goiters can become a cosmetic embarrassment. Nodules can grow large enough to cause discomfort, hoarseness, or dysphagia. Nodules that cause ipsilateral recurrent laryngeal nerve palsy are more likely to be malignant. Retrosternal large multinodular goiters can cause dyspnea due to tracheal compression. Large substernal goiters may cause superior

Table 29–6. Clinical evaluation of thyroid nodules.[1]

Clinical Evidence	Low Index of Suspicion	High Index of Suspicion
History	Family history of goiter; residence in area of endemic goiter	Previous therapeutic radiation of head, neck, or chest; hoarseness
Physical characteristics	Older women; soft nodule; multinodular goiter	Young adults, men; solitary, firm nodule; vocal fold paralysis; enlarged lymph nodes; distant metastatic lesions
Serum factors	High titer of thyroid peroxidase antibody; hypothyroidism; hyperthyroidism	Elevated serum calcitonin
Fine-needle aspiration cytology	Colloid nodule or adenoma	Papillary carcinoma, follicular lesion, medullary or anaplastic carcinoma
Scanning techniques		
Uptake of ^{123}I	Hot nodule	Cold nodule
Ultrasonogram	Cystic lesion	Solid lesion
Radiograph	Shell-like calcification	Punctate calcification

[1] Clinically suspicious nodules should be evaluated with fine-needle aspiration cytology and molecular testing, when indicated.

vena cava syndrome, manifested by facial erythema and jugular vein distention that progress to cyanosis and facial edema when both arms are kept raised over the head.

Goiters and thyroid nodules may be associated with hypothyroidism (autoimmune thyroiditis, endemic goiter) or hyperthyroidism (Graves disease, toxic nodular goiter, subacute thyroiditis, and thyroid cancer with metastases).

B. Laboratory Findings

A serum TSH and FT_4 determine if the thyroid is hyperfunctioning. Patients with a subnormal serum TSH must have a radionuclide (^{123}I or ^{99m}Tc pertechnetate) thyroid scan to examine whether the nodule is hyperfunctioning; hyperfunctioning nodules are usually, but not always, benign. Serum calcitonin is obtained if a medullary thyroid carcinoma is suspected in a patient with a family history of medullary thyroid carcinoma or MEN types 2 or 3.

C. Imaging

Neck ultrasonography should be performed and is generally preferred over CT, MRI, or radioiodine scans. The ACR Thyroid Imaging Reporting and Data System (TI-RADS) classifies thyroid nodules into five categories based on risk of malignancy (in parentheses) with recommended management and follow up:

1. TR1: Benign (0%). No FNA required.
2. TR2: Not suspicious (< 2%). No FNA required.
3. TR3: Mildly suspicious (3%). Nodules ≥ 1.5 cm require follow-up at 1, 3, and 5 years; nodules ≥ 2.5 cm require FNA.
4. TR4: Moderately suspicious (19%). Nodules ≥ 1.0 cm require follow-up at 1, 2, 3, and 5 years; nodules ≥ 1.5 cm require FNA.
5. TR5: Highly suspicious (80%). Nodules ≥ 0.5 cm follow-up annually for 5 years; nodules ≥ 1.0 cm require FNA.

D. Fine-Needle Aspiration (FNA) & Molecular Testing of Thyroid Nodules

FNA is the best method to assess a thyroid nodule for malignancy. For multinodular goiters, the four largest nodules (1 cm or larger) are usually biopsied to minimize the risk of missing a malignancy. Samples are obtained for cytopathology and a sample is reserved for molecular testing if the cytopathology is indeterminate for malignancy. FNA cytology is reported using The Bethesda System for Reporting Thyroid Cytopathology (TBSRTC):

I. **Nondiagnostic or unsatisfactory:** The malignancy risk is about 12%. The usual management is a repeat FNA under ultrasound guidance.

II. **Benign:** The malignancy risk is about 2%. The usual management is clinical and ultrasound follow-up.

III. **Atypia of undetermined significance (AUS):** The malignancy risk is about 16%, higher with sonographic features of malignancy. The usual management is a repeat FNA, molecular testing, diagnostic thyroid lobectomy, or surveillance.

IV. **Follicular neoplasm (FN):** The malignancy risk is about 23%, higher when Hürthle cells are present and in patients over age 50. The usual management is molecular testing or thyroid lobectomy.

V. **Suspicious for malignancy (SFM):** The malignancy risk is about 65%. The usual management is molecular testing, thyroid lobectomy, or near-total thyroidectomy.

VI. **Malignant:** The malignancy risk is about 94%. The usual management is thyroid lobectomy or near-total thyroidectomy.

Molecular testing is useful when cytopathology is indeterminate for malignancy (Bethesda categories III, IV, or V). The detection of a *BRAF* mutation indicates the presence of a papillary thyroid carcinoma with a 98% probability. Molecular testing reduces the need for surgery by about 50%.

Surveillance & Treatment

All thyroid nodules, including those that are benign, need to be monitored by regular periodic palpation and ultrasound every 6 months initially. After several years of stability, yearly examinations are sufficient. Thyroid nodules should be rebiopsied if growth occurs. Excessive iodine intake should be minimized; a toxic multinodular goiter and hyperthyroidism may develop in patients who have had exposure to large amounts of iodine, either orally (eg, amiodarone) or intravenously (eg, radiographic contrast).

Patients with hyperthyroidism caused by thyroid nodules or multinodular goiter may be treated with propranolol, thioureas, surgery, or radioiodine.

A. Levothyroxine Suppression Therapy

Patients with nodules larger than 2 cm and elevated or normal TSH levels may be considered for TSH suppression with levothyroxine, starting at doses of 50 mcg orally daily. Levothyroxine suppression therapy is not recommended if the serum TSH is low or for small benign thyroid nodules if the serum TSH level is normal. Levothyroxine suppression therapy is more successful in iodine-deficient areas. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging but only 20% shrink > 50%. Thyroid nodule size increased in 29% of patients treated with levothyroxine versus 56% of patients not receiving levothyroxine. Levothyroxine suppression also reduces the emergence of new nodules: 8% with levothyroxine and 29% without levothyroxine. Levothyroxine suppression therapy is not given to patients with ischemic heart disease since it increases the risk for angina and atrial fibrillation.

Levothyroxine suppression needs to be carefully monitored, since it carries a 17% risk of inducing hyperthyroidism. All patients receiving levothyroxine suppression therapy should have serum TSH levels monitored at least annually, with the levothyroxine dose adjusted to keep the serum TSH mildly suppressed (between 0.1 mIU/L and 0.8 mIU/L).

B. Surgery

Total thyroidectomy is required for thyroid nodules that are malignant on FNA biopsy. More limited thyroid surgery is indicated for benign nodules with indeterminate or suspicious cytologic test results, compression symptoms, discomfort, or cosmetic embarrassment. Surgery may also be used to remove hyperfunctioning "hot" thyroid adenomas or toxic multinodular goiter causing hyperthyroidism.

C. Radiofrequency Ablation (RFA)

Ultrasound-guided radiofrequency ablation (RFA) is a therapeutic option for cytology-proven benign thyroid nodules that are 3 cm or larger and predominantly solid. Autonomously functioning thyroid nodules can cause subclinical or overt hyperthyroidism that can be reversed by RFA. Radiofrequency ablation shrinks benign thyroid nodules by about 67% after 6 months, improving pressure symptoms and dysphagia in most patients and reducing the size of cosmetically embarrassing thyroid nodules. Side effects include mild neck discomfort, swelling, bruising, and dysphagia that generally resolves within 5 days. Transient hyperthyroidism occurs in 9% and responds to therapy with β blockade. Mild hypothyroidism may also occur. Radiofrequency ablation–induced damage to the recurrent laryngeal nerve can cause hoarseness.

D. Radioiodine (^{131}I) Therapy

^{131}I is a treatment option for hyperthyroid patients with toxic thyroid adenomas, multinodular goiter, or Graves disease. See **Precautions** for RAI use, above. RAI is not recommended for benign, nontoxic thyroid nodules. ^{131}I therapy may be used to shrink large multinodular goiters; it may rarely induce Graves disease or cause hypothyroidism that may develop years after therapy.

Prognosis

Benign thyroid nodules may involute but usually persist or grow slowly. Most thyroid nodules will increase their volume by 15% or more over 5 years. Significant nodule growth (> 2 mm in two dimensions) is more common in younger patients (< 45 years) and in patients with multiple nodules. Cytologically benign nodules that grow are unlikely to be malignant. Very small (< 1 cm), incidentally discovered, nonpalpable thyroid nodules that have a benign ultrasound appearance require no FNA cytology and only yearly palpation and clinical follow-up. Larger nodules (> 1 cm) and small nodules with a suspicious ultrasound appearance may require FNA cytology or thyroid ultrasound every 1–2 years. Thyroid nodules that are benign-appearing on ultrasound and or have benign FNA cytology require yearly follow-up with neck palpation. Ultrasound follow-up can be performed every 3–5 years.

THYROID CANCER

ESSENTIALS OF DIAGNOSIS

- Painless swelling in region of thyroid.
- Thyroid function tests are usually normal.
- Possible history of childhood irradiation to head and neck region.
- Positive thyroid FNA cytology.

General Considerations

Thyroid cancers historically were discovered by detection of a thyroid mass by the patient or provider. Over the last 40 years, small nonpalpable thyroid malignancies have been detected with increasing frequency as a result of the widespread use of ultrasound, CT, MRI, and PET imaging. The yearly incidence of diagnosed thyroid malignancy in the United States has therefore tripled during this period to about 44,000 cases annually, but the mortality has remained relatively stable at 2400 deaths annually. Thyroid cancers are diagnosed three times more frequently in women than men. However, the mortality rate from thyroid cancer is nearly as high in men compared to women. Larger differentiated thyroid cancers (palpable or larger than 1 cm) are more likely to behave in a malignant fashion and usually require treatment.

Of thyroid cancers that are detected incidentally on imaging, most are nonpalpable, small (< 1 cm) papillary microcarcinomas. Although these microcarcinoma fulfill pathologic criteria for malignancy, they are almost all indolent; as such, a new terminology has been proposed for them: “indolent lesion of epithelial origin (IDLE).” In routine autopsy series, thyroid papillary microcarcinoma (smaller than 1 cm) is found in 11.5% in both women and men.

Four histologic types account for 97% of thyroid cancer: papillary, follicular, medullary, and anaplastic (Table 29–7).

Pure papillary (and mixed papillary-follicular) carcinoma represents over 85% of all diagnosed thyroid cancers. It usually presents as a single thyroid nodule but can arise out of a multinodular goiter. Papillary thyroid carcinoma is commonly multifocal and involves both lobes in 30% of patients.

Papillary thyroid carcinoma is the least aggressive thyroid malignancy. It tends to grow slowly and often remains confined to the thyroid and regional lymph nodes for years. In about 80% of patients, there are microscopic (smaller than 2 mm) metastases to cervical lymph nodes, which does not appear to affect survival. The malignancy may become more aggressive in patients over age 45 years, especially in older adults. The cancer may invade the trachea and local muscles and spread to the lungs.

Childhood exposure to head and neck radiation therapy poses a particular threat because of an increased lifetime risk of developing thyroid cancer, including papillary carcinoma. These cancers may emerge 10–40 years after exposure, with a peak occurrence 20–25 years later.

Papillary thyroid carcinoma can occur in familial syndromes as an autosomal dominant trait, caused by loss of various tumor suppressor genes.

Microscopic “micropapillary” carcinomas (smaller than 2 mm) are found in 24% of thyroidectomies performed for benign thyroid disease. These are invisible on thyroid ultrasound, seldom become clinically significant, and may be considered a variant of normal. Surgical pathology may report such tiny micropapillary carcinomas, but treatment and surveillance are not warranted.

Follicular thyroid carcinoma and its variants (eg, Hürthle cell carcinoma) account for 11% of thyroid malignancies; follicular carcinomas are generally more aggressive than papillary carcinomas. Most absorb iodine, making diagnostic scanning and treatment with ^{131}I after total thyroidectomy possible. Poorly differentiated and Hürthle cell (oncocytic) variants of follicular thyroid carcinoma are associated with a higher risk of metastasis and recurrence.

Medullary thyroid carcinoma represents 2% of thyroid cancers. They arise from thyroid parafollicular cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, CRH, and other peptides that may cause symptoms and can be used as tumor markers. About one-third are sporadic, one-third are familial, and one-third are associated with MEN type 2A or 2B. Discovery of a medullary thyroid carcinoma makes genetic analysis mandatory. Medullary thyroid carcinoma is often caused by an activating mutation of the *ret* protooncogene on chromosome 10.

Anaplastic thyroid carcinoma represents 1% of thyroid cancers. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. This tumor does not concentrate iodine, which precludes the therapeutic use of RAI.

Other thyroid malignancies represent about 3% of thyroid cancers. Primary thyroid lymphomas are most

Table 29–7. Some characteristics of thyroid cancer.

	Papillary	Follicular	Medullary	Anaplastic
Incidence	Most common	Common	Uncommon	Uncommon
Average age (years)	42	50	50	57
Females	77%	72%	56%	56%
Invasion				
Lymph nodes	+++++	+	++++++	+++
Blood vessels	+	+++	+++	+++++
Distant sites	+	+++	++	++++
^{123}I uptake	+	++++	0	0
10-year disease-specific survival	98%	92%	78%	7.3%

commonly diffuse large B-cell lymphomas (50%), mucosa-associated lymphoid tissue lymphoma (23%), or mixed type; other types include follicular, small lymphocytic, and Burkitt lymphoma and Hodgkin disease. Cancers may sometimes metastasize to the thyroid, particularly bronchogenic, breast, renal carcinoma, and melanoma.

Clinical Findings

A. Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender thyroid nodule. Most thyroid carcinomas are asymptomatic, but large thyroid cancers can cause neck discomfort, dysphagia, or hoarseness (due to pressure on the recurrent laryngeal nerve). **Papillary thyroid cancer** presents with palpable lymph node involvement in 10%; it may invade the trachea and local muscles. Occult metastases to the lung occur in 10–15%. **Follicular thyroid carcinoma** commonly metastasizes to neck nodes, bones, and lung, but nearly every organ can be involved (Table 29–7).

Medullary thyroid carcinoma typically metastases to local nodes and adjacent muscle and trachea as well as mediastinal lymph nodes. Metastases may appear in the bones, lungs, adrenals, or liver. It frequently causes flushing and diarrhea (30%), which may be the initial clinical features. Cushing syndrome develops in 5% of patients from tumor secretion of ACTH or CRH.

Anaplastic thyroid carcinoma is more apt to be advanced at the time of diagnosis, presenting with signs of pressure or invasion of surrounding tissue, resulting in dysphagia, hoarseness, or recurrent laryngeal nerve palsy or dyspnea due to lung metastases.

B. Laboratory Findings

FNA cytology is discussed in Thyroid Nodules, above. Thyroid function tests are generally normal unless there is concomitant thyroiditis. However, with a heavy tumor burden, functioning follicular or papillary thyroid carcinomas can sometimes secrete enough thyroid hormone to produce thyrotoxicosis and suppress the serum TSH.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating Tg Ab can cause erroneous thyroglobulin determinations. However, declining levels of Tg Ab are a good prognostic sign after treatment. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases.

Serum calcitonin is usually elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. Serum calcitonin may be elevated in thyroiditis; pregnancy; kidney disease; hypergastrinemia; hypercalcemia; and other malignancies, particularly neuroendocrine tumors (including pheochromocytomas, carcinoid tumors) and carcinomas of the lung, pancreas, breast, and colon. Serum calcitonin and carcinoembryonic antigen (CEA) determinations should be obtained before surgery, then regularly in postoperative follow-up: every 4 months for 5 years, then every 6 months for life. Serum calcitonin levels > 250 ng/L (73 pmol/L) or rising levels of calcitonin are the best indication of recurrence or metastatic disease. Serum pro-calcitonin levels also appear to be a reasonable tumor marker for medullary cancer. Serum CEA levels are elevated but are not specific for medullary thyroid carcinoma.

C. Imaging

1. Ultrasound of the neck—Ultrasound of the neck should be performed on all patients with thyroid cancer for the initial diagnosis and for follow-up. Ultrasound is useful in determining the size and location of the malignancy as well as the location of any neck metastases.

2. Radioactive iodine scanning—RAI (^{131}I or ^{123}I) thyroid and whole-body scanning is used after thyroidectomy for differentiated thyroid cancer utilizing the protocol described later. (See Radioactive Iodine (^{131}I) Therapy for Differentiated Thyroid Cancer, below.) Medullary thyroid cancer does not take up RAI.

3. CT and MRI scanning—CT scanning may demonstrate metastases and is particularly useful for localizing and monitoring lung metastases but is less sensitive than ultrasound for detecting metastases within the neck. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so. MRI is particularly useful for imaging bone metastases.

4. PET scanning—PET scanning is especially helpful for detecting thyroid cancer metastases that do not have sufficient iodine uptake to be visible on RAI scans. Thyroid cancer metastases may be detected with ^{18}FDG-PET whole-body scanning. Patients with medullary thyroid cancer are monitored with MRI and ^{18}FDG PET/CT scanning. ^{68}Ga-DOTATATE-PET imaging is superior for detecting medullary thyroid cancer metastases in certain patients, particularly those with very high serum calcitonin levels (above 500 pg/mL).

Differential Diagnosis

Head-neck RAI uptake is seen in normal thyroid, salivary glands, nasal mucosa, thyroglossal duct remnants, and sinusitis.

Negative RAI scans are common in early metastatic differentiated thyroid carcinoma. Negative RAI scans also occur frequently with advanced metastatic thyroid carcinoma, making it difficult to detect and to distinguish from nonthyroidal neoplasms. An elevated serum thyroglobulin in patients with a negative RAI scan should arouse suspicion for metastases that are not avid for RAI. Medullary thyroid carcinoma does not concentrate iodine.

Complications

Hyperthyroidism can develop in patients with a heavy tumor burden. One-third of medullary thyroid carcinomas secrete serotonin and prostaglandins, producing flushing and diarrhea. The management of patients with medullary carcinomas may be complicated by the coexistence of pheochromocytomas or hyperparathyroidism.

Treatment of Differentiated Thyroid Carcinoma

A. Surgical Treatment

For low-risk papillary or papillary/follicular thyroid microcarcinoma (smaller than or equal to 1 cm), both active surveillance and unilateral thyroid lobectomy (hemithyroidectomy) are acceptable treatment options; since the 5-year disease-specific survival is over 98%, active surveillance is becoming more common. **For low-risk differentiated thyroid cancers (papillary or follicular) between 1 and 4 cm**, either hemithyroidectomy or total thyroidectomy can be used. Both provide the same overall 5-year survival, although recurrence is more common after hemithyroidectomy. Hemithyroidectomy is increasingly preferred, as it has no risk of hypoparathyroidism, decreased risk for recurrent laryngeal nerve palsy, and a 30% chance that postoperative thyroid replacement will not be required.

For medium and high-risk papillary and follicular thyroid carcinoma, total or near-total thyroidectomy is usually performed, particularly for patients with tumors over 4 cm and those with evidence for local or distant metastases. The advantages of total thyroidectomy for differentiated thyroid carcinoma include the resection of carcinoma foci in the contralateral lobe. Furthermore, it removes all remaining normal thyroid tissue that would otherwise compete with uptake of radioiodine administered for diagnostic scans or treatment of residual cancer.

Patients with nodal metastases can have a central neck lymph node dissection at the time of thyroidectomy. Metastases to the brain are treated surgically or with gamma-knife radiosurgery, since treatment with RAI is ineffective. Levothyroxine, 0.05–0.1 mg orally daily, is begun immediately postoperatively. About 2–4 months after surgery, patients require reevaluation and often ^{131}I therapy.

Following surgical resection, permanent injury to one recurrent laryngeal nerve (rarely both) occurs in 1–7% of patients, temporary laryngeal nerve palsies in 5%, and hypoparathyroidism (usually temporary) in 20%. Thyroidectomy requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany can occur. *Ambulatory thyroidectomy is potentially dangerous and should not be done*. Following surgery, staging (Table 29–8) should be done to help determine prognosis and to plan therapy and follow-up.

In pregnant women with thyroid cancer, surgery is usually delayed until after delivery, except for fast-growing tumors that may be resected after 24 weeks' gestation; there has been no difference in survival or tumor recurrence rates in women who underwent surgery during or after their pregnancy.

Table 29–8. Staging and prognosis for patients with papillary thyroid carcinoma using MACIS scoring.

Total Score[1] - Stage	Percentage of Patients with Papillary Thyroid Carcinoma	20-Year Survival
< 6.0 = Stage I	74.2%	96–99%
6.0–6.99 = Stage II	8.5%	68–89%
7.0–7.99 = Stage III	9.2%	55–56%
≥ 8.0 = Stage IV	8.1%	17–24%

[1] Total score = 3.1 (if aged ≤ 39 years) *or* 0.08 × age (if aged ≥ 40 years) + 0.3 × tumor size (cm), + 1 (if incompletely resected), + 1 (if locally invasive), + 3 (if distant metastases).

MACIS, metastases, age, complete resection, invasion, size.

B. Active Surveillance for Papillary Thyroid Carcinoma

Most papillary thyroid carcinomas (PTCs) that are < 1 cm (microcarcinomas) are indolent with an excellent prognosis. Conservative management is usually warranted for patients with these low-risk tumors. The active surveillance protocol typically consists of clinical examination and neck ultrasound every 6 months. Larger PTCs (1–4 cm) that are intrathyroidal and nonmetastatic are typically treated with hemithyroidectomy; however, active surveillance is increasingly employed for larger PTCs with low-risk characteristics.

C. Levothyroxine Suppression of TSH

Levothyroxine is no longer prescribed for euthyroid patients with low-risk differentiated thyroid cancer (DTC) who have had a unilateral thyroid lobectomy. Levothyroxine is prescribed for other patients with DTC in doses to achieve certain target levels of serum TSH as follows: (1) For high-risk DTC, the target TSH range is 0.1 mIU/L (while maintaining clinical euthyroidism). (2) For intermediate-risk DTC, the serum TSH target is 0.1 to 0.4 mIU/L. (3) For low-risk DTC, the TSH target range is 0.4 to 2 mIU/L. (4) For all patients with DTC who have atrial fibrillation, the serum TSH should be kept at or above 0.1 mIU/L.

D. Radioactive Iodine (^{131}I) Therapy for Differentiated Thyroid Cancer (DTC)

Following total or near-total thyroidectomy for DTC, ^{131}I therapy may improve survival in: (1) High-risk patients with gross extrathyroidal extension or distant metastases; (2) Intermediate-risk patients with over 5 microscopic lymph node metastases, mediastinal lymph node metastases, primary tumor size above 4 cm diameter with extrathyroidal extension or in patients over age 50, or tumor above 1 cm diameter with aggressive histology or vascular invasion. ^{131}I is usually administered 2–4 months after surgery.

1. RAI thyroid remnant ablation—For patients with low-risk differentiated thyroid carcinoma (DTC), radioiodine is no longer recommended either for thyroid remnant ablation or for adjuvant therapy following total or near-total thyroidectomy. Low-risk DTC includes a single papillary or follicular thyroid cancer < 2 cm diameter or multiple tumors < 1 cm diameter with no significant nodal disease, no extrathyroidal extension, and no unfavorable histopathology.

2. RAI treatment of metastases—Therapy with ^{131}I improves survival and reduces recurrence rates of differentiated thyroid cancer for patients with stage III–IV cancer and those with stage II cancer having gross extrathyroidal extension. RAI therapy is also given to patients with stage II cancer who have distant metastases, a primary tumor larger than 4 cm, or primary tumors 1–4 cm with lymph node metastases or other high-risk features. Brain metastases do not usually respond to ^{131}I and are best resected or treated with gamma knife radiosurgery.

Staging with RAI scanning or ^{18}FDG-PET/CT scanning assists with determining the activity of ^{131}I to be administered. Patients with differentiated thyroid carcinoma who have little or no uptake of RAI into metastases (about 35% of cases) should not be treated with ^{131}I. Patients with asymptomatic, stable, RAI-resistant metastases should receive levothyroxine to suppress serum TSH and should be carefully monitored for tumor progression.

3. Recombinant human TSH (rhTSH)-stimulated ^{131}I therapy—Recombinant human thyroid-stimulating hormone (rhTSH, Thyrogen) can be given to increase the sensitivity of serum thyroglobulin for residual cancer and to increase the uptake of ^{131}I into residual thyroid tissue (thyroid remnant "ablation") or cancer.

Thyrogen should not be administered to patients with an intact thyroid gland because it can cause severe thyroid swelling and hyperthyroidism. Hyperthyroidism can also occur in patients with significant metastases or residual normal thyroid. Other side effects include nausea (11%) and headache (7%). Thyrotropin has caused neurologic deterioration in 7% of patients with CNS metastases.

4. Thyroid-withdrawal stimulated ^{131}I therapy—Thyroid withdrawal is sometimes used because of its lower cost than rhTSH, despite the discomforts of becoming hypothyroid. Levothyroxine is withdrawn for 14 days and the patient is allowed to become hypothyroid; high levels of endogenous TSH stimulate the uptake of RAI and production of thyroglobulin by thyroid cancer or residual thyroid. Three days after ^{131}I therapy, levothyroxine therapy may be resumed at full replacement dose.

5. Side effects from ^{131}I therapy—Patients treated with ^{131}I have a slightly higher risk of developing secondary malignancies than patients treated with surgery alone.

^{131}I therapy can cause gastritis, temporary oligospermia, sialadenitis, tearing, and xerostomia. It can cause neurologic decompensation in patients with thyroid brain metastases. Cumulative doses of ^{131}I over 500 mCi (18.5 GBq) can cause infertility, pancytopenia (4%), leukemia (0.3%), and pulmonary fibrosis.

E. Other Therapies for Differentiated Thyroid Cancer

Patients with osteolytic metastases to bone from differentiated thyroid cancer may be treated with zoledronic acid or denosumab.

Patients with aggressive differentiated thyroid cancers may have metastases that are refractory to ^{131}I therapy. Recurrence in the neck may be treated with surgical debulking and external beam radiation therapy. Patients with RAI-refractory differentiated thyroid cancer metastases that are advanced and rapidly progressive may be treated with chemotherapy tailored to the genetic defect exhibited by the tumor.

Treatment of Other Thyroid Malignancies

Medullary thyroid carcinoma is best treated with surgery for the primary tumor and metastases. Medullary thyroid carcinoma does not respond to ^{131}I therapy. Patients should be monitored closely, with serum calcitonin levels checked about every 3 months. Since medullary thyroid carcinoma can be indolent, patients should receive treatment only if they have rapidly progressive metastases, as evidenced by a doubling time of serum calcitonin or CEA of < 2 years. ^{177}Lu-DOTATATE peptide receptor radionuclide therapy (PRRT, Lutathera) is an option for patients with progressive medullary thyroid carcinoma metastases that are very avid for ^{64}Cu-DOTATATE on diagnostic imaging or demonstrate high SSTR2a receptor expression on immunohistochemical staining. Patients with progressing medullary thyroid carcinomas (with germline or sporadic *RET* proto-oncogene mutations or fusions) are treated with selpercatinib or pralsetinib, selective *RET* inhibitors. *Patients with medullary thyroid carcinoma should not receive diabetic or weight-loss therapy with glucagon-like peptide-1 (GLP-1) agonists, because they may stimulate the growth of medullary thyroid carcinoma.*

Anaplastic thyroid carcinoma is treated with local resection and radiation. It does not respond to ^{131}I therapy. Anaplastic thyroid cancers with mTOR mutations may be inhibited by everolimus. In patients with *BRAF*^{V600E} mutant anaplastic thyroid cancer, combined treatment with dabrafenib and trametinib has induced durable responses.

Thyroid lymphoma: Thyroid mucosa-associated lymphoid tissue lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive lymphoma (Table 44–2).

External beam radiation therapy may be delivered to bone metastases, especially those that are without radioiodine uptake or are RAI-refractory. Local neck radiation therapy may also be given to patients with anaplastic thyroid carcinoma. Brain metastases can be treated with gamma knife radiosurgery.

Follow-Up

Most recurrences of differentiated thyroid carcinoma become manifest within 5–10 years after thyroidectomy. All patients require at least a yearly thyroid ultrasound and serum thyroglobulin level (while taking levothyroxine). Patients at higher risk usually require at least two annual consecutively negative stimulated serum thyroglobulin determinations < 1 ng/mL and normal RAI scans (if done) and neck ultrasound scans before they are considered to be in remission. The first surveillance occurs with stimulated postoperative serum thyroglobulin, ^{131}I therapy, and post-therapy scanning about 2–4 and 9–12 months after surgery. Serum thyroglobulin and RAI scanning are stimulated by either rhTSH or thyroid hormone withdrawal according to the protocols described above for ^{131}I treatment. Patients need not have repeated ^{131}I therapies if persistent RAI uptake is confined to the thyroid bed, neck ultrasounds appear normal, and stimulated serum thyroglobulin levels remain < 2 ng/mL. Patients with differentiated thyroid carcinoma must be monitored long term for recurrent or metastatic disease. Further RAI or other scans may be required for patients with more aggressive differentiated thyroid cancer, prior metastases, rising serum thyroglobulin levels, or other evidence of metastases.

1. Levothyroxine suppression for differentiated thyroid cancer—Patients who have had a total or near-total thyroidectomy for differentiated thyroid cancer must take levothyroxine replacement for life. (See Levothyroxine Suppression of TSH, above.) Thyrotoxicosis can be caused by over-replacement with levothyroxine or by the growth of functioning metastases. Patients receiving levothyroxine suppression therapy should have periodic bone densitometry.

2. Serum thyroglobulin—Thyroglobulin is produced by normal thyroid tissue and by most differentiated thyroid carcinomas. After a total or near-total thyroidectomy and ^{131}I remnant ablation, thyroglobulin becomes a useful marker for residual or metastatic tumor in for patients with differentiated papillary or follicular thyroid cancer, particularly for patients who do not have serum Tg Ab. In patients receiving levothyroxine following thyroidectomy (with TSH suppression), baseline thyroglobulin levels are insensitive for detection of residual or recurrent disease. Therefore, *stimulated* serum thyroglobulin measurements should be used. Following stimulation by either rhTSH or levothyroxine withdrawal, serum thyroglobulin levels 2 ng/mL or higher indicate the need for a repeat neck ultrasound and further scanning with RAI or ^{18}FDG-PET (see ^{131}I Treatment).

3. Neck ultrasound—Neck ultrasound should be used in all patients with thyroid carcinoma at 3 months postoperatively and regularly thereafter. Ultrasound is more sensitive for lymph node metastases than either CT or MRI scanning. Ultrasound-guided FNA biopsy should be performed on suspicious lesions.

4. Radioactive iodine (RAI: ^{131}I or ^{123}I) neck and whole-body scanning—Despite its limitations, RAI scanning has traditionally been used to detect metastatic differentiated thyroid cancer and to determine whether it is amenable to treatment with ^{131}I. RAI scanning is particularly useful for high-risk patients and those with persistent Tg Ab that make serum thyroglobulin determinations unreliable.

Following total or near-total thyroidectomy, about 65% of metastases are detectable by RAI scanning. The combination of rhTSH-stimulated scanning and thyroglobulin levels detects a thyroid remnant or cancer with a sensitivity of 84%. It is reasonable to perform a rhTSH-stimulated scan and thyroglobulin level 2–3 months after the initial neck surgery. If the scan is negative and the serum thyroglobulin is < 2 ng/mL, low-risk patients may not require further scanning but should continue to be monitored with neck ultrasound and serum thyroglobulin levels every 6–12 months. In about 21% of low-risk patients, rhTSH stimulates serum thyroglobulin to above 2 ng/mL; such patients have a 23% risk of local neck metastases and a 13% risk of distant metastases. The rhTSH-stimulated RAI neck and whole-body scan detects only about half of these metastases because they are small or not avid for iodine. For higher-risk patients, the rhTSH-stimulated thyroglobulin and RAI scan may be repeated about 1 year after surgery and then again if warranted.

5. Positron emission tomography scanning—^{18}FDG-PET scanning is particularly useful for detecting differentiated thyroid cancer metastases in patients with a detectable serum thyroglobulin (especially serum thyroglobulin levels > 10 ng/mL and rising) who have a normal whole-body RAI scan and an unrevealing neck ultrasound. It is also sensitive for detecting metastases from medullary thyroid carcinoma. ^{18}FDG-PET scanning can be combined with a CT scan; the resultant ^{18}FDG-PET/CT fusion scan is 60% sensitive for detecting metastases that are not visible by other methods. This scan is less sensitive for small brain metastases.

^{68}Ga-DOTATATE-PET scanning is useful for staging patients with medullary thyroid carcinoma. It is also useful to determine whether a patient can be treated with PRRT.

6. Other scanning—Thallium-201 (^{201}Tl) scans may be useful for detecting metastatic differentiated thyroid carcinoma when the ^{131}I scan is normal but serum thyroglobulin is elevated. MRI scanning is useful for imaging metastases in the brain, mediastinum, or bones. CT scanning is useful for imaging and monitoring pulmonary metastases.

Prognosis

1. Papillary thyroid carcinoma—This cancer has an overall mortality rate of 2%. It is best staged using the MACIS (metastasis, age, completeness of resection, invasion, size) scoring system (Table 29–8). ^{18}FDG-PET scanning showing pulmonary, brain, or bone metastases independently predicts lower overall survival. Unlike other forms of cancer, patients with papillary thyroid carcinoma who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased. The best prognosis has been with the follicular variant of papillary thyroid cancer.

2. Follicular thyroid carcinoma—The mortality rate of follicular thyroid carcinoma is 3.4 times higher than that of papillary carcinoma. Patients with primary tumors larger than 1 cm who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received ^{131}I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Patients with a normal ^{18}FDG-PET scan have a 98% 5-year survival. Five-year survival is 95% with local metastases, 70% with regional (supraclavicular, mediastinal) metastases, and 35% with distant metastases.

3. Medullary thyroid carcinoma—This cancer is more aggressive than differentiated thyroid cancer but is typically indolent. However, medullary thyroid carcinoma with a somatic *RET* codon *M918T* mutation has a poorer prognosis. When postoperative serum calcitonin levels are above 500 pg/mL (146 pmol/L), distant metastases are likely. Patients with metastatic medullary thyroid carcinoma whose serum calcitonin doubling time is over 2 years also have a relatively good prognosis.

Patients treated with selpercatinib have had one-year sustained response rates of 67%, whereas those treated with vandetanib or cabozantinib had response rates of 38%.

4. Other thyroid carcinomas—Lymphoma has a 5-year survival of nearly 100% if localized and 63% if there is extension beyond the thyroid. **Anaplastic thyroid carcinoma** carries a 1-year survival rate of 10% and a 5-year survival rate of 5%; immunotherapy may be used as an adjunct therapy.

IODINE DEFICIENCY DISORDER & ENDEMIC GOITER

ESSENTIALS OF DIAGNOSIS

- Common in regions with low-iodine diets.
- High rate of congenital hypothyroidism and cretinism.
- Goiters may become multinodular and enlarge.
- Most adults with endemic goiter are euthyroid; however, some are hypo- or hyperthyroid.

General Considerations

Moderate iodine deficiency during gestation and infancy can cause manifestations of hypothyroidism, deafness, and short stature and lower a child's intelligence quotient by 10–15 points. Even mild-to-moderate iodine deficiency appears to impair a child's perceptual reasoning and global cognitive index. Severe iodine deficiency increases the risk of miscarriage and stillbirth. Cretinism occurs in about 0.5% of live births in iodine-deficient areas.

Although iodine deficiency is the most common cause of endemic goiter, there are other natural goitrogens, including certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron, zinc), and water pollutants, which can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. In iodine-deficient patients, cigarette smoking can induce goiter growth. Pregnancy aggravates iodine deficiency. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

Clinical Findings

A. Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy, increasing the size of thyroid nodules and causing new nodules; compressive symptoms may occur.

Substernal goiters are usually asymptomatic but can cause tracheal compression, respiratory distress, dysphagia, superior vena cava syndrome, palsies of the phrenic or recurrent laryngeal nerves, or Horner syndrome. The incidence of significant malignancy is < 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

B. Laboratory Findings

The serum T_4 and TSH are generally normal. TSH is low in hyperthyroidism if a multinodular goiter has become autonomous and there is sufficient iodine for thyroid hormone synthesis. TSH increases with hypothyroidism. Thyroid RAI uptake is usually elevated, but it may be normal if iodine intake has improved. Serum antithyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated above 13 mcg/L.

Differential Diagnosis

Endemic goiter must be distinguished from other forms of nodular goiter that may coexist in an endemic region.

Prevention

The daily minimum dietary requirement for iodine is 150 mcg daily in nonpregnant adults and 250 mcg daily for pregnant or lactating women. Iodized salt contains iodine at about 20 mg per kg salt. Other sources of iodine include commercial bread, milk, and seafood. Initiating iodine supplementation in an iodine-deficient area greatly reduces the emergence of new goiters but causes an increased frequency of hyperthyroidism during the first year.

Treatment

Most patients with iodine-deficient goiter are euthyroid. Dietary iodine supplementation is recommended to avoid hypothyroidism but has proven ineffective in shrinking such goiters. Thyroidectomy may be required for cosmesis, compressive symptoms, or thyrotoxicosis. There is a high goiter recurrence rate in iodine-deficient geographic areas, so near-total thyroidectomy is preferred when surgery is indicated.

Complications

Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction, which may cause hypo- or hyperthyroidism. Excessive iodine intake can actually cause endemic goiter. High-dose iodine supplementation may precipitate thyrotoxicosis. Suppression of TSH by administering levothyroxine carries the risk of inducing hyperthyroidism, particularly in patients with autonomous multinodular goiters. Levothyroxine suppression should not be started in patients with a low TSH level. Treating patients with ^{131}I for large multinodular goiter may shrink the gland; however, Graves disease develops in some patients 3–10 months following therapy.

DISEASES OF THE ADRENAL CORTEX

PRIMARY ADRENAL INSUFFICIENCY (Addison Disease)

ESSENTIALS OF DIAGNOSIS

- Deficiency of cortisol secretion from the adrenal cortex.
- Weakness, vomiting, diarrhea; abdominal pain, arthralgias; amenorrhea.
- Increased skin pigmentation, especially of creases, pressure areas, and nipples.
- Hypovolemic hypotension.
- Hyponatremia; hyperkalemia; hypoglycemia; eosinophilia.
- Elevated plasma ACTH level; cosyntropin unable to stimulate serum cortisol to ≥ 20 mcg/dL (550 nmol/L).
- **Acute adrenal crisis:** above manifestations become critical, with fever, shock, confusion, coma, death.

General Considerations

Primary adrenal insufficiency (Addison disease) is caused by dysfunction or absence of the adrenal cortices. Secondary adrenal insufficiency is caused by deficient secretion of ACTH. Addison disease refers to a chronic deficiency of cortisol caused by adrenocortical insufficiency; plasma ACTH and α-MSH levels are consequently elevated, causing pigmentation that ranges from none to strikingly dark.

Addison disease is an uncommon disorder. In the United States, the prevalence is about 90–140 cases per million and the annual incidence is about 5–6 cases per million. Patients with destruction of the adrenal cortices or with classic 21-hydroxylase deficiency also have mineralocorticoid deficiency, typically with hyponatremia, volume depletion, and hyperkalemia. In contrast, mineralocorticoid deficiency is not present in patients with familial corticosteroid deficiency, Allgrove syndrome, or secondary adrenal insufficiency.

Acute adrenal (Addisonian) crisis is an emergency caused by insufficient cortisol. Crisis may occur in the course of treatment of chronic adrenal insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency than in secondary adrenal insufficiency. It is usually precipitated by one of the following: (1) severe stress (eg, infection, trauma, surgery, hyperthyroidism, or prolonged fasting), or minor stress (vaccinations) in patients with latent or treated adrenal insufficiency; (2) hyperthyroidism or prescription of thyroid hormone to patients with untreated adrenal insufficiency; (3) nonadherence to glucocorticoid replacement or sudden withdrawal of adrenocortical hormone in patients with chronic primary or secondary adrenal insufficiency; (4) bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal gland; (5) sudden destruction of the pituitary gland (pituitary necrosis) or damage to both adrenals (by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection or, rarely, metastatic carcinoma); or (6) administration of intravenous etomidate (used for rapid anesthesia induction or intubation).

Etiology

Autoimmunity is the most common cause of Addison disease in industrialized countries, accounting for about 90% of spontaneous cases; adrenal function decreases over several years as it progresses to overt adrenal insufficiency. Over half the cases of autoimmune Addison disease occur as part of an autoimmune polyendocrine syndrome (APS-1, APS-2). Addison disease can also occur following treatment for malignancies with a PD-1 immune checkpoint inhibitor (ICI). Symptoms of adrenal insufficiency may emerge at any time after ICI therapy, with a median of 10 weeks.

Bilateral adrenal infiltrative diseases cause primary adrenal insufficiency. Causative neoplasms include lymphomas, breast cancer, and lung cancer. Causative infections include tuberculosis, coccidiomycosis, histoplasmosis, cytomegalovirus, cryptococcus, and syphilis.

Infections of the adrenal glands, particularly with cytomegalovirus, are found in nearly half of patients with untreated HIV at autopsy. However, a much lower percentage have clinical Addison disease. The diagnosis of adrenal insufficiency in patients with HIV is often problematic. A cortisol resistance syndrome has been described in patients with HIV, and a revision of normal range for the cosyntropin test for these patients has been advocated (normal peak cortisol over 22 mcg/dL).

Bilateral adrenal hemorrhage may occur with sepsis, heparin-associated thrombocytopenia, anticoagulation, or the antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting about 1 week later with pain, fever, and shock. It may also occur spontaneously and present with flank pain. Meningococcemia may be associated with purpura and adrenal insufficiency secondary to adrenal infarction (Waterhouse-Friderichsen syndrome).

Adrenoleukodystrophy is an X-linked peroxisomal disorder causing accumulation of very long-chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. Adrenal insufficiency ultimately occurs in 80% of affected patients. It presents most commonly in childhood or adolescence but can manifest at any age.

Congenital adrenal insufficiency occurs in several conditions. Familial corticosteroid deficiency is an autosomal recessive disease that is caused by germline mutations in the adrenal ACTH receptor (melanocortin 2 receptor, MC2R). It is characterized by isolated cortisol deficiency and ACTH resistance and may present with neonatal hypoglycemia, frequent infections, and dark skin pigmentation. Triple A (Allgrove) syndrome is caused by a mutation in the AAAS gene that encodes a protein known as ALADIN (alacrima, ***a***chalasia, a***d***renal ***i***nsufficiency, ***n***eurologic disorder). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life.

Congenital adrenal hyperplasia is caused by various genetic defects in the enzymes responsible for steroid synthesis. Due to defective cortisol synthesis, patients have variable degrees of adrenal insufficiency and increased levels of ACTH that causes hyperplasia of the adrenal cortex. The most common enzyme defect is *P450c21 (21-hydroxylase deficiency)*.

Drugs that cause primary adrenal insufficiency include mitotane, abiraterone acetate, and the tyrosine kinase inhibitors lenvatinib and vandetanib. **Rare causes** of adrenal insufficiency include lymphoma, metastatic carcinoma, scleroderma, amyloidosis, and hemochromatosis.

Clinical Findings

A. Symptoms and Signs

The onset of symptoms can occur suddenly but usually develops gradually over months or years. The diagnosis is often delayed, since many early symptoms are nonspecific. Over 90% of patients describe fatigue, reduced stamina, weakness, anorexia, and weight loss. Over 80% of affected patients present with symptoms of orthostatic hypotension (aggravated by dehydration caused by nausea or vomiting), lightheadedness with standing, salt craving, and eventually hyperpigmentation of skin and gums. Abdominal pain, nausea, and vomiting eventually develop in most patients; diarrhea can occur, aggravating dehydration and hypotension. Fevers and lymphoid tissue hyperplasia may also occur. Patients often have significant pain: arthralgias, myalgias, chest pain, abdominal pain, back pain, leg pain, or headache. Psychiatric symptoms include anxiety, irritability, and depression; by the time of diagnosis, over 40% of patients have been told that their symptoms were psychological. Cerebral edema can cause headache, vomiting, gait disturbance, and intellectual dysfunction that may progress to coma. Hypoglycemia can occur and worsen the patient's weakness and mental functioning. Patients treated long-term for adrenal insufficiency appear to be more prone to pneumonia and GI and UTIs.

Skin hyperpigmentation due to increased pituitary secretion of α-MSH varies among affected patients (eg, from none to increased freckling to diffuse darkening that resembles a suntan or a bronze appearance). Sun-exposed areas darken the most, but nonexposed areas darken as well. Hyperpigmentation is often especially prominent over the knuckles, elbows, knees, posterior neck, palmar creases, gingival mucosa, and vermilion border of the lips. Nail beds may develop longitudinal pigmented bands. Nipples and areolas tend to darken. The skin also darkens in pressure areas, such as the belt or brassiere lines and the buttocks. Skin folds and new scars may also become pigmented. Conversely, patches of autoimmune vitiligo can be found in about 10% of patients. Scant axillary and pubic hair typically develops in women.

In pregnancy, undiagnosed adrenal insufficiency is rare, since the condition tends to cause anovulation and reduced fertility. Undiagnosed adrenal insufficiency can cause intrauterine growth retardation and fetal loss. Pregnant women with undiagnosed adrenal insufficiency can experience shock from adrenal crisis, particularly during the first trimester, concurrent illness, labor, or postpartum.

Patients with preexistent type 1 diabetes experience more frequent hypoglycemia with the onset of adrenal insufficiency, such that their insulin dosage must be reduced.

Acute adrenal crisis is an immediate threat to life. Affected patients have magnified symptoms of chronic adrenal insufficiency and experience an acute deterioration in their health, typically with acute GI symptoms and fever that can mimic an abdominal emergency. Infections (lower respiratory, urinary, or GI) are common triggers for acute adrenal crisis. Patients also frequently experience back pain, arthralgias, and profound fatigue. They may have delirium or coma, sometimes aggravated by hypoglycemia. Adrenal crisis is marked by orthostatic dizziness and hypotension (blood pressure below 100 mm Hg systolic or 20 mm Hg lower than their baseline). Reversible cardiomyopathy and HF can also occur, causing hypotension that can progress to life-threatening shock that does not respond to intravenous fluids and vasopressors.

B. Laboratory Findings

Typically, there is mild anemia, moderate neutropenia, lymphocytosis, and eosinophilia (total eosinophil count over 300/mcL). Among patients with chronic adrenal insufficiency, the serum sodium is usually low (88%) and the potassium elevated (64%). However, patients with vomiting or diarrhea may not be hyperkalemic. Fasting hypoglycemia is common. Hypercalcemia may be present.

A plasma cortisol < 3 mcg/dL (83 nmol/L) at 8 AM is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level > 200 pg/mL (44 pmol/L). The diagnosis is confirmed by a simplified cosyntropin stimulation test: (1) Synthetic ACTH_{1-24} (cosyntropin), 0.25 mg, is given intramuscularly. (2) Serum cortisol is obtained 45 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL (550 pmol/L), whereas patients with adrenal insufficiency have stimulated serum cortisol levels < 20 mcg/dL (550 pmol/L). For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol. Cosyntropin is usually well tolerated, but infrequent (< 5%) side effects have included hypersensitivity reactions with nausea, headache, dizziness, dyspnea, palpitations, flushing, edema, and local injection site reactions.

One or more serum anti-adrenal antibodies are found in about 50% of cases of autoimmune Addison disease. The sensitivity of four serum anti-adrenal antibodies is as follows: cytoplasmic antibodies (26%), 21-hydroxylase antibodies (21%), 17-hydroxylase antibodies (21%), and side-chain cleavage antibodies (16%). Antibodies to thyroid (45%) and other tissues may also be present.

Elevated plasma renin activity (PRA) indicates the presence of depleted intravascular volume and the need for fludrocortisone administration. Serum epinephrine levels are low in untreated patients with adrenal insufficiency.

Salt-wasting congenital adrenal hyperplasia due to 21-hydroxylase deficiency is usually diagnosed at birth. The specific diagnosis requires elevated serum levels of 17-OH progesterone.

Young men with idiopathic Addison disease are screened for X-linked adrenoleukodystrophy by determining plasma very long-chain fatty acid levels; affected patients have high levels.

In acute adrenal crisis, blood, sputum, or urine cultures may be positive if bacterial infection is the precipitating cause.

C. Imaging

When adrenal insufficiency is not clearly autoimmune, a CT scan of the adrenal glands should be obtained. The adrenals are enlarged in about 85% of cases related to metastatic or granulomatous disease. Adrenal calcifications occur in 50% of tuberculous Addison cases but are also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma. Small, noncalcified adrenals are seen in autoimmune Addison disease.

Differential Diagnosis

Patients with secondary adrenal insufficiency due to ACTH deficiency have normal mineralocorticoid production and do not develop hyperkalemia (see Hypopituitarism). In contrast to Addison disease, patients with secondary adrenal insufficiency have normal to decreased skin pigmentation that has been described as "alabaster skin." Hemochromatosis also causes bronze skin hyperpigmentation, and hemochromatosis may in fact be the cause of Addison disease. Acute adrenal crisis must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic).

The constitutional symptoms may be mistaken for cancer, anorexia nervosa, or emotional stress. Acute adrenal insufficiency must be distinguished from an acute abdomen in which neutrophilia is the rule, whereas in adrenal insufficiency there is lymphocytosis and eosinophilia. The neurologic manifestations of Allgrove syndrome and adrenoleukodystrophy (especially in women) may mimic multiple sclerosis. Hyperkalemia can be caused by hyporeninemic hypoaldosteronism from type IV renal tubular acidosis. Hyperkalemia is also seen with rhabdomyolysis, hyperkalemic paralysis, and some drugs (eg, ACE inhibitors, spironolactone, and drospirenone) (see Chapter 24).

Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, HF, cirrhosis, vomiting, diarrhea, severe illness, or major surgery) (see Figure 24–1). Nearly 40% of critically ill patients have low serum cortisol levels due to low serum albumin levels; their total serum cortisol levels may be low but their serum free cortisol levels are normal.

Complications

Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur in adrenal insufficiency, and intercurrent infections may precipitate an acute adrenal crisis. Associated autoimmune diseases are common (see above).

Treatment

A. General Measures

Patients and family members must be thoroughly educated about adrenal insufficiency. *Patients are advised to wear a medical alert bracelet or medal reading, "Adrenal insufficiency—takes cortisone."* They need to be provided with a dose escalation schedule for increased corticosteroids for illness, accidents, or prior to minor surgical procedures and for increased fludrocortisone for hot weather or prolonged strenuous exercise. Corticosteroids and fludrocortisone must be prescribed in liberal amounts with automatic refills to avoid the patient's running out of medication. It is also advisable to prescribe a routine antiemetic such as ondansetron ODT 8-mg tablets to be taken every 8 hours for nausea. Parenteral hydrocortisone (Solu-Cortef) 100 mg is also prescribed for patient self-injection in the event of vomiting. Patients must receive advance instructions to seek medical attention at an emergency facility immediately in the event of vomiting or severe illness. All infections should be treated immediately and vigorously, with hydrocortisone administered at appropriately increased doses.

B. Specific Therapy

Replacement therapy should include corticosteroids with mineralocorticoids for primary adrenal insufficiency. In mild cases, corticosteroids alone may be adequate.

1. Corticosteroid replacement therapy—Maintenance therapy for most patients with Addison disease is 15–30 mg of hydrocortisone orally daily in two divided doses (10–20 mg in the morning; 5–10 mg in the evening) or three divided doses (eg, 10 mg at 7 AM, 10 mg at 1 PM, and 5 mg at 7 PM). Some patients respond better to prednisone or methylprednisolone in doses of about 3–6 mg daily in divided doses. Adjustments in dosage are made according to the clinical response. The corticosteroid dose should be kept at the lowest level at which the patient feels clinically well.

Patients with partial ACTH deficiency (basal morning serum cortisol above 8 mg/dL [220 mmol/L]) require hydrocortisone replacement in lower doses of about 5 mg orally twice daily or even 10 mg every morning. Some patients feel better with the substitution of prednisone (2–7.5 mg/day orally) or methylprednisolone (2–6 mg/day orally), given in divided doses. Fludrocortisone is not required. Additional corticosteroid must be given during stress (eg, infection, trauma, or surgical procedures). For mild illness or mild-moderate surgical stress, corticosteroid doses are doubled or tripled. For severe illness, trauma, or major surgical stress, hydrocortisone 100 mg is given intravenously, followed by 200 mg daily, given as either a continuous intravenous infusion or as 50 mg boluses given every 6 hours intravenously or intramuscularly and then reduced to usual doses as the stress subsides.

Plenadren MR (5- or 20-mg modified-release tablets) is a once-daily dual-release oral preparation of hydrocortisone that may be administered in the morning (usual dose range is 20–30 mg daily). Plenadren may improve quality of life in some patients with adrenal insufficiency. It is not available in the United States but is available in Canada and elsewhere.

Patients must be monitored carefully for clinical signs of over- or under-replacement of corticosteroid replacement therapy. A proper corticosteroid dose usually results in clinical improvement. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent hypothyroidism or diabetes mellitus. A WBC count with a differential can be useful, since a relative neutrophilia and lymphopenia can indicate corticosteroid over replacement, and vice versa. Serum ACTH levels vary substantially and should not be used to determine dosing.

Caution: Increased corticosteroid dosing is required in circumstances of infection, trauma, surgery, stressful diagnostic procedures, or other forms of stress. For severe stress of major illness, surgery, or delivery, a maximum stress dose of hydrocortisone is given as 50–100 mg intravenously or intramuscularly, followed by 50 mg every 6 hours (continuous intravenous infusion or boluses), then reduced over several days. However, following major trauma, increased doses of replacement hydrocortisone may be required for up to several weeks. Lower doses, oral or parenteral, are used for less severe stress. For immunizations that are given with an adjuvant, such as varicella zoster (Shingrix), there is sufficient local inflammation that increased doses of hydrocortisone are recommended for 5 days following the immunization. The dose is reduced back to normal as the stress subsides. Decreased corticosteroid dosing is required when medications are prescribed that inhibit corticosteroid metabolism by blocking the isoenzyme CYP34A, particularly the antifungals ketoconazole or itraconazole, the antidepressant nefazodone, anti-HIV protease inhibitors, and cobicistat. Rifampin increases hydrocortisone clearance, necessitating increased corticosteroid dosing. During the third trimester of pregnancy, corticosteroid requirements are higher, so usual corticosteroid doses are increased by 50%.

2. Mineralocorticoid replacement therapy—Fludrocortisone acetate has a potent sodium-retaining effect. The dosage is 0.05–0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, an elevated PRA indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased. During treatment with hydrocortisone with maximum doses appropriate for stress, fludrocortisone replacement is not required. Some patients cannot tolerate fludrocortisone and must substitute NaCl tablets to replace renal sodium loss.

3. DHEA replacement therapy—DHEA is given to some women with adrenal insufficiency. In a double-blind clinical trial, women taking DHEA 50 mg orally each morning experienced an improved sense of well-being, increased muscle mass, and a reversal in bone loss at the femoral neck. Older women who receive DHEA should be monitored for androgenic effects. Because over-the-counter preparations have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade micronized DHEA.

4. Treatment of hyperandrogenism in women with congenital adrenal hyperplasia—See Hirsutism & Virilization.

5. Treatment of acute adrenal crisis—If acute adrenal crisis is suspected but the diagnosis of adrenal insufficiency is not yet established, intravenous access must be established. Blood is drawn for cultures, plasma ACTH, serum cortisol, serum glucose, BUN, creatinine, and electrolyte levels. A UA is obtained to screen for a UTI. Without waiting for the results, treatment is initiated *immediately* with hydrocortisone, 100 mg by intravenous bolus followed by 50 mg intravenously every 6 hours as either intravenous boluses or a continuous intravenous infusion. The hydrocortisone dosage may then be reduced according to the clinical picture and laboratory test results.

Intravenous fluids are administered as either 0.9% normal saline or 0.9% normal saline/5% dextrose solutions. A volume of 2–3 L is given quickly and then the intravenous rate is reduced according to clinical parameters and frequent serum electrolytes and glucose determinations. When intravenous saline is stopped, mineralocorticoid replacement is commenced with fludrocortisone, starting with 0.1 mg orally daily and adjusted according to serum electrolyte determinations.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures (see Table 35–5). The patient must also be treated for electrolyte abnormalities, hypoglycemia, and dehydration, as indicated.

When the patient can take food by mouth, hydrocortisone is administered orally in doses of 10–20 mg every 6 hours, and the dosage is reduced to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (10–20 mg in the morning; 5–10 mg in the evening). Mineralocorticoid replacement is not needed when large amounts of hydrocortisone are given, but as its dose is reduced, it is usually necessary to add fludrocortisone acetate, 0.05–0.2 mg orally daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be evaluated to assess the degree of permanent adrenal insufficiency and to establish the cause, if possible.

Prognosis

The life expectancy of patients with Addison disease is reasonably normal, as long as they are compliant with their medications and knowledgeable about their condition. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of corticosteroids. Cushing syndrome can develop, imposing its own risks, in patients who take excessive doses of corticosteroid replacement.

Acute adrenal crisis usually responds to rapid treatment. However, if adrenal crisis is unrecognized and untreated, shock that is unresponsive to fluid replacement and vasopressors can result in death.

CUSHING SYNDROME (Hypercortisolism)

ESSENTIALS OF DIAGNOSIS

- Central obesity, muscle wasting, hirsutism, purple striae.
- Psychological changes and cognitive impairment.
- Osteoporosis, hypertension, poor wound healing.
- Hyperglycemia, leukocytosis, lymphocytopenia, hypokalemia.
- Elevated serum cortisol and urinary free cortisol. Lack of normal suppression by dexamethasone.

General Considerations

The term Cushing "syndrome" refers to the manifestations of excessive corticosteroids. Endogenous Cushing syndrome refers to increased cortisol production by the adrenal cortex. It is a rare disease with an estimated incidence of about 2.4 cases per million per year in the United States. About 75% of such cases are due to excessive ACTH secretion, while 25% are due to autonomous cortisol production by the adrenal cortex. Exogenous Cushing syndrome is most commonly due to supraphysiologic doses of corticosteroid drugs.

A. Cushing Disease with Elevated or Normal ACTH Levels (75%)

About 90% of cases of ACTH-dependent hypercortisolism are due to Cushing "disease," caused by a benign ACTH-secreting pituitary adenoma. The adenoma is typically smaller than 5 mm and located in the anterior pituitary (94%); however, about 6% are ectopic in locations such as the cavernous sinus, sphenoid sinus, ethmoid sinus, or posterior pituitary. Cushing disease is at least three times more frequent in women than men, and the median age is 41 years at diagnosis.

About 10% of cases of ACTH-dependent hypercortisolism are due to nonpituitary neuroendocrine neoplasms that produce ectopic ACTH. Ectopic locations include the lungs (55%), pancreas (9%), mediastinum-thymus (8%), adrenal (6%), GI tract (5%), thyroid (4%), and other sites (13%). About 15% of cases are due to ACTH from a source that cannot be initially located.

B. Cushing Syndrome with Low or Low-Normal ACTH (25%)

About 25% of cases of spontaneous Cushing syndrome are due to excessive *autonomous* secretion of cortisol by the adrenals. Cortisol secretion is independent of ACTH, and plasma ACTH levels are usually low or low-normal. Most cases are due to a unilateral adrenal tumor. Benign adrenal adenomas are generally small and produce mostly cortisol. Adrenocortical carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens but may be nonsecretory. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells' abnormal stimulation by hormones such as catecholamines, arginine vasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food-dependent, and plasma ACTH levels may not be completely suppressed. Bilateral primary pigmented adrenal macronodular adrenocortical disease may be an isolated condition or part of the Carney complex, an autosomal dominant condition with additional features consisting of myxomas of the heart and skin with spotty skin pigmentation and facial freckles.

Clinical Findings

A. Symptoms and Signs

The manifestations of Cushing syndrome vary considerably. Early in the course of the disease, patients frequently describe nonspecific symptoms, such as fatigue or reduced endurance but may have few, if any, of the physical stigmata described below. Most patients eventually develop weight gain with central obesity and a plethoric "moon face," "buffalo hump," supraclavicular fat pads, protuberant abdomen, and thin extremities. Muscle atrophy causes weakness, with difficulty standing up from a seated position or climbing stairs. Patients may also experience backache, headache, hypertension, osteoporosis, avascular necrosis of bone, acne, hirsutism, superficial skin infections, and oligomenorrhea or amenorrhea in women or erectile dysfunction and diminished libido in men. Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (especially around the thighs, breasts, and abdomen, and easy bruising. Unusual bacterial or fungal infections are common. Wound healing is impaired. Cushing syndrome adversely affects the brain, resulting in cognitive impairment and emotional disorders. Patients frequently have diminished ability to concentrate, impaired memory, reduced executive function, increased depression, and increased lability of mood. Anxiety may sometimes be accompanied by psychosis. Hyperglycemia with diabetes mellitus is common. Patients are susceptible to opportunistic infections. Hyperpigmentation is common with ectopic ACTH-secreting neoplasms that tend to produce very high plasma ACTH levels; hyperpigmentation is uncommon with pituitary Cushing disease.

Adrenal carcinomas that are symptomatic usually have gross metastases by the time of diagnosis. Microscopic metastases are not visible by scanning but can be inferred from the presence of detectable cortisol levels following removal of the primary adrenal tumor in patients with a cortisol-secreting carcinoma and Cushing syndrome. More than 30% of adrenal carcinomas are diagnosed incidentally and tend to be less symptomatic.

B. Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing syndrome often have leukocytosis with granulocytosis (AGC > 8000 cells/mcL) and relative lymphocytopenia (RLC < 24%). Hypokalemia may be present, particularly in cases of ectopic ACTH secretion.

1. Diagnostic tests for hypercortisolism—Testing for hypercortisolism involves determining whether the following characteristics of Cushing syndrome are present: (1) lack of cortisol diurnal variation, (2) reduced suppressibility of cortisol by dexamethasone, (3) increased 24-hour urine free cortisol. At least two of these three tests must be positive to make a diagnosis of Cushing syndrome. In patients with a known adrenal mass, suppression of plasma ACTH also indicates hypercortisolism. Conflicting results are common.

Late-night (10–11 PM) salivary cortisol determinations are particularly useful, especially for ACTH-dependent hypercortisolism. Normal late-night salivary cortisol levels are < 150 ng/dL (4.0 nmol/L). Late-night salivary cortisol levels that are consistently > 250 ng/dL (7.0 nmol/L) are considered abnormal. The late-night salivary cortisol test has a relatively high sensitivity and specificity for Cushing syndrome.

The **overnight dexamethasone suppression test** is an easy screening test for hypercortisolism and is particularly sensitive for mild ACTH-independent hypercortisolism from an adrenal nodule. Dexamethasone 1 mg is given orally at 11 PM and serum collected for cortisol determination at 8 AM the next morning; a cortisol level < 1.8 mcg/dL (50 nmol/L) excludes Cushing syndrome with some certainty. However, 8% of established patients with pituitary Cushing disease have dexamethasone-suppressed cortisol levels < 2 mcg/dL (55 nmol/L). Several antiseizure drugs and rifampin accelerate the metabolism of dexamethasone, causing a lack of cortisol suppression by dexamethasone. Estrogens—during pregnancy or as oral contraceptives or HRT—may also cause lack of dexamethasone suppressibility.

A 24-hour urinary free cortisol and creatinine is usually used to confirm hypercortisolism in patients with a high late-night salivary cortisol or an abnormal dexamethasone suppression test. A high 24-hour urine free cortisol (> 50 mcg/day or 140 nmol/day in adults), or free cortisol to creatinine ratio of > 95 mcg cortisol/g creatinine, helps confirm hypercortisolism. However, many patients with mild hypercortisolism have a urinary free cortisol that is within the reference range. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal.

2. Diagnostic tests for the source of hypercortisolism—Once hypercortisolism is confirmed, a plasma ACTH and DHEAS are obtained. A plasma ACTH below 6 pg/mL (1.3 pmol/L), with a low DHEAS, indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic ACTH-secreting tumors. Serum dehydroepiandrosterone sulfate (DHEAS) levels can be used as a proxy for ACTH, since DHEAS secretion is ACTH-dependent; levels below the reference range and particularly below 40 mcg/dL (1.1 mcmol/L) imply ACTH-independent hypercortisolism.

C. Imaging

In ACTH-independent Cushing syndrome, CT of the adrenals usually detects a mass lesion, which is most often an adrenal adenoma. Adrenocortical carcinomas can usually be distinguished from benign adrenal adenomas since they are generally larger (average 11 cm) and many have metastases that are visible on preoperative scans.

In ACTH-dependent Cushing syndrome, MRI of the pituitary gland demonstrates a pituitary lesion in about 85% of cases; lesions tend to be small (median 9.1 mm). Very small lesions (< 5 mm) are not diagnostic. When the pituitary MRI is normal or shows a tiny (< 5 mm) irregularity that may be incidental, selective catheterization of the inferior petrosal sinus veins draining the pituitary is performed. ACTH levels in the inferior petrosal sinus that are more than twice the simultaneous peripheral venous ACTH levels are indicative of pituitary Cushing disease.

When inferior petrosal sinus ACTH concentrations are not above the requisite levels, a search for an ectopic source of ACTH is undertaken. Location of ectopic sources of

ACTH begins with CT scanning of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals.

For Cushing syndrome due to ectopic ACTH, CT scanning fails to detect the source of ACTH in about 34% of cases. In such cases, the most sensitive (82%) scanning technique is whole-body imaging with ^{64}Cu-DOTATATE-PET/CT.

Differential Diagnosis

Cushing syndrome without hypercortisolism is often due to iatrogenic glucocorticoid exposure (oral, topical, or inhaled).

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing syndrome. Pregnant women have elevated serum ACTH levels, increased urine free cortisol, and high serum cortisol levels due to high serum levels of cortisol-binding globulin. Critically ill patients frequently have hypercortisolism, usually with suppression of serum ACTH. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing syndrome but without clinical signs of Cushing syndrome. Anorexia nervosa and bulimia can be mistaken for Cushing syndrome, owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing syndrome. Excessive ingestion of γ-hydroxybutyric acid (GHB, sodium oxybate) can also induce ACTH-dependent Cushing syndrome that resolves after the drug is stopped.

Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as "striae distensae" and are not indicative of Cushing syndrome. Patients receiving antiretroviral therapy for HIV-1 infection frequently develop partial lipodystrophy with thin extremities and central obesity with a dorsocervical fat pad ("buffalo hump") causing pseudo-Cushing syndrome.

Treatment

Patients must receive treatment for cortisol-dependent comorbidities, including osteoporosis, psychiatric disorders, diabetes mellitus, hypertension, hypokalemia, muscle weakness, and infections. Bone densitometry is recommended for all patients and treatment is commenced for patients with osteoporosis.

A. Surgical Therapy

Pituitary Cushing disease is best treated with transsphenoidal selective resection of the pituitary adenoma, even when the pituitary MRI is normal or inconclusive. With an experienced pituitary neurosurgeon, remission rates range from 80% to 90%. Postoperative hyponatremia occurs frequently; serum sodium should be monitored often for the first 2 weeks postoperatively. The patient should be screened for secondary hypothyroidism with a serum free T_4 within 1–2 weeks after surgery. After successful pituitary surgery, the rest of the pituitary usually returns to normal function; however, the pituitary corticotrophs remain suppressed and require 6–36 months to recover normal function. Therefore, patients receive empiric replacement-dose hydrocortisone postoperatively. The cosyntropin test becomes abnormal by 2 weeks following successful pituitary surgery. Patients with secondary adrenal insufficiency and their families require patient education about the condition and must continue corticosteroid replacement until a cosyntropin stimulation test is normal.

Cushing disease may persist after pituitary surgery, particularly when there has been cavernous sinus involvement. After apparent successful pituitary surgery, Cushing disease recurs in 16% after a mean of 38 months. A pituitary MRI is obtained about 3 months postoperatively and repeated as indicated for clinical evidence of recurrent Cushing disease. For patients with persistent or recurrent Cushing disease, repeat transsphenoidal pituitary surgery may be warranted if the recurrent tumor is visible and deemed resectable. Otherwise, bilateral laparoscopic adrenalectomy is usually the best treatment option. Residual or recurrent ACTH-secreting pituitary tumors may also be treated with stereotactic radiosurgery, which normalizes urine free cortisol in 70% of patients within a mean of 17 months, compared with a 23% remission rate with conventional radiation therapy. Pituitary radiosurgery can also be used to treat Nelson syndrome.

Ectopic ACTH-secreting tumors should be surgically resected. If the tumor cannot be localized or is metastatic, laparoscopic bilateral adrenalectomy is usually recommended. Patients with metastatic ACTH-secreting neuroendocrine tumors that are avid for DOTATATE on PET imaging may be treated with peptide receptor radionuclide therapy (PRRT) with a radioisotope-tagged octreotide analogue. Medical treatment with an oral combination of mitotane (3–5 g/24 hours), ketoconazole (0.4–1.2 g/24 hours), and metyrapone (3–4.5 g/24 hours) often suppresses the hypercortisolism.

Cortisol-secreting benign adrenal adenomas may be resected laparoscopically if they are smaller than 6 cm; cure is achieved in most patients. However, most patients experience prolonged secondary adrenal insufficiency. Patients with bilateral adrenal macronodular hyperplasia usually require bilateral adrenalectomies and an evaluation for Carney complex.

Adrenocortical carcinomas are resected surgically. If the adrenocortical carcinoma was functional, postoperative secondary adrenal insufficiency is a good prognostic sign, with an increased chance that the tumor was completely resected without metastases; however, detectable postoperative cortisol levels predict metastases, even if no metastases are detectable on scans.

B. Medical Therapy

For patients with Cushing syndrome who decline surgery or for whom surgery has been unsuccessful, medical therapy may be considered: **Osilodrostat** orally twice daily can normalize urine free cortisol and improve the manifestations of hypercortisolism. It reduces cortisol synthesis by blocking the adrenal enzyme 11b-hydroxylase. Adverse effects include adrenal insufficiency, a prolonged cardiac QT interval, hypertension, hirsutism, and acne. **Ketoconazole** inhibits adrenal steroidogenesis and is another treatment option when given in doses of about 200 mg orally every 6 hours; however, it is marginally effective and can cause liver toxicity. **Metyrapone** can suppress hypercortisolism; required median oral daily doses are 1250–1500 mg/day in divided doses. It may be combined with other therapies. Metyrapone also may be used for patients with secretory adrenocortical carcinoma whose hypercortisolism is not fully controlled with mitotane. **Mitotane** is approved for use with adrenocortical carcinoma and reduces cortisol secretion over several weeks. It accelerates hydrocortisone clearance, so glucocorticoid replacement is usually required at double usual doses. **Etomidate** is an intravenous anesthetic agent that blocks adrenal steroidogenesis. It can be given in sub-anesthetic doses to control severe hypercortisolism in severely ill patients with Cushing syndrome.

Mineralocorticoid hypertension can be treated with spironolactone, eplerenone, finerenone, or dihydropyridine calcium channel blockers. Women with hyperandrogenism may be treated with flutamide. Cabergoline, 0.5–3.5 mg orally twice weekly, reduced hypercortisolemia in 40% of patients with Cushing disease in one small study. Pasireotide, a multireceptor-targeting somatostatin analog, is a treatment option for refractory ACTH-secreting pituitary tumors causing Cushing disease or Nelson syndrome.

Metastatic ACTH-producing tumors that are visible with Octreoscan or ^{68}Ga-DOTATATE-PET imaging have somatostatin receptors. Such tumors may respond to therapy with somatostatin analogs; pasireotide LAR (60 mg intramuscularly every 28 days) or octreotide LAR (30–40 mg intramuscularly every 28 days) slows progression of the malignancy and reduces ACTH secretion in up to half such patients. Radionuclide therapy with several cycles of ^{177}Lu-DOTATATE has produced remissions in some patients.

Patients who are successfully surgically treated for Cushing syndrome typically develop "cortisol withdrawal syndrome," even when given replacement corticosteroids for adrenal insufficiency. Manifestations can include hypotension, nausea, fatigue, arthralgias, myalgias, pruritus, and flaking skin. Increasing the hydrocortisone replacement to 30 mg orally twice daily can improve these symptoms; the dosage is then reduced slowly as tolerated.

Patients with secretory adrenocortical carcinomas are usually treated with mitotane postoperatively, particularly if metastases are visible or cortisol is detectable postoperatively. Patients with nonsecretory metastatic adrenocortical carcinomas have also responded to mitotane. Mitotane is typically given for 2–5 years postoperatively. Mitotane can cause hypogonadism and primary adrenal insufficiency. Replacement hydrocortisone or prednisone should be started when mitotane doses reach 2 g daily. The replacement dose of oral hydrocortisone starts at 15 mg in the morning and 10 mg in the afternoon but must often be doubled or tripled because mitotane increases cortisol metabolism and cortisol-binding globulin levels; the latter can artifactually raise serum cortisol levels. Mitotane also causes central hypothyroidism in 95% of patients within the first year of treatment. Combined chemotherapy with etoposide, doxorubicin, cisplatin, and mitotane (EDP-M) appears to be the most effective regimen for recurrent or metastatic adrenocortical carcinoma.

Prognosis

The manifestations of Cushing syndrome regress with time, but patients may have residual cognitive or psychiatric impairment, muscle weakness, osteoporosis, and sequelae from vertebral fractures. Continued impaired quality of life is more common in women compared to men. Younger patients have a better chance for full recovery.

Patients with Cushing syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful, which can be predicted if the postoperative nonsuppressed serum cortisol is < 2 mcg/dL (55 nmol/L). Following successful treatment, overall mortality remains particularly higher for patients with older age at diagnosis, higher preoperative ACTH concentrations, and longer duration of hypercortisolism. Patients in remission from Cushing disease continue to experience a higher mortality rate than expected, particularly from ischemic heart disease and from cerebral infarction, bacterial infections, and suicide.

Patients who have a complete remission after transsphenoidal surgery have about a 15–20% chance of recurrence over the next 10 years. Recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors depends on the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%.

In patients with adrenocortical carcinoma, 5-year survival rates of treated patients have correlated with the ENSAT stage. For stage 1, the 5-year survival was 81%; for stage 2, 61%; for stage 3, 50%; and for stage 4, 13%.

Complications

Following bilateral adrenalectomy for Cushing disease, a pituitary adenoma may enlarge progressively (Nelson syndrome), causing local destruction (eg, visual field impairment, cranial nerve palsy) and hyperpigmentation. Following successful therapy for Cushing syndrome, secondary adrenal insufficiency occurs and requires long-term corticosteroid replacement. Five years after successful surgery, secondary hypoadrenalism resolves in about 58% of patients with pituitary Cushing disease, 82% of those with ectopic ACTH, and only 38% of those who had an adrenal tumor.

When to Refer

Dexamethasone suppression test is abnormal.

When to Admit

- Transsphenoidal hypophysectomy.
- Adrenalectomy.
- Resection of ectopic ACTH-secreting tumor.

PRIMARY ALDOSTERONISM

ESSENTIALS OF DIAGNOSIS

- Hypertension may be severe or drug-resistant.
- Hypokalemia (in minority of patients) may cause polyuria, polydipsia, muscle weakness.
- Low plasma renin; elevated plasma and urine aldosterone levels.

General Considerations

Primary aldosteronism (hyperaldosteronism) refers to renin-independent, inappropriately high and nonsuppressible aldosterone secretion and is associated with adverse cardiovascular disorders. Although most affected patients have hypertension, some may be normotensive. The prevalence of primary aldosteronism is 5–10% in hypertensive patients and at least 20% in patients with resistant hypertension. Primary aldosteronism should be suspected when the patient has early-onset hypertension or stroke (before age 50 years). Primary aldosteronism and cases of low renin essential hypertension may overlap, making distinguishing between them difficult. Patients of all ages may be affected, but the peak incidence is between 30 years and 60 years. Excessive aldosterone production increases sodium retention; increases renal potassium excretion, which can lead to hypokalemia; and suppresses plasma renin. Cardiovascular events are more prevalent in patients with aldosteronism (35%) than in those with essential hypertension (11%).

Primary aldosteronism is most frequently caused by bilateral adrenal cortical hyperplasia (75%) that is more common in men with a 4:1 ratio, peaking between ages 50 and 60. Primary aldosteronism may be also caused by a unilateral aldosterone-producing adrenal cortical adenoma (Conn syndrome, 25%) that is more common in women with a 2:1 ratio, peaking between ages 30 and 50. It is important to distinguish the two, since a unilateral aldosteronoma (Conn syndrome) may be cured by surgical resection, whereas patients with bilateral adrenal hyperplasia are treated medically.

Clinical Findings

A. Symptoms and Signs

Primary aldosteronism is the most common cause of refractory hypertension in youths and middle-aged adults. Patients have hypertension that is typically moderate but may be severe. Some patients have only diastolic hypertension, without other symptoms and signs. Edema is rarely seen in primary aldosteronism. Hypokalemia can produce muscle weakness, paresthesias with tetany, headache, polyuria, and polydipsia.

B. Laboratory Findings

Plasma potassium should be determined in hypertensive individuals. However, hypokalemia, once thought to be the hallmark of hyperaldosteronism, is present in only 37% of affected patients: 50% of those with an aldosterone-producing adenoma and 17% of those with adrenal hyperplasia. An elevated serum bicarbonate (HCO_3) concentration indicates metabolic alkalosis and is commonly present.

Testing for primary aldosteronism should be considered for all hypertensive patients with any of the following: (1) sustained hypertension above 150/100 mm Hg on 3 different days; (2) hypertension resistant to three conventional antihypertensive drugs, including a diuretic; (3) controlled blood pressure requiring four or more antihypertensive drugs; (4) hypokalemia, particularly when unrelated to diuretics; (5) personal or family history of early-onset hypertension or cerebrovascular accident at age 40 or younger; (6) first-degree relative with primary aldosteronism; (7) presence of an adrenal mass; and (8) low PRA.

For at least 2 weeks prior to testing, patients should have any hypokalemia corrected, consume a diet high in NaCl (> 6 g/day) and, ideally, withhold certain medications: diuretics, ACE inhibitors and ARBs (stimulate PRA), β-blockers, clonidine, NSAIDs (suppress PRA), oral estrogens, and oral contraceptives.

For blood testing, the patient should be out of bed for at least 2 hours and seated for 15–60 minutes before the blood draw, which should preferably be obtained between 8 AM and 10 AM. The blood should be drawn slowly with a syringe and needle (rather than a vacutainer) at least 5 seconds after tourniquet release and without fist clenching. Plasma potassium, rather than the routine serum potassium, should be measured in cases of unexpected hyperkalemia. Plasma potassium levels must be normal since hypokalemia suppresses aldosterone. Patients with primary aldosteronism have a suppressed PRA below or near 1.0 ng/mL/hour. Suppressed PRA with a serum aldosterone concentration > 15 ng/dL (420 pmol/L) indicates probable primary hyperaldosteronism. Serum aldosterone (ng/dL) to PRA (ng/mL/hour) ratios < 24 exclude primary aldosteronism; ratios between 24 and 30 are indeterminate; ratios between 30 and 64 are suspicious; a ratio above 64 helps confirm the diagnosis of primary aldosteronism. To help confirm the diagnosis of aldosteronism, especially for patients with a suppressed PRA but lower serum aldosterone levels, a 24-hour urine aldosterone > 12 mcg/24 hours (33 nmol/24 hours) confirms primary aldosteronism with 93% specificity.

Genetic testing for familial corticosteroid-remediable aldosteronisms is recommended for patients with confirmed primary aldosteronism by age 20 years and those with a family history of primary aldosteronism or stroke at young age (under age 40).

C. Imaging

Some patients with undiagnosed primary aldosteronism are incidentally found to have an adrenal nodule (incidentaloma) during abdominal or chest imaging. All patients with biochemically confirmed primary aldosteronism require a thin-section CT scan of the adrenals to screen for a rare adrenal carcinoma or an adrenal adenoma. In the absence of a large adrenal adenoma, adrenal CT scanning cannot reliably distinguish unilateral from bilateral aldosterone excess, having both a sensitivity and specificity of 78% for unilateral aldosteronism. Therefore, adrenal vein sampling is often required.

D. Adrenal Vein Sampling

Bilateral selective adrenal vein sampling is invasive, expensive, and not widely available. Adrenal vein sampling has a sensitivity of 95% and a specificity of 100% but only when performed by an experienced radiologist. This procedure entails a 0.6% risk of major complications.

The procedure may not be required for patients whose blood pressure is well controlled with spironolactone or eplerenone and for those with familial hyperaldosteronism. It is indicated only if surgery is contemplated in order to direct the surgeon to the correct adrenal gland. In such cases, adrenal vein sampling can be useful to identify the adrenal to be removed when there is no visible adrenal adenoma on CT imaging. Adrenal vein sampling can also help avoid mistaken removal of an incidental nonsecreting adrenal adenoma. Adrenal vein sampling is not required in patients who have a classic adrenal adenoma (Conn syndrome), which is characterized by spontaneous hypokalemia and a unilateral adrenal adenoma 10 mm or larger on CT.

Before this procedure, the patient must be properly prepared (see Laboratory Findings). However, patients with a persistently suppressed PRA may continue mineralocorticoid blockade. Lateralization is present when the aldosterone:cortisol ratio from one adrenal vein is at least four times that from the opposite adrenal vein.

Aldosterone hypersecretion that is lateralized to one adrenal usually indicates that adrenal has a unilateral aldosteronoma or hyperplasia, particularly when aldosterone secretion from the contralateral adrenal is suppressed.

Differential Diagnosis

The differential diagnosis of primary aldosteronism includes other causes of hypokalemia in patients with essential hypertension, especially diuretic therapy; chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism (see Table 24–3).

Apparent mineralocorticoid excess syndrome may be caused by real (black) licorice (derived from anise) or anise-flavored drinks (sambuca, pastis), which contain glycyrrhizinic acid. Abiraterone, a drug therapy for prostate cancer, causes hypertension and hypokalemia. Similarly, posaconazole, an oral antifungal drug, can cause pseudohyperaldosteronism with hypertension and hypokalemia.

Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia but PRA is high. Excessive adrenal secretion of other corticosteroids (besides aldosterone), certain congenital adrenal enzyme disorders, and primary cortisol resistance may also cause hypertension with hypokalemia. The differential diagnosis also includes Liddle syndrome, an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low.

Complications

Cardiovascular complications occur more frequently in primary aldosteronism than in idiopathic hypertension. Following unilateral adrenalectomy for Conn syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

Treatment

The **unilateral adrenal adenoma** of Conn syndrome is usually treated by laparoscopic adrenalectomy. During pregnancy, such surgery is best performed during the second trimester. Long-term medical therapy is an option for unilateral hyperaldosteronism, if adequate blood pressure control can be maintained.

Bilateral adrenal hyperplasia is best treated with medical therapy. Medical treatment must include a potassium-sparing diuretic. **Spironolactone** is the most effective drug. It is initiated at a dose of 25 mg orally once daily and titrated to a maximum of 200 mg daily. Spironolactone has antiandrogen activity and men usually experience breast tenderness, gynecomastia, or reduced libido. Spironolactone might lead to undervirilization of male infants and is contraindicated in pregnancy; reproductive-age women are cautioned to use contraception during therapy. **Canrenone** is an active metabolite of spironolactone that has less antiandrogenic effects; it is available in Europe. **Eplerenone**, 25–50 mg orally twice daily, is favored during pregnancy (FDA pregnancy category B) and for men, since it does not have antiandrogen effects. **Finerenone** is a nonsteroidal mineralocorticoid receptor antagonist with no antiandrogenic effects. Although not formally approved for aldosteronism, it can be used off-label for patients with eGFR > 25 mL/min/1.73 m^2. The starting dose is 20 mg/day if eGFR is > 60 mL/min/1.73 m^2, and 10 mg/day if eGFR is 25–60 mL/min/1.73 m^2. When beginning these anti-mineralocorticoid medications, blood pressure must be measured daily. Other antihypertensive drugs may be required, particularly amlodipine, ARBs, or ACE inhibitors; however, significant drops in blood pressure may occur when anti-mineralocorticoid and other antihypertensives are used together.

Prognosis

The hypertension from unilateral adrenal adenoma is reversible in about two-thirds of cases but persists or returns despite surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

PHEOCHROMOCYTOMA & PARAGANGLIOMA

ESSENTIALS OF DIAGNOSIS

- “Attacks” of headache, perspiration, palpitations, anxiety. Multisystem crisis.
- Hypertension: sustained but often paroxysmal, especially during surgery or delivery; may be orthostatic.
- Elevated plasma free fractionated metanephrines.

General Considerations

Pheochromocytomas and sympathetic paragangliomas (collectively called PPGLs) are a type of neuroendocrine tumor with distinct genetics, secretions, and clinical presentations. They are rare, with a yearly incidence of 2–6 cases/million; however, many cases are undiagnosed during life. These tumors may be located in either or both adrenals; anywhere along the sympathetic nervous chain; and sometimes in the mediastinum, heart, or bladder. Pheochromocytomas arise from the adrenal medulla and are considered “intra-adrenal sympathetic paragangliomas”; they secrete epinephrine and norepinephrine. Paragangliomas arise from sympathetic paraganglia; about 50% of paragangliomas secrete norepinephrine, while the rest are nonfunctional or secrete only dopamine, normetanephrine, or chromogranin A (CgA). Nonsecretory paragangliomas arise in the head or neck, particularly in the carotid body, jugular-tympanic region, or vagal body. All PPGLs are potentially malignant, with metastases occurring in about 10–15% of adrenal pheochromocytomas and 35–40% of paragangliomas.

PPGLs are dangerous and deceptive, causing death in up to one-third of patients prior to diagnosis. They account for < 0.4% of hypertension cases. The incidence is higher in hypertensive children and patients with moderate to severe hypertension, particularly in the presence of suspicious symptoms of headache, significant palpitations, or diaphoretic episodes. Nearly 50% of PPGLs are discovered incidentally on imaging studies. They account for about 4% of adrenal incidentalomas.

PPGLs are more heritable than any other tumor. About 40% of patients harbor a germline mutation in 1 of at least 30 known susceptibility genes, usually in an autosomal dominant manner with incomplete phenotypic penetrance. Genetic testing is recommended for all patients with these tumors.

von Hippel–Lindau (VHL) disease type 2 is associated with a 30% lifetime incidence of pheochromocytoma that can present as early as age 5 years or later in adulthood. The pheochromocytomas in VHL are less likely to be malignant (3.5%) compared to pheochromocytomas without VHL (about 10%). About 25% of these patients are asymptomatic and normotensive at diagnosis. The condition is also associated with hemangiomas of the retina, cerebellum, brainstem, and spinal cord; hyperparathyroidism; pancreatic cysts; endolymphatic sac tumors; cystadenomas of the adnexa or epididymis; pancreatic neuroendocrine tumors; and renal cysts, adenomas, and carcinomas; inheritance is autosomal dominant.

MEN 2 (MEN 2A) is associated with pheochromocytomas, medullary thyroid carcinoma, hyperparathyroidism, and cutaneous lichen amyloidosis. Pheochromocytomas are often silent in MEN 2; at diagnosis, only about 50% have symptoms and fewer are hypertensive. The lack of symptoms may be due to earlier diagnosis through yearly screening of mutation carriers. **MEN 3 (MEN 2B)** may be familial, but usually arises from a de novo *ret* mutation; MEN 3 is associated with pheochromocytoma (50%), aggressive medullary thyroid carcinoma, mucosal neuromas, and Marfan-like habitus.

von Recklinghausen neurofibromatosis type 1 (NF-1) is associated with an increased risk of pheochromocytomas/paragangliomas as well as cutaneous neurofibromas, optic and brainstem gliomas, astrocytomas, vascular anomalies, hamartomas, malignant nerve sheath tumors, and smooth-bordered café au lait spots.

Clinical Findings

A. Symptoms and Signs

Clinical manifestations of PPGLs vary according to the manner in which the tumor is discovered. Among PPGLs that are discovered incidentally on imaging study (64% of PPGLs), hypertension is present in 68% and a triad of headaches, palpitations, and sweats in 14%. Among PPGLs discovered through workup of patients with symptoms (32% of PPGLs), hypertension is present in 93% and the symptom triad in 28%. Approximately 4% of PPGLs are discovered during family surveillance for carriers of pathologic germline mutations, among whom hypertension and other symptoms usually are absent. PPGLs can be lethal unless they are diagnosed and treated appropriately.

PPGLs are "great mimics," presenting with a variety of symptoms that also are seen in more common conditions. Among patients with symptoms suspicious of a PPGLs who undergo diagnostic evaluations, < 1% have a confirmed diagnosis of PPGL. Hypertension may be sustained, paroxysmal, or sustained with paroxysmal spikes. A PPGL should be suspected if hypertension is severe or associated with palpitations or sweats. About 60% of patients have episodic nonspecific "spells." Other symptoms include anxiety, weakness/fatigue, dyspnea, nausea/vomiting, tremor, dizziness, chest pain, abdominal pain, paresthesias, or constipation. Vasospasm during an attack can cause Raynaud syndrome, mottled cyanosis, or facial pallor. As the attack subsides, facial flushing and drenching sweats can occur. Epinephrine secretion by a pheochromocytoma can cause episodic tachyarrhythmias, orthostatic hypotension, or syncope. Cardiac manifestations include acute coronary syndrome, cardiomyopathy, HF, and potentially fatal dysrhythmias. Catecholamine-induced cardiomyopathy can present with shock. Confusion, psychosis, paresthesias, seizures, transient ischemic attacks, or stroke may occur with cerebrovascular vasoconstriction or hemorrhagic stroke. Abdominal pain, nausea, vomiting, and even ischemic bowel can occur. Patients may experience increased appetite, loss of weight, numbness, or fevers. During pregnancy, pheochromocytomas can produce hypertension and proteinuria, mimicking eclampsia; vaginal delivery can produce hypertensive crisis followed by postpartum shock. Painful bony metastases may be a presenting symptom of metastatic pheochromocytoma.

Catastrophic hypertensive crisis and fatal cardiac arrhythmias can occur spontaneously or may be triggered by needle biopsy or manipulation of the mass, glucagon injection, vaginal delivery, trauma, anesthesia, or surgery (both unrelated to the tumor or for its removal). Exercise, bending, lifting, or emotional stress can trigger paroxysms. Bladder paragangliomas may present with paroxysms during micturition. Certain drugs can precipitate attacks: decongestants, amphetamines, cocaine, epinephrine, corticosteroids, fluoxetine and other SSRIs, metoclopramide, MAO inhibitors, caffeine, nicotine, and ionic intravenous contrast.

PPGLs can also produce other "ectopic" peptide hormones that rarely cause Cushing syndrome (ACTH), Verner-Morrison syndrome (VIP), or hypercalcemia (PTHrP). PPGLs can also release cytokines that can cause proteinuria, nephrotic syndrome, and acute respiratory distress syndrome (ARDS) that can occur alone or as part of a **multisystem crisis** (kidney dysfunction, liver failure, cardiomyopathy, cardiovascular collapse, and death).

B. Laboratory Findings

Plasma fractionated free metanephrines is the most sensitive test for secretory PPGLs. Free metanephrines are lower when the patient is supine than when ambulatory. The test is 97% sensitive for secretory tumors, so normal levels rule out secretory pheochromocytoma and paraganglioma with some certainty. Among patients with severe hypertension or "spells" caused by PPGLs, plasma fractionated free metanephrines are ordinarily at least three times the upper limit of normal. Misleading results arise in patients with relatively minor elevations in tumor markers (< 3 times the upper normal limit), in whom a secretory PPGL is rarely confirmed. (The exceptions are patients who are being monitored because they harbor a germline mutation for familial pheochromocytoma.) False-positive test results should be suspected when the ratio of normetanephrine to norepinephrine is < 0.52 or the ratio of metanephrine to epinephrine is < 4.2. In such cases, it is best to repeat biochemical testing under optimal conditions, including discontinuation of drugs and foods associated with false-positive testing for at least 2 weeks and having the patient lying supine in a quiet room for 30–90 minutes before the blood is drawn. Patients with persistent mild elevations in tumor markers may be followed clinically or undergo additional abdominal imaging (especially if they harbor a germline mutation for familial PPGL).

Urinary fractionated metanephrines and creatinine effectively confirm most pheochromocytomas that were detected by elevated plasma fractionated free metanephrines, including patients with marginal elevations. A 24-hour urine specimen is obtained, although an overnight or shorter collection may be used. Patients with pheochromocytomas generally have > 2.2 mcg of total metanephrine per milligram of creatinine, and > 135 mcg total catecholamines per gram creatinine. Urinary assay for total metanephrines is 97% sensitive for detecting functioning pheochromocytomas.

Plasma fractionated catecholamines may be helpful to confirm whether an adrenal tumor is a secretory pheochromocytoma. The test may also be useful for normotensive patients with a paraganglioma; the tumor may secrete only dopamine, which can be followed as a tumor marker.

Serum CgA is elevated in about 85% of patients with pheochromocytoma or paraganglioma and the levels correlate with tumor size, being higher in patients with metastatic disease. Serum CgA must be assayed in the fasting state, since levels rise after meals. Serum CgA is not specific for pheochromocytoma, so its measurement is not very useful for the initial diagnosis.

Clonidine suppression testing can help distinguish whether elevated plasma free normetanephrine levels are physiologic or indicative of pheochromocytoma. Plasma fractionated free metanephrines are measured before the administration of clonidine (0.3 mg orally) and 3 hours afterward. A fall of plasma normetanephrine into the normal range or a fall of > 40% from baseline helps rule out the presence of a tumor.

Hyperglycemia is present in about 35% of patients but is usually mild. Proteinuria is present in about 10–20% of patients. Leukocytosis is common.

C. Imaging

About 95% of pheochromocytomas and sympathetic paragangliomas arise in the abdomen or pelvis. Of these, about 90% are pheochromocytomas located in one or both adrenals. Extra-adrenal paragangliomas can be located anywhere sympathetic ganglia are present, particularly in the periaortic and perinephric region (75%), bladder and pelvis (15%), and thorax (10%). Imaging may also detect distant metastases to bones, lungs, or liver.

1. CT and MRI scanning—When an adrenal pheochromocytoma is suspected, a *noncontrast* CT scan of the abdomen is performed, with thin sections through the adrenals. *Glucagon should not be used during scanning, since it can provoke hypertensive crisis in patients with a pheochromocytoma.*

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and for serial imaging. Both CT and MRI scanning have a sensitivity of 90% for adrenal pheochromocytoma and 95% for adrenal tumors over 0.5 cm. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

2. Nuclear imaging—^{64}Gu-DOTATATE-PET scanning is the most sensitive scan, detecting about 90% of pheochromocytomas, paragangliomas, and metastases. However, it is not entirely specific for these tumors. PET imaging gives crisper imaging than scintigraphy. Nuclear imaging is usually combined with volumetric imaging (CT or MRI) to determine the precise size and location of tumors.

^{18}FDG-PET scanning detects about 54% of metastases but is more sensitive for patients with *SDHB* germline mutations. However, ^{18}FDG-PET scanning is not specific for pheochromocytoma or paraganglioma.

^{123}I-MIBG whole-body scintigraphy can lateralize and confirm adrenal pheochromocytomas with a sensitivity of over 90%, but it is only 67% sensitive for extra-adrenal (paraganglioma) tumors and metastases and is also less sensitive for MEN 2– or MEN 3–related pheochromocytomas. ^{123}I-MIBG scintigraphy is also less sensitive for particularly aggressive tumors. Prior to the scan, the patient is given KI to competitively inhibit the uptake of free ^{123}I into the thyroid. Also, drugs that reduce ^{123}I-MIBG uptake should be avoided. Drug interference is suspected in negative ^{123}I-MIBG scans that do not show normal uptake in salivary glands.

Differential Diagnosis

Conditions that mimic pheochromocytoma include thyrotoxicosis, labile essential hypertension, myocarditis, glomerulonephritis or other renal lesions, eclampsia, acute intermittent porphyria, hypogonadal vascular instability (hot flushes), anxiety attacks, cocaine or amphetamine use, and clonidine withdrawal. Patients taking nonselective MAO inhibitor antidepressants can have hypertensive crisis after eating foods that contain tyramine. Patients with erythromelalgia can have hypertensive crises. Renal artery stenosis can cause severe hypertension. Plasma fractionated free metanephrines can be elevated in sleep apnea or with stressful illness. On CT scan, adrenal pheochromocytomas must be distinguished from adrenal adenomas and other masses.

Complications

All the complications of severe hypertension may be encountered. In addition, a catecholamine-induced cardiomyopathy may develop. Severe HF and cardiovascular collapse may develop in patients during a paroxysm. Sudden death may occur due to cardiac arrhythmia. ARDS and multisystem crisis can occur acutely and thus the initial manifestation of pheochromocytoma may be hypotension or even shock. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of AKI or MI. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor.

Pheochromocytomas and paragangliomas may metastasize. Cells can also be seeded within the peritoneum, either spontaneously or as a complication during surgical resection. Such seeding of the abdomen can lead to multifocal recurrent intra-abdominal tumors, a condition known as pheochromocytomatosis.

Medical Treatment

Patients must receive adequate treatment for hypertension and tachyarrhythmias prior to surgery for pheochromocytoma/paraganglioma. Patients are advised to measure their blood pressures daily and immediately during paroxysms. Some patients with pheochromocytoma or paraganglioma are not hypertensive and do not require preoperative antihypertensive management. α-Blockers or calcium channel blockers can be used, either alone or in combination. Blood pressure should be controlled before cardioselective β-blockers are added for control of tachyarrhythmias.

α-Blockers are usually administered in preparation for surgery. Phenoxybenzamine is a long-acting nonselective α-blocker with a half-life of 24 hours; it is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually by about 10 mg/day about every 3 days until hypertension is controlled. Maintenance doses range from 10 mg/day to 120 mg/day. Doxazosin (half-life 22 hours), a selective α_1-blocker, may also be used in doses of 2–32 mg daily. Optimal α-blockade is achieved when supine arterial pressure is below 140/90 mm Hg or as low as possible for the patient to have a standing arterial systolic pressure above 90 mm Hg.

Dihydropyridine calcium channel blockers (nifedipine ER, nicardipine ER, amlodipine) are very effective and are usually added to α-blockers but may be used alone. Nifedipine ER is initially given orally at a dose of 30 mg/day, increasing the dose gradually to a maximum of 60 mg twice daily. Calcium channel blockers are superior to phenoxybenzamine for long-term use, since they cause less fatigue, nasal congestion, and orthostatic hypotension. However, they should not be used for patients with severe HF. For acute hypertensive crisis (systolic blood pressure higher than 170 mm Hg), a nifedipine 10-mg capsule may be chewed and swallowed. Nifedipine is quite effective for treating acute hypertension in patients with PPGLs; it is reasonably safe as long as the blood pressure is carefully monitored.

β-Blockers (eg, metoprolol XL) are often required after institution of α-blockade or calcium channel blockade. *The use of a β-blocker as initial antihypertensive therapy has resulted in an "unopposed α" status that causes paradoxical worsening of hypertension*. Labetalol has combined α- and β-blocking activity and is an effective agent but can also cause paradoxical hypertension if used as the initial antihypertensive agent.

Surgical Treatment

Surgical removal of pheochromocytomas or abdominal paragangliomas is the treatment of choice. For surgery, a team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. Laparoscopic surgery is preferred, but large and invasive tumors require open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years.

Prior to surgery, blood pressure control should be maintained for a minimum of 4–7 days or until optimal cardiac status is established. It may take a week or even months to correct ECG changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases. Patients must be very closely monitored during surgery to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Pheochromocytoma & Paraganglioma in Pregnancy

Although rare, PPGLs must be considered in women with hypertension or tachycardia who are planning pregnancy. Susceptible members of known kindreds with familial pheochromocytoma syndromes should be screened for pheochromocytoma *while planning* pregnancy, even if totally asymptomatic. The diagnosis is typically delayed, since hypertension, tachycardia, abdominal pain, and chest pains are often attributed to preeclampsia and pregnancy itself. PPGL (versus preeclampsia) should be considered when hypertension presents before 20 weeks' gestation, is paroxysmal or severe, or if ankle edema and hyperuricemia are absent. Untreated pheochromocytoma results in mortality rates of 25% for the mother and 50% in the fetus. MRI (without gadolinium contrast) is preferred to detect an adrenal mass. Affected women with hypertension are treated with α blockade with doxazosin or phenoxybenzamine, calcium channel blockade (nifedipine or nicardipine), or both. β-Blockers should be used judiciously, since they can cause intrauterine growth retardation. The optimal time for laparoscopic surgical removal of a pheochromocytoma is during the second trimester and before 24 weeks' gestation. Women with a pheochromocytoma diagnosed after 28 weeks' gestation are best treated medically and usually have an elective cesarean section at 38 weeks' gestation.

Metastatic Pheochromocytoma & Paraganglioma

All PPGLs must be approached as possibly malignant. Surgical histopathology for PPGLs cannot reliably determine whether a tumor is malignant. About 15% of pheochromocytomas and up to 50% of abdominal paragangliomas eventually metastasize. Of patients with metastases, about 35% are detected when the primary tumor is discovered. Other metastases become clinically apparent 5.5 years (range 0.3–53 years) after initial diagnosis. Following initial surgery for PPGLs, it is essential to recheck blood pressure and plasma fractionated free metanephrine levels 6 weeks postoperatively, every 6 months for 5 years, and then yearly for life. Metanephrine levels also should be checked if hypertension, suspicious symptoms, or metastases become evident.

Since some metastases are indolent, it is important to tailor treatment according to the tumor's aggressiveness. Most surgeons resect the main tumor and larger metastases (debulking). Some asymptomatic, indolent metastases may be kept under close surveillance without treatment.

A. Somatostatin Analogs

Nearly 90% of metastatic pheochromocytomas and paragangliomas express somatostatin receptors and are visible on ^{64}Cu-DOTATATE-PET imaging. Patients with such tumors may receive a treatment trial of a somatostatin analog.

B. Chemotherapy

The most common chemotherapy regimen combines intravenous cyclophosphamide, vincristine, and dacarbazine (see Table 44–3). About one-third of patients experience some degree of temporary remission. Another chemotherapy regimen uses temozolomide, which is usually the best-tolerated chemotherapy and is particularly effective for metastatic pheochromocytoma or paraganglioma in patients with *SDHB* germline mutations. Tyrosine kinase inhibitor (TKI) therapy can also produce remissions. Metyrosine reduces catecholamine synthesis but does not slow the growth of metastases.

C. Targeted Radioisotope Therapy

1. Peptide receptor radionuclide treatment (PRRT)—This therapy uses a radioisotope-tagged somatostatin analog against neuroendocrine tumors that express somatostatin receptors. ^{177}Lu-DOTATATE (Lutathera) is FDA-approved for treating patients with metastatic gastroenteropancreatic neuroendocrine tumors (GEP-NETs); it is being used off-label to treat patients with metastatic PPGLs, 90% of which are avid for DOTATATE. The objective response rate is 25%, and the short-term disease control rate is 84%.

2. ^{131}I-iobenguane—About 60% of metastatic PPGLs have tumors with sufficient uptake of ^{123}I-MIBG scanning to allow for therapy with high-specific-activity ^{131}I-MIBG. Azedra (iobenguane I-131), an FDA-approved agent for treating patients with metastatic pheochromocytoma or paraganglioma, was discontinued by the manufacturer in 2024.

D. Treatment for Bone Metastases

Osteolytic bone metastases may be treated with external beam radiation therapy. Vertebral metastases and spinal cord compression require surgical decompression and kyphoplasty. Intravenous zoledronic acid or subcutaneous denosumab may also be administered to patients with osteolytic bone metastases.

Prognosis

The prognosis is good for patients with pheochromocytomas that are resected before causing cardiovascular damage. Hypertension usually resolves after successful surgery but may persist or return in 25% of patients despite successful surgery. In such cases, biochemical reevaluation is required to detect a possible second or metastatic pheochromocytoma.

The surgical mortality is under 3% with the use of laparoscopic surgical techniques, intraoperative monitoring, and preoperative blood pressure control with α-blockers or calcium channel blockers.

Even if no metastases are evident at the time of surgery, lifetime surveillance is indicated for detection of later metastases. Patients with metastatic PPGLs have an extremely variable prognosis. Some metastases are indolent for several decades after the primary tumor diagnosis. Overall survival is better for patients with tumors that are nonfunctional, avid for MIBG, or have a Ki67 below 10%. Metastases from head-neck paragangliomas are particularly slow-growing.

INCIDENTALLY DISCOVERED ADRENAL MASSES

Incidental adrenal masses (IAMs) are defined as adrenal nodules that are discovered incidentally on abdominal imaging obtained for other reasons. Their incidence is 4%, of which 20% are bilateral. They are uncommon in patients younger than 30 years (0.2%) and more common in patients older than 70 years (7%). About 85% are nonfunctioning adrenal adenomas; however, 14% secrete cortisol or aldosterone, which can cause Cushing syndrome or aldosteronism, respectively, and 7% are pheochromocytomas. Another 4% of IAMs represent metastases or adrenal adenocarcinomas. Other causes may include adrenal infection, hemorrhage, and cysts.

Autonomous cortisol secretion typically results in Cushing syndrome with low or low-normal plasma ACTH and serum DHEAS. Patients should be further assessed with a 1 mg dexamethasone suppression test (DST). (See Cushing Syndrome for details.) On the DST, an 8 AM serum cortisol ≥ 1.8 mcg/dL (50 nmol/L) indicates either Cushing syndrome or mild autonomous cortisol excess and a level ≥ 3 mcg/dL (83 nmol/L) portends an increased mortality risk, even without clinical manifestations of Cushing syndrome.

Patients with hypertension are screened for primary aldosteronism with a PRA and serum aldosterone (see Primary Aldosteronism).

All patients with an adrenal incidentaloma should be screened for pheochromocytoma with plasma fractionated free metanephrines, except those whose nodules meet all the following criteria: (1) normotensive, (2) nodule density on unenhanced CT density 10 HU or less, (3) size 3 cm diameter or less, and (4) morphology not suspicious. (See Pheochromocytoma.)

Surgical resection is recommended in adrenal incidentalomas larger than 4 cm, unless it is an unmistakably benign myelolipoma, hemorrhage, or adrenal cyst. The most important caveat is to not miss an adrenal adenocarcinoma or pheochromocytoma. Carcinomas account for 25% of adrenal masses larger than 6 cm diameter, 6% of masses 4–6 cm diameter, and 2% of masses smaller than 4 cm diameter. Smaller adrenal incidentalomas are usually observed after endocrine testing. Suspicion for malignancy in smaller adrenal incidentalomas is increased in patients under age 40 or and lesions that have suspicious features (heterogeneity or irregularity). A *noncontrast* CT should be performed to determine the density of the mass. Over 99% of adrenal pheochromocytomas and adrenocarcinomas have a density of 10 HU or more; patients with adrenal incidentalomas with densities of 10 HU or more that are not resected require both clinical follow-up and CT follow-up in 6–12 months.

Disorders of Parathyroid Glands & Bone Metabolism

Anne Schafer, MD
Paul A. Fitzgerald, MD

DISEASES OF THE PARATHYROIDS

The concentration of calcium in the blood is tightly regulated and maintained within a narrow physiologic range. That homeostasis is orchestrated by parathyroid hormone (PTH), which is secreted by the parathyroid glands in response to decreased serum calcium concentration. PTH increases osteoclastic activity in bone, increases the renal tubular reabsorption of calcium, and stimulates the synthesis of 1,25-dihydroxycholecalciferol by the kidney. Meanwhile, PTH inhibits the reabsorption of phosphate and bicarbonate by the renal tubule. All of these effects cause a net increase in serum calcium.

HYPOPARATHYROIDISM & PSEUDOHYPOPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Tetany, carpopedal spasms, tingling of lips and hands, muscle cramps, irritability.
- Chvostek sign and Trousseau phenomenon.
- Hypocalcemia with low serum PTH; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- Serum magnesium may be low.

General Considerations

Acquired hypoparathyroidism is most commonly caused by anterior neck surgery. After total thyroidectomy, it occurs in 25% of patients transiently and 4% of patients permanently. The risk of permanent postoperative hypoparathyroidism can be reduced during thyroid surgery by taking parathyroid glands with suspected vascular damage and autotransplanting them into the sternocleidomastoid muscle.

Transient hypocalcemia may occur after surgical removal of a single parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids or after the resection of multiple parathyroid adenomas. It may be considered permanent if it persists > 12 months following surgery. Patients with severe hyperparathyroidism who undergo parathyroidectomy are also at risk for postoperative hypocalcemia from accelerated remineralization of the skeleton. Called "hungry bone syndrome," this is distinguishable from hypoparathyroidism because the PTH level is elevated and the phosphorus level is low.

All patients undergoing thyroidectomy or parathyroidectomy must be observed closely for 12–24 hours with serum calcium and PTH. Hypocalcemia can be quite severe, particularly in patients with preoperative hyperparathyroid bone disease or vitamin D or magnesium deficiency.

Autoimmune hypoparathyroidism may be isolated or combined with other endocrine deficiencies. Autoimmune polyendocrine syndrome type I (APS-I) is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED).

Parathyroid deficiency may also be the result of damage from heavy metals, granulomas, tumors, infection, and neck irradiation.

Magnesium deficiency causes functional hypoparathyroidism, blunting the actions of PTH on target organs. More profound hypomagnesemia (below 1.2 mg/dL) inhibits PTH secretion. Correction of hypomagnesemia results in rapid disappearance of the condition.

Congenital hypoparathyroidism causes hypocalcemia beginning in infancy. However, it may not be diagnosed for many years. Since hypoparathyroidism can be familial, genetic screening for *autoimmune regulator (AIRE) gene* variants is recommended for any patient with idiopathic hypoparathyroidism who has other manifestations of autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (APECED).

Clinical Findings

A. Symptoms and Signs

Symptoms of hypocalcemia depend on its severity as well as its rate of development. Patients with acute hypocalcemia after parathyroidectomy may manifest symptoms despite having mildly low or low-normal serum calcium levels, while patients with chronic severe hypocalcemia may have few symptoms. **Neuromuscular irritability** presents with perioral numbness, paresthesias of the feet or hands, myalgias, muscle cramping, generalized muscle spasms with tetany, hyperactive reflexes, and laryngospasm that can cause respiratory stridor. Chvostek sign (facial muscle contraction on tapping the facial nerve in front of the tragus) is present in 70% of patients with hypocalcemia and 15% of individuals who are normocalcemic. Trousseau sign (flexion of the wrist and metacarpal-phalangeal joints with adduction of the fingers after application of a sphygmomanometer cuff inflated to over systolic blood pressure for 3 minutes) is present in over 90% of patients with hypocalcemia but in only about 1% of normocalcemic individuals. **Cardiovascular** manifestations of acute hypocalcemia include arrhythmias (7%), such as bradycardia, ventricular arrhythmias, and reduced EF. **CNS** manifestations include seizures (11%) as well as depression (12%), psychiatric changes, irritability, fatigue, cognitive impairment, and extrapyramidal symptoms. **Ophthalmic** manifestations include cataracts (17%); severe hypocalcemia may cause papilledema. **Renal** manifestations of chronic hypoparathyroidism occur due to hypercalciuria and include nephrolithiasis or nephrocalcinosis (15%), and renal insufficiency (12%). **Dermatologic** manifestations include dry, rough skin; dry hair; scalp and eyebrow hair loss; and brittle fingernails with transverse grooves. Chronic hypocalcemia with hyperphosphatemia can cause calcifications in soft tissues, such as joints, skin, and arteries.

B. Laboratory Findings

Serum calcium is low. Because serum calcium is largely bound to albumin, the serum *ionized* calcium should be determined in patients with hypoalbuminemia. Alternatively, the serum calcium level can be corrected for serum albumin level as follows:

$$\text{“Corrected” serum } Ca^{2+} = \text{Serum } Ca^{2+} \text{ mg/dL} + (0.8 \times [4.0 - \text{Albumin g/dL}])$$

Serum PTH levels are usually low but may be inappropriately within the normal reference range. To confirm the diagnosis, serum PTH and calcium levels should be confirmed on a second test at least 2 weeks apart. Serum magnesium levels should always be measured.

Other lab abnormalities caused by hypoparathyroidism support the diagnosis, including an elevated serum phosphorus, low 1,25-dihydroxyvitamin D, and high fractional urinary excretion of calcium.

C. Imaging

The kidneys should be imaged by noncontrast CT to determine the presence of nephrolithiasis or nephrocalcinosis. CT scanning of the brain may reveal calcifications of the basal ganglia and other areas in over 50% of patients with chronic hypocalcemia. The bones may appear denser than normal and bone mineral density (BMD) is usually increased, particularly in the lumbar spine. Cutaneous calcification may occur.

D. Other Examinations

Slit-lamp examination may show early posterior lenticular cataract formation. The ECG may show heart block, a prolonged QTc interval, and ST-T changes suggestive of an MI.

Complications

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring tracheostomy. Seizures are common in untreated patients. Hypocalcemia can also cause HF and dysrhythmias. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Overtreatment with vitamin D and calcium may produce nephrocalcinosis and impairment of kidney function. There may be associated autoimmunity causing celiac disease, pernicious anemia, or Addison disease.

Differential Diagnosis

Respiratory alkalosis from hyperventilation causes increased binding of calcium to albumin and thus can cause an acute drop in free ionized calcium.

Hypocalcemia may be caused by certain medications: loop diuretics, plicamycin, phenytoin, foscarnet, denosumab, and bisphosphonates. Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D. Hypocalcemia may develop in patients with osteoblastic metastatic carcinomas (especially breast, prostate) instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial autosomal dominant syndrome involving a germline mutation in the calcium-sensing receptor; patients have serum PTH levels that are in the normal range, distinguishing it from hypoparathyroidism. Such patients are hypercalciuric; treatment with calcium and vitamin D may cause nephrocalcinosis.

Pseudohypoparathyroidism is a genetic disorder characterized by hypocalcemia due to resistance to PTH. Subtypes are caused by different mutations involving the renal PTH receptor, the receptor's G protein, or adenylyl cyclase. Serum PTH levels are high. Hypocalcemia results from hypercalciuria due to renal tubular resistance to PTH.

Treatment

A. Prophylaxis Against Severe Postoperative Hypocalcemia

Post-thyroidectomy hypocalcemia can be detected early by closely monitoring serum PTH and calcium. If the serum calcium falls below 8.0 mg/dL (2.0 mmol/L) with a serum PTH below 10–15 pg/mL (1.0–1.5 pmol/L) after thyroid or parathyroid surgery, the patient is at high risk for hypocalcemia and can be prophylactically treated with calcitriol and calcium. An oral prophylactic regimen is calcitriol, 0.25–1 mcg twice daily, and calcium carbonate (with meals), 500–1000 mg twice daily.

B. Emergency Treatment for Acute Hypocalcemia

1. Airway—Be sure an adequate airway is present.

2. Intravenous calcium gluconate—For urgent treatment, the preferred intravenous salt is calcium gluconate (10 mL [10% solution] = 1 g calcium gluconate = 90 mg elemental calcium = 4.65 mEq). The first 10 mL is infused slowly over 10 min with ECG monitoring, and this can be followed by a second 10 mL infused over 10 min with the same close monitoring until tetany ceases. Generally, an infusion is begun. One method is to prepare 11 g calcium gluconate in D5W to provide a final volume of 1000 mL (~1 mg elemental calcium/mL), and to infuse it at a rate of 0.5 to 2.0 mg elemental calcium/kg/h, adjusted to restore calcium concentration to the lower end of normal range.

3. Oral calcium—Oral calcium salts should be given as soon as possible to supply 1–2 g of elemental calcium daily.

4. Vitamin D preparations—(Table 30–1) Vitamin D therapy should be started as soon as oral calcium is begun. 1,25-Dihydroxycholecalciferol (calcitriol) has a very rapid onset of action and is not as long-lasting as vitamin D_3 if hypercalcemia occurs. Begin calcitriol at a dose of 0.25 mcg (1000 IU) orally each morning and titrate upward to near normocalcemia. Ultimately, doses of 0.5–4 mcg/day may be required.

5. Magnesium—If hypomagnesemia is present, it must be corrected to treat the resulting hypocalcemia.

C. Maintenance Treatment of Hypoparathyroidism

Patients with mild hypoparathyroidism may require no therapy but need close monitoring for manifestations of hypocalcemia. Therapy is ordinarily required for symptomatic hypocalcemia or serum calcium below 8.0 mg/dL (2 mmol/L).

Vitamin D, calcium, and magnesium therapy: Patients with hypoparathyroidism have a reduced renal tubular reabsorption of calcium and are thus prone to hypercalciuria and kidney stones if the serum calcium is normalized with calcium and vitamin D therapy. Therefore, the goal is to maintain the serum calcium at the low end of normal or in a slightly low but asymptomatic range, approximately 8–8.6 mg/dL (2–2.15 mmol/L). It is prudent to monitor urine calcium with "spot" urine determinations and keep the level below 30 mg/dL (7.5 mmol/L), if possible. Hypercalciuria may respond to oral hydrochlorothiazide, 25 mg daily. Serum magnesium should be monitored and kept in the normal range with supplemental magnesium, if required. Serum phosphate should also be monitored and the serum calcium × phosphate product kept below 55 mg^2/dL^2 (4.4 $mmol^2/L^2$).

Calcium supplements include calcium carbonate (40% elemental calcium) that is best absorbed at the low gastric pH that occurs with meals. Calcium citrate (21% elemental calcium) is absorbed with or without meals and is a better choice for patients taking PPIs or H_2-blockers; it causes less GI intolerance than calcium carbonate. Calcium supplements are given orally in divided doses, and high doses may be required in hypoparathyroidism.

Vitamin D analogs are generally required for patients with chronic hypoparathyroidism (Table 30–1). The dosage of vitamin D preparations required to maintain target serum calcium levels can vary over time. In hypoparathyroidism, there is a deficiency in renal 1-hydroxylation of vitamin D; therefore, vitamin D analogs that are already 1-hydroxylated (activated) (such as calcitriol and alfacalcidol) are usually used. These active preparations have biologic half-lives of about 8 hours. Monitoring serum calcium, serum phosphate, and serum 25-(OH) vitamin D levels is recommended at least every 3–4 months.

For patients with recurrent hypocalcemia despite treatment with active vitamin D analogs, the use of cholecalciferol (vitamin D_3) or ergocalciferol (vitamin D_2) is a treatment option (Table 30–1). High doses may be needed because patients with hypoparathyroidism have reduced conversion of 1,25-OH_2D to 25-OHD. Because of their prolonged duration of action, if hypercalcemia or hypercalciuria develops, it may persist for weeks after the preparation is discontinued.

PTH-based therapies include **palopegteriparatide** and **teriparatide**. FDA-approved in 2024 for the treatment of adults with hypoparathyroidism, palopegteriparatide is a long-acting prodrug of PTH (1-34) that patients self-administer subcutaneously daily. It is an option for patients with difficulty maintaining stable serum and urinary

Table 30–1. Vitamin D preparations used in the treatment of hypoparathyroidism.

	Available Preparations	Daily Dose	Duration of Action
Calcitriol (Rocaltrol)	0.25 mcg (1000 IU) and 0.5 mcg (2000 IU) capsules; 1 mcg/mL oral solution; 1 mcg/mL for injection	0.25–3 mcg divided into 2 doses daily	3–5 days
Alfacalcidol	0.25 mcg, 0.5 mcg, and 1 mcg capsules	0.25 mcg with calcitriol, 0.5–3.0 mcg (divided into 2 doses) without calcitriol	3–5 days
Cholecalciferol (vitamin D_3)	400 IU/mL liquid, 1000–50,000 IU capsules (not available commercially in United States; may be compounded)	400–4000 IU with calcitriol, 10,000–100,000 IU without calcitriol	4–8 weeks
Ergocalciferol, ergosterol (vitamin D_2, calciferol)	8000 IU/mL liquid, 50,000 IU capsules	400–4000 IU with calcitriol, 50,000–200,000 IU without calcitriol	1–2 weeks

calcium levels with calcium and vitamin D preparations. Teriparatide does not have regulatory approval for the treatment of hypoparathyroidism but has been used off-label. Due to its shorter half-life, it may be administered subcutaneously twice daily.

Transplantation of cryopreserved parathyroid tissue, removed during prior surgery, restores normocalcemia in about 23% of cases.

Hypoparathyroidism in pregnancy presents special challenges. Maternal hypocalcemia can adversely affect the skeletal development of the fetus and cause compensatory hyperparathyroidism in the newborn. Serum calcium levels should ideally be maintained in the lower half of normal reference range, since maternal hypercalcemia can suppress fetal parathyroid development, resulting in neonatal hypocalcemia. Serum calcium levels should be determined every 4 weeks during pregnancy and breast feeding and more frequently for the 3 months prepartum and postpartum. PTH and PTH analogues as well as thiazide diuretics are generally avoided during pregnancy.

Prognosis

Patients with mild hypoparathyroidism generally do well. Periodic serum calcium levels are required, since changes may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

Despite optimal therapy, patients with moderate-to-severe hypoparathyroidism have an overall reduced quality of life. Chronically affected patients frequently develop calcifications in their kidneys and basal ganglia. They have an increased risk of calcium kidney stones and kidney dysfunction as well as seizures, mood and psychiatric disorders, and a reduced overall sense of well-being. Therapy with rhPTH may prevent or improve these manifestations.

PRIMARY HYPERPARATHYROIDISM

Hyperparathyroidism is a condition of increased production of the hormone PTH. **Primary hyperparathyroidism** occurs when a parathyroid gland disorder results in the increased production. **Secondary hyperparathyroidism** occurs, in contrast, when another condition causes low calcium levels in the blood, which causes the parathyroid glands to respond with increased PTH secretion. Tertiary hyperparathyroidism occurs when long-standing and usually severe secondary hyperparathyroidism progresses and some degree of parathyroid autonomy develops. Secondary and tertiary hyperparathyroidism usually occur with CKD (see Chapter 25). Other causes of secondary hyperparathyroidism include vitamin D deficiency and are addressed in Rickets & Osteomalacia.

ESSENTIALS OF DIAGNOSIS

- Often found incidentally by routine blood testing.
- Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Elevated serum PTH, serum and urine calcium, and urine phosphate; serum phosphate low to normal; alkaline phosphatase normal to elevated.

General Considerations

Primary hyperparathyroidism is the most common cause of hypercalcemia, with an estimated prevalence of 0.89% of the US population, but it is underdiagnosed and undertreated. It occurs at all ages but most commonly in the seventh decade and in women (74%).

Parathyroid glands vary in number and location, and ectopic parathyroid glands have been found within the thyroid gland, high in the neck or carotid sheath, the retroesophageal space, and the thymus or mediastinum. Hyperparathyroidism is usually caused by a single parathyroid adenoma (80%), and less commonly by hyperplasia or adenomas of two or more parathyroid glands (20%), or carcinoma (< 1%). When hyperparathyroidism presents before age 30 years, there is a higher incidence of multiglandular disease (36%) and parathyroid carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 5–10% of cases; hyperparathyroidism presenting before age 45 has a higher chance of being familial. Parathyroid hyperplasia commonly arises in MEN types 1, 2 (2A), and 4 (see Table 30–4).

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hypercalcemia resulting in increase in calcium in the glomerular filtrate overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least 5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly.

Parathyroid carcinoma is a rare cause of hyperparathyroidism, accounting for < 1% of hyperparathyroidism. Distant metastases arise most commonly in the lungs but also in bones, liver, brain, and mediastinum.

Clinical Findings

A. Symptoms and Signs

Hypercalcemia is often discovered incidentally by routine chemistry panels. Many patients are asymptomatic or have only mild symptoms. Parathyroid adenomas are usually small, located deeply in the neck, and almost never palpable.

Symptomatic patients are said to have problems with "bones, stones, abdominal groans, psychic moans, with fatigue overtones."

1. Skeletal manifestations—Low bone density is typically most prominent at the distal one-third of the radius, a site of mostly cortical bone. Lumbar (trabecular) spine bone density is often spared and is higher compared to the distal radius. Hip bones are a mixture of trabecular and cortical bone, and the risk for hip fractures is increased by 50%. Postmenopausal women are prone to asymptomatic vertebral fractures, but severe vertebral demineralization is uncommon in mild hyperparathyroidism. More commonly, patients experience arthralgias and bone pain, particularly involving the legs. Severe chronic hyperparathyroidism can cause **osteitis fibrosa cystica**, which is the replacement of calcified bone matrix with fibrous tissue forming cystic brown tumors of bone that can be palpable in the jaw.

2. Hypercalcemic manifestations—Mild hypercalcemia may be asymptomatic. However, symptom severity is not entirely predicted by the level of serum calcium or PTH; even mild hypercalcemia can cause significant symptoms, particularly depression, constipation, and bone and joint pain. **Neuromuscular** manifestations include paresthesias, muscle cramps and weakness, and diminished deep tendon reflexes. **Neuropsychiatric** manifestations include malaise, headache, fatigue, insomnia, irritability, and depression. Patients may have cognitive impairment that can vary from intellectual weariness to severe disorientation, psychosis, or stupor. **Cardiovascular** manifestations include hypertension, palpitations, prolonged P-R interval, shortened Q-T interval, bradyarrhythmias, heart block, asystole, and sensitivity to digitalis. Overall cardiovascular mortality is increased in patients with chronic moderate to severe hypercalcemia. **Renal** manifestations include polyuria and polydipsia from hypercalcemia-induced nephrogenic diabetes insipidus. Among patients with newly discovered hyperparathyroidism, calcium-containing renal calculi have occurred or are detectable in about 18%. Patients with asymptomatic hyperparathyroidism have a 5% incidence of asymptomatic calcium nephrolithiasis. **GI** symptoms include anorexia, nausea, heartburn, vomiting, abdominal pain, weight loss, constipation, and obstipation. Pancreatitis occurs in 3%. **Dermatologic** symptoms may include pruritus. Calcium may precipitate in the corneas ("band keratopathy"), in extravascular tissues (calcinosis), and in small arteries, causing small vessel thrombosis and skin necrosis (calciphylaxis).

3. Normocalcemic primary hyperparathyroidism—Patients with normocalcemic primary hyperparathyroidism generally have few symptoms. Affected patients can have subtle symptoms, such as mild fatigue, that may not be appreciated.

4. Hyperparathyroidism during pregnancy—Pregnant women having mild hyperparathyroidism with a serum calcium below 11.0 mg/dL (< 2.75 mmol/L) generally tolerate pregnancy well with normal outcomes. However, pregnant women with more severe hypercalcemia may experience complications such as nephrolithiasis, hyperemesis, pancreatitis, muscle weakness, and cognitive changes. About 30% of affected women experience preeclampsia and two-thirds of eclamptic women have preterm delivery. Hypercalcemic crisis may occur, especially postpartum. About 80% of fetuses experience complications of maternal hyperparathyroidism, including fetal demise, preterm delivery, and low birth weight. Newborns have hypoparathyroidism that can be permanent.

5. Parathyroid carcinoma—Hyperparathyroidism with a large palpable neck mass, or vocal fold paralysis from recurrent laryngeal nerve palsy, raises concern for parathyroid carcinoma. Some cases present with smaller tumors, less severe hypercalcemia, and benign-appearing histologic features. *FNA biopsy is not recommended because it may seed the biopsy tract with tumor and cytologic distinction between benign and malignant tumors is problematic.* Parathyroid carcinoma is more frequent in patients with hyperparathyroidism–jaw tumor syndrome as well as patients with MEN 1 and MEN 2A. Therefore, patients should have genetic testing.

B. Laboratory Findings

The hallmark of primary hyperparathyroidism is hypercalcemia, with the serum adjusted total calcium > 10.5 mg/dL (2.6 mmol/L). The adjusted total calcium = measured serum calcium in mg/dL + [0.8 × (4.0 − patient's serum albumin in g/dL)]. Serum ionized calcium levels are elevated (above 1.36 mmol/L).

To confirm the diagnosis of hyperparathyroidism, assess urinary calcium excretion. In primary hyperparathyroidism, the urine calcium excretion is normal (100–300 mg/day [25–75 mmol/day]) or high. Low urine calcium excretions (below 100 mg/day [25 mmol/day]) in the absence of thiazide diuretics occur in only 4% of cases of primary hyperthyroidism and raise the differential diagnosis of familial hypocalciuric hypercalcemia.

In primary hyperparathyroidism, serum phosphate may be < 2.5 mg/dL (0.8 mmol/L) due to an excessive loss of phosphate in the urine (25% of cases). A serum calcium:phosphate (Ca/P) ratio above 2.5 (mg/dL) or above 2.17 (mmol/L) helps confirm the diagnosis of primary hyperparathyroidism. The alkaline phosphatase is elevated only if bone disease is present. The plasma chloride and uric acid levels may be elevated. Serum 25-OH vitamin D levels should be measured, since vitamin D deficiency is common in patients with hyperparathyroidism. Serum 25-OH vitamin D levels below 20 mcg/L (50 nmol/L) can aggravate hyperparathyroidism and its bone manifestations.

Elevated serum levels of intact PTH confirm the diagnosis of hyperparathyroidism. Parathyroid carcinoma must always be suspected in patients with a serum calcium of 14.0 mcg/dL (3.5 mmol/L) or more and a serum PTH 5 or more times the upper limit of normal.

Patients with low bone density, normal serum calcium, and an elevated serum PTH must be evaluated for causes of secondary hyperparathyroidism (eg, vitamin D or calcium deficiency, hyperphosphatemia, CKD). In the absence of secondary hyperparathyroidism, patients with an elevated serum PTH but normal serum calcium have **normocalcemic hyperparathyroidism.** Such individuals require monitoring since hypercalcemia develops in about 19% of patients over 3 years of follow-up.

Genetic testing is recommended for patients with documented primary hyperparathyroidism who are younger than age 40, have a family history of hyperparathyroidism, or have multiglandular disease.

C. Imaging

Parathyroid imaging is not necessary for the diagnosis of hyperparathyroidism but is performed for most patients prior to parathyroid surgery.

Ultrasound should scan the neck from the mandible to the superior mediastinum in an effort to locate ectopic parathyroid adenomas. Ultrasound has a sensitivity of 79% for single adenomas but only 35% for multiglandular disease. Ultrasound is useful for the surgeon to localize parathyroid adenomas while also assessing the vocal folds.

Sestamibi scintigraphy with ^{99m}Tc-sestamibi is most useful for localizing parathyroid adenomas. However, false-positive scans are common, caused by thyroid nodules, thyroiditis, or cervical lymphadenopathy. Sestamibi-SPECT imaging improves sensitivity for single parathyroid adenomas. Small benign thyroid nodules are discovered incidentally in nearly 50% of patients with hyperparathyroidism who have imaging with ultrasound or MRI.

^{18}F-flurocholine PET/MRI is a useful scan for patients with primary hyperparathyroidism and negative or discordant localization imaging on neck ultrasound and sestamibi scanning. This scan correctly localizes a parathyroid adenoma in about 75% of cases.

Conventional CT and MRI imaging are not usually required prior to a first neck surgery for hyperparathyroidism. However, a four-dimensional CT (4D-CT) is useful for preoperative imaging when ultrasonography and sestamibi scans are negative. It can also be helpful for patients who have had prior neck surgery and for those with ectopic parathyroid glands. MRI may also be useful for repeat neck operations and when ectopic parathyroid glands are suspected. MRI shows better soft tissue contrast than CT.

Noncontrast CT scanning of the kidneys in patients with hyperparathyroidism can visualize calcium-containing stones. However, for patients with mild and apparently asymptomatic hyperparathyroidism, only about 5% are found to have unsuspected nephrolithiasis.

Bone density measurements by dual energy x-ray absorptiometry (DXA) are helpful in determining the amount of cortical bone loss in patients with hyperparathyroidism. DXA should include three areas: distal radius (cortical), hip (cortical and trabecular), and lumbar vertebrae (trabecular).

Complications

Pathologic long bone fractures are a complication of hyperparathyroidism. UTI due to stone and obstruction may lead to kidney disease and uremia. If the serum calcium level rises rapidly, clouding of sensorium, kidney disease, and rapid precipitation of calcium throughout the soft tissues may occur (calciphylaxis). Peptic ulcer and pancreatitis may be intractable before surgery. In patients with MEN type 1 insulinomas, gastrinomas or pituitary tumors may be associated. Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypocalcemia.

In tertiary hyperparathyroidism due to CKD, high serum calcium and phosphate levels may cause calciphylaxis; calcification of arteries can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure.

Differential Diagnosis

Artifactual hypercalcemia is common, so a confirmatory serum calcium level should be drawn after an overnight fast along with a serum protein, albumin, and triglyceride while ensuring that the patient is well-hydrated. Hypercalcemia may be due to high serum protein concentrations; in the presence of very high or low serum albumin concentrations, an adjusted serum calcium or a serum ionized calcium is more dependable than the total serum calcium concentration. Hypercalcemia may also be seen with dehydration.

Hypercalcemia in the setting of a low PTH level indicates that another process is causing the hypercalcemia and the parathyroid glands are responding appropriately with decreased secretion of PTH. There are many causes of **non-PTH-mediated hypercalcemia**. **Hypercalcemia of malignancy** occurs most frequently with breast, lung, pancreatic, uterine, and renal cell carcinoma, and paraganglioma. Most of these tumors secrete PTH-related protein (PTHrP) that has structural homologies to PTH and causes bone resorption and hypercalcemia similar to those caused by PTH. Serum PTH levels are low or low-normal while serum PTHrP levels are elevated; phosphate is often low. Other tumors can secrete excessive 1,25 $(OH)_2$ vitamin D_3, particularly lymphoproliferative and ovarian malignancies. Plasma cell myeloma causes hypercalcemia in older individuals. Other hematologic cancers associated with hypercalcemia include monocytic leukemia, T-cell leukemia and lymphoma, and Burkitt lymphoma. The clinical features of malignant hypercalcemia can closely simulate hyperparathyroidism.

Pseudohyperparathyroidism of pregnancy presents with hypercalcemia during pregnancy. It is caused by hypersensitivity of the breasts to PRL. The breasts become abnormally enlarged and secrete excessive amounts of PTHrP that causes hypercalcemia. Treatment with dopamine agonists reverses the hypercalcemia.

Sarcoidosis and other granulomatous disorders, such as tuberculosis, berylliosis, histoplasmosis, coccidioidomycosis, leprosy, and foreign-body granuloma, can cause hypercalcemia. Sarcoid granulomas can secrete PTHrP, but granulomas secrete $1,25(OH)_2D_3$ and serum levels of $1,25(OH)_2D_3$ are usually elevated in the presence of hypercalcemia.

Dietary factors can cause hypercalcemia. Excessive calcium, vitamin D, or vitamin A ingestion can cause hypercalcemia, especially in patients who concurrently take thiazide diuretics, which reduce urinary calcium loss. Hypercalcemia is reversible following withdrawal of calcium and vitamin D supplements. In vitamin D intoxication, hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol (25[OH]D_3) are helpful to confirm the diagnosis. A brief course of corticosteroid therapy may be necessary if hypercalcemia is severe.

Familial hypocalciuric hypercalcemia (FHH) is an uncommon autosomal dominant inherited disorder. Reduced function of the CaSR causes the parathyroid glands to falsely "sense" hypocalcemia and inappropriately release excessive amounts of PTH. The renal tubule CaSRs are also affected, causing hypocalciuria.

Adults with hypercalcemia due to FHH are either asymptomatic or have nonspecific complaints such as fatigue, weakness, or cognitive issues. Recurrent pancreatitis can occur.

FHH is characterized by a mildly elevated serum calcium that is usually below 11.0 mg/dL (2.75 mmol/L) and a low urine calcium excretion that is usually < 50 mg/24 hours (13 mmol/24 hours). FHH is confirmed with genetic testing for *FHH* gene mutations. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. Cinacalcet, a calcimimetic, may be helpful.

Prolonged immobilization at bed rest commonly causes hypercalcemia, particularly in adolescents, critically ill patients, and patients with extensive Paget disease of bone. Hypercalcemia develops in about one-third of acutely ill patients being treated in ICUs, particularly patients with AKI. Serum calcium elevations are typically mild but may reach 15 mg/dL (3.75 mmol/L). Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism but may be suppressed or normal.

Rare causes of hypercalcemia include untreated adrenal insufficiency. Modest hypercalcemia is occasionally seen in patients taking thiazide diuretics or lithium; the PTH level may be inappropriately nonsuppressed with hypercalcemia. Hyperthyroidism causes increased turnover of bone and occasional hypercalcemia. Bisphosphonates can increase serum calcium in 20% and serum PTH becomes high in 10%, mimicking hyperparathyroidism. Other causes of hypercalcemia are shown in Table 24–7.

Treatment

A. "Asymptomatic" Hyperparathyroidism

Normocalcemic or mild hyperparathyroidism should be considered "asymptomatic" only after obtaining a detailed patient medical history. Many patients may not recognize subtle manifestations, such as cognitive slowing, having become accustomed to them over years. It is important to assess blood pressure, serum BUN and creatinine, and to determine the presence of nephrolithiasis or nephrocalcinosis by radiography, ultrasonography, or CT of the kidneys. Truly asymptomatic patients may be closely monitored and advised to keep active, avoid immobilization, and drink adequate fluids. For postmenopausal women with hyperparathyroidism, estrogen replacement therapy reduces serum calcium by an average of 0.75 mg/dL (0.19 mmol/L) and slightly improves bone density. For patients with hypercalciuria (> 400 mg daily) or calcium nephrolithiasis, hydrochlorothiazide may be used in doses of 12.5–25 mg daily to reduce calciuria; however, serum calcium must be monitored carefully. Parathyroidectomy does not improve the bone density of patients with osteoporosis who have normocalcemia or normocalcemic hyperparathyroidism.

Affected patients should avoid large doses of thiazide diuretics, vitamin A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked at least twice yearly, kidney function and urine calcium once yearly, and three-site bone density (lumbar vertebrae, hip, and distal radius) every 2 years. Rising serum calcium should prompt further evaluation and determination of serum PTH levels.

If it is not clear whether a patient with primary hyperparathyroid is symptomatic, it is reasonable to consider a trial of medical therapy with cinacalcet.

B. Medical Measures

1. Fluids—Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline.

2. CaSR activators—Cinacalcet is a calcimimetic agent that binds to sites of the parathyroid glands' extracellular CaSRs to increase the glands' affinity for extracellular calcium, thereby decreasing PTH secretion. Cinacalcet may be used as the initial therapy for patients with hyperparathyroidism or for failed surgical parathyroidectomy. For primary hyperparathyroidism with mild hypercalcemia, begin cinacalcet (15 mg orally) and monitor the serum calcium closely; increase the dose every 2 weeks if hypercalcemia persists until the patient becomes normocalcemic. This is successful in about 65% of sporadic cases and 80% of familial cases. Patients with parathyroid carcinoma and severe hypercalcemia are treated with cinacalcet in addition to the bisphosphonate, zoledronic acid. Cinacalcet is usually well tolerated but may cause nausea and vomiting (11%), myalgia, or malaise. Cinacalcet does not usually correct hypercalciuria. Cinacalcet may cause hypocalcemia.

About 50% of azotemic patients with secondary or tertiary hyperparathyroidism have hypercalcemia that is resistant to vitamin D analogs. In such cases, surgical parathyroidectomy offers lower mortality rates than cinacalcet. For patients in whom surgery is contraindicated, or as an interim therapy, cinacalcet may be given in doses of 30 mg orally daily to a maximum of 250 mg daily, with dosage adjustments to keep the serum PTH in the range of 150–300 pg/mL (15.8–31.6 pmol/L). Etelcalcetide also activates the parathyroid glands' CaSR and reduces hypercalcemia in dialysis patients; it is given intravenously at the end of hemodialysis sessions, thereby avoiding the GI side effects of cinacalcet.

3. Bisphosphonates—Intravenous bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism. Pamidronate (30–90 mg) and zoledronic acid (5 mg) cause a gradual decline in serum calcium over several days that may last for weeks to months. Oral bisphosphonates, such as alendronate, are not effective for treating the hypercalcemia or hypercalciuria of hyperparathyroidism. However, oral alendronate has been shown to improve BMD in the trabecular bone of the lumbar spine and hip (not distal radius) and may be used for asymptomatic patients with hyperparathyroidism who have a low BMD.

4. Denosumab—For patients with severe hypercalcemia due to parathyroid carcinoma, denosumab 120 mcg subcutaneously may be effective.

5. Vitamin D and vitamin D analogs—For patients with primary hyperparathyroidism and vitamin D deficiency, vitamin D replacement may reduce PTH levels. Aggravation of hypercalcemia does not ordinarily occur if replacement is cautious.

6. Other measures—Estrogen replacement reduces hypercalcemia slightly in postmenopausal women with hyperparathyroidism. β-Blockers, such as propranolol, may also be useful for preventing the adverse cardiac effects of hypercalcemia. Parathyroid carcinoma metastases may be treated with radiofrequency ablation or arterial embolization.

C. Surgical Parathyroidectomy

Parathyroidectomy is recommended for patients with hyperparathyroidism who are symptomatic or who have nephrolithiasis or parathyroid bone disease. During pregnancy, parathyroidectomy is performed in the second trimester for women who are symptomatic or have a serum calcium above 11 mg/dL (2.75 mmol/L).

Some patients with seemingly asymptomatic hyperparathyroidism may be surgical candidates for other reasons such as (1) serum calcium 1 mg/dL (0.25 mmol/L) above the upper limit of normal, (2) urine calcium excretion > 400 mg/day (10 mmol/day), (3) eGFR < 60 mL/min/1.73 m^2, (4) nephrolithiasis or nephrocalcinosis, (5) cortical bone density (wrist, hip, or distal radius) indicating osteoporosis (T score below –2.5) or previous fragility bone fracture, (6) relative youth (under age 50 years), (7) difficulty ensuring medical follow-up, or (8) pregnancy.

Surgery for patients with "asymptomatic" hyperparathyroidism may improve cortical BMD and confer modest benefits in social and emotional well-being and overall quality of life in comparison to similar patients being monitored without surgery. Cognitive function may benefit with improvements in nonverbal abstraction and memory.

Without preoperative localization studies, bilateral neck exploration is usually advisable for the following: (1) patients with a family history of hyperparathyroidism, (2) patients with a personal or family history of MEN, and (3) patients wanting an optimal chance of success with a single surgery. Parathyroid glands are often supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum).

For patients with MEN type 1, the optimal surgical management is subtotal parathyroidectomy. Recurrent hyperparathyroidism develops in 18%, and the rate of postoperative hypoparathyroidism is high. In such cases, a parathyroid gland may be transplanted into a neck muscle, from which it may be easily removed if hyperparathyroidism persists. About 30% of patients with successful parathyroid surgery continue to have an elevated serum PTH postoperatively, despite normal serum calcium levels; this is sometimes due to vitamin D deficiency.

Parathyroid hyperplasia is commonly seen with secondary or tertiary hyperparathyroidism associated with uremia that is resistant to vitamin D analogues. Parathyroidectomy offers lower mortality rates, compared with cinacalcet. When surgery is performed, a subtotal parathyroidectomy is optimal; three and one-half glands are usually removed.
